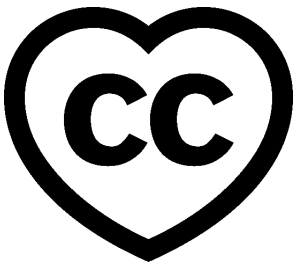
Part I

Introduction to Ada

Warning: This version of the website contains UNPUBLISHED contents. Please do not share it externally!

Copyright © 2018 – 2022, AdaCore

This book is published under a CC BY-SA license, which means that you can copy, redistribute, remix, transform, and build upon the content for any purpose, even commercially, as long as you give appropriate credit, provide a link to the license, and indicate if changes were made. If you remix, transform, or build upon the material, you must distribute your contributions under the same license as the original. You can find license details on this page[4]



This course will teach you the basics of the Ada programming language and is intended for those who already have a basic understanding of programming techniques. You will learn how to apply those techniques to programming in Ada.

This document was written by Raphaël Amiard and Gustavo A. Hoffmann, with review from Richard Kenner.

Note: The code examples in this course use a 50-column limit, which greatly improves the readability of the code on devices with a small screen size. This constraint, however, leads to an unusual coding style. For instance, instead of calling `Put_Line` in a single line, we have this:

```
Put_Line
  (" is in the northeast quadrant");
```

or this:

```
Put_Line ("  (X => "
          & Integer'Image (P.X)
          & ")");
```

Note that typical Ada code uses a limit of at least 79 columns. Therefore, please don't take the coding style from this course as a reference!

Note: Each code example from this book has an associated "code block metadata", which contains the name of the "project" and an MD5 hash value. This information is used to identify a single code example.

You can find all code examples in a zip file, which you can download from the learn website[5]. The directory structure in the zip file is based on the code block metadata. For example, if you're searching for a code example with this metadata:

- Project: Courses.Intro_To_Ada.Imperative_Language.Greet
- MD5: cba89a34b87c9dfa71533d982d05e6ab

[4] http://creativecommons.org/licenses/by-sa/4.0
[5] https://learn.adacore.com/zip/learning-ada_code.zip

you will find it in this directory:

```
projects/Courses/Intro_To_Ada/Imperative_Language/Greet/
cba89a34b87c9dfa71533d982d05e6ab/
```

In order to use this code example, just follow these steps:

1. Unpack the zip file;
2. Go to target directory;
3. Start GNAT Studio on this directory;
4. Build (or compile) the project;
5. Run the application (if a main procedure is available in the project).

CHAPTER

ONE

INTRODUCTION

1.1 History

In the 1970s the United States Department of Defense (DOD) suffered from an explosion of the number of programming languages, with different projects using different and non-standard dialects or language subsets / supersets. The DOD decided to solve this problem by issuing a request for proposals for a common, modern programming language. The winning proposal was one submitted by Jean Ichbiah from CII Honeywell-Bull.

The first Ada standard was issued in 1983; it was subsequently revised and enhanced in 1995, 2005 and 2012, with each revision bringing useful new features.

This tutorial will focus on Ada 2012 as a whole, rather than teaching different versions of the language.

1.2 Ada today

Today, Ada is heavily used in embedded real-time systems, many of which are safety critical. While Ada is and can be used as a general-purpose language, it will really shine in low-level applications:

- Embedded systems with low memory requirements (no garbage collector allowed).
- Direct interfacing with hardware.
- Soft or hard real-time systems.
- Low-level systems programming.

Specific domains seeing Ada usage include Aerospace & Defense, civil aviation, rail, and many others. These applications require a high degree of safety: a software defect is not just an annoyance, but may have severe consequences. Ada provides safety features that detect defects at an early stage — usually at compilation time or using static analysis tools. Ada can also be used to create applications in a variety of other areas, such as:

- Video game programming[6]
- Real-time audio[7]
- Kernel modules[8]

This is a non-comprehensive list that hopefully sheds light on which kind of programming Ada is good at.

[6] https://github.com/AdaDoom3/AdaDoom3
[7] http://www.electronicdesign.com/embedded-revolution/assessing-ada-language-audio-applications
[8] http://www.nihamkin.com/tag/kernel.html

In terms of modern languages, the closest in terms of targets and level of abstraction are probably C++[9] and Rust[10].

1.3 Philosophy

Ada's philosophy is different from most other languages. Underlying Ada's design are principles that include the following:

- Readability is more important than conciseness. Syntactically this shows through the fact that keywords are preferred to symbols, that no keyword is an abbreviation, etc.
- Very strong typing. It is very easy to introduce new types in Ada, with the benefit of preventing data usage errors.
  - It is similar to many functional languages in that regard, except that the programmer has to be much more explicit about typing in Ada, because there is almost no type inference.
- Explicit is better than implicit. Although this is a Python[11] commandment, Ada takes it way further than any language we know of:
  - There is mostly no structural typing, and most types need to be explicitly named by the programmer.
  - As previously said, there is mostly no type inference.
  - Semantics are very well defined, and undefined behavior is limited to an absolute minimum.
  - The programmer can generally give a *lot* of information about what their program means to the compiler (and other programmers). This allows the compiler to be extremely helpful (read: strict) with the programmer.

During this course, we will explain the individual language features that are building blocks for that philosophy.

1.4 SPARK

While this class is solely about the Ada language, it is worth mentioning that another language, extremely close to and interoperable with Ada, exists: the SPARK language.

SPARK is a subset of Ada, designed so that the code written in SPARK is amenable to automatic proof. This provides a level of assurance with regard to the correctness of your code that is much higher than with a regular programming language.

There is a dedicated *course for the SPARK language* (page 973) but keep in mind that every time we speak about the specification power of Ada during this course, it is power that you can leverage in SPARK to help proving the correctness of program properties ranging from absence of run-time errors to compliance with formally specified functional requirements.

CHAPTER

TWO

IMPERATIVE LANGUAGE

Ada is a multi-paradigm language with support for object orientation and some elements of functional programming, but its core is a simple, coherent procedural/imperative language akin to C or Pascal.

In other languages

One important distinction between Ada and a language like C is that statements and expressions are very clearly distinguished. In Ada, if you try to use an expression where a statement is required then your program will fail to compile. This rule supports a useful stylistic principle: expressions are intended to deliver values, not to have side effects. It can also prevent some programming errors, such as mistakenly using the equality operator `=` instead of the assignment operation `:=` in an assignment statement.

2.1 Hello world

Here's a very simple imperative Ada program:

Listing 1: greet.adb

```
with Ada.Text_IO;

procedure Greet is
begin
   --  Print "Hello, World!" to the screen
   Ada.Text_IO.Put_Line ("Hello, World!");
end Greet;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Greet
MD5: cba89a34b87c9dfa71533d982d05e6ab
```

Runtime output

```
Hello, World!
```

which we'll assume is in the source file `greet.adb`.

There are several noteworthy things in the above program:

- A subprogram in Ada can be either a procedure or a function. A procedure, as illustrated above, does not return a value when called.
- **with** is used to reference external modules that are needed in the procedure. This is similar to `import` in various languages or roughly similar to *#include* in C and C++.

We'll see later how they work in detail. Here, we are requesting a standard library module, the `Ada.Text_IO` package, which contains a procedure to print text on the screen: `Put_Line`.

- `Greet` is a procedure, and the main entry point for our first program. Unlike in C or C++, it can be named anything you prefer. The builder will determine the entry point. In our simple example, **`gprbuild`**, GNAT's builder, will use the file you passed as parameter.
- `Put_Line` is a procedure, just like `Greet`, except it is declared in the `Ada.Text_IO` module. It is the Ada equivalent of C's `printf`.
- Comments start with `--` and go to the end of the line. There is no multi-line comment syntax, that is, it is not possible to start a comment in one line and continue it in the next line. The only way to create multiple lines of comments in Ada is by using `--` on each line. For example:

```
--  We start a comment in this line...
--  and we continue on the second line...
```

In other languages

Procedures are similar to functions in C or C++ that return **`void`**. We'll see later how to declare functions in Ada.

Here is a minor variant of the "Hello, World" example:

Listing 2: greet.adb

```
1 with Ada.Text_IO; use Ada.Text_IO;
2
3 procedure Greet is
4 begin
5    --  Print "Hello, World!" to the screen
6    Put_Line ("Hello, World!");
7 end Greet;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Greet_2
MD5: a58a1193207df44aa6edaa4fe1c14280
```

Runtime output

```
Hello, World!
```

This version utilizes an Ada feature known as a **`use`** clause, which has the form **`use`** *package-name*. As illustrated by the call on `Put_Line`, the effect is that entities from the named package can be referenced directly, without the *package-name.* prefix.

2.2 Imperative language - If/Then/Else

This section describes Ada's **if** statement and introduces several other fundamental language facilities including integer I/O, data declarations, and subprogram parameter modes.

Ada's **if** statement is pretty unsurprising in form and function:

Listing 3: check_positive.adb

```
with Ada.Text_IO;         use Ada.Text_IO;
with Ada.Integer_Text_IO; use Ada.Integer_Text_IO;

procedure Check_Positive is
   N : Integer;
begin
   --  Put a String
   Put ("Enter an integer value: ");

   --  Read in an integer value
   Get (N);

   if N > 0 then
      --  Put an Integer
      Put (N);
      Put_Line (" is a positive number");
   end if;
end Check_Positive;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Check_Positive
MD5: 2e8b4b2f3f258fd9e02c2d65846af101
```

The **if** statement minimally consists of the reserved word **if**, a condition (which must be a Boolean value), the reserved word **then** and a non-empty sequence of statements (the **then** part) which is executed if the condition evaluates to True, and a terminating **end if**.

This example declares an integer variable N, prompts the user for an integer, checks if the value is positive and, if so, displays the integer's value followed by the string " is a positive number". If the value is not positive, the procedure does not display any output.

The type Integer is a predefined signed type, and its range depends on the computer architecture. On typical current processors Integer is 32-bit signed.

The example illustrates some of the basic functionality for integer input-output. The relevant subprograms are in the predefined package `Ada.Integer_Text_IO` and include the `Get` procedure (which reads in a number from the keyboard) and the `Put` procedure (which displays an integer value).

Here's a slight variation on the example, which illustrates an **if** statement with an **else** part:

Listing 4: check_positive.adb

```
with Ada.Text_IO;         use Ada.Text_IO;
with Ada.Integer_Text_IO; use Ada.Integer_Text_IO;

procedure Check_Positive is
   N : Integer;
begin
   --  Put a String
   Put ("Enter an integer value: ");
```

(continues on next page)

(continued from previous page)

```
9
10    --  Reads in an integer value
11    Get (N);
12
13    --  Put an Integer
14    Put (N);
15
16    if N > 0 then
17       Put_Line (" is a positive number");
18    else
19       Put_Line (" is not a positive number");
20    end if;
21 end Check_Positive;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Check_Positive_2
MD5: 28fca0d7840d06d478e5933e8182d1db
```

In this example, if the input value is not positive then the program displays the value followed by the String " is not a positive number".

Our final variation illustrates an **if** statement with **elsif** sections:

Listing 5: check_direction.adb

```
1  with Ada.Text_IO;         use Ada.Text_IO;
2  with Ada.Integer_Text_IO; use Ada.Integer_Text_IO;
3
4  procedure Check_Direction is
5     N : Integer;
6  begin
7     Put ("Enter an integer value: ");
8     Get (N);
9     Put (N);
10
11    if N = 0 or N = 360 then
12       Put_Line (" is due north");
13    elsif N in 1 .. 89 then
14       Put_Line (" is in the northeast quadrant");
15    elsif N = 90 then
16       Put_Line (" is due east");
17    elsif N in 91 .. 179 then
18       Put_Line (" is in the southeast quadrant");
19    elsif N = 180 then
20       Put_Line (" is due south");
21    elsif N in 181 .. 269 then
22       Put_Line (" is in the southwest quadrant");
23    elsif N = 270 then
24       Put_Line (" is due west");
25    elsif N in 271 .. 359 then
26       Put_Line (" is in the northwest quadrant");
27    else
28       Put_Line (" is not in the range 0..360");
29    end if;
30 end Check_Direction;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Check_Direction
MD5: 7759d30c9bb0bfb88efdf12128f9c382
```

This example expects the user to input an integer between 0 and 360 inclusive, and displays which quadrant or axis the value corresponds to. The **in** operator in Ada tests whether a scalar value is within a specified range and returns a Boolean result. The effect of the program should be self-explanatory; later we'll see an alternative and more efficient style to accomplish the same effect, through a **case** statement.

Ada's **elsif** keyword differs from C or C++, where nested **else .. if** blocks would be used instead. And another difference is the presence of the **end if** in Ada, which avoids the problem known as the "dangling else".

2.3 Imperative language - Loops

Ada has three ways of specifying loops. They differ from the C / Java / Javascript for-loop, however, with simpler syntax and semantics in line with Ada's philosophy.

2.3.1 For loops

The first kind of loop is the **for** loop, which allows iteration through a discrete range.

Listing 6: greet_5a.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Greet_5a is
begin
   for I in 1 .. 5 loop
      --  Put_Line is a procedure call
      Put_Line ("Hello, World!"
                  & Integer'Image (I));
      --         ^ Procedure parameter
   end loop;
end Greet_5a;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Greet_5a
MD5: 7f588b67947126f789333adfaaf1b638
```

Runtime output

```
Hello, World! 1
Hello, World! 2
Hello, World! 3
Hello, World! 4
Hello, World! 5
```

A few things to note:

- `1 .. 5` is a discrete range, from `1` to `5` inclusive.
- The loop parameter `I` (the name is arbitrary) in the body of the loop has a value within this range.
- `I` is local to the loop, so you cannot refer to `I` outside the loop.
- Although the value of `I` is incremented at each iteration, from the program's perspective it is constant. An attempt to modify its value is illegal; the compiler would reject the program.

- `Integer'Image` is a function that takes an Integer and converts it to a `String`. It is an example of a language construct known as an *attribute*, indicated by the ' syntax, which will be covered in more detail later.
- The `&` symbol is the concatenation operator for String values
- The `end loop` marks the end of the loop

The "step" of the loop is limited to 1 (forward direction) and -1 (backward). To iterate backwards over a range, use the `reverse` keyword:

Listing 7: greet_5a_reverse.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Greet_5a_Reverse is
begin
   for I in reverse 1 .. 5 loop
      Put_Line ("Hello, World!"
                & Integer'Image (I));
   end loop;
end Greet_5a_Reverse;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Greet_5a_Reverse
MD5: a0d5dcfc471fb1a107477c934fa527c2
```

Runtime output

```
Hello, World! 5
Hello, World! 4
Hello, World! 3
Hello, World! 2
Hello, World! 1
```

The bounds of a `for` loop may be computed at run-time; they are evaluated once, before the loop body is executed. If the value of the upper bound is less than the value of the lower bound, then the loop is not executed at all. This is the case also for `reverse` loops. Thus no output is produced in the following example:

Listing 8: greet_no_op.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Greet_No_Op is
begin
   for I in reverse 5 .. 1 loop
      Put_Line ("Hello, World!"
                & Integer'Image (I));
   end loop;
end Greet_No_Op;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Greet_No_Op
MD5: 5070693fb0324d3e4e43a8c8c4f046e1
```

Build output

```
greet_no_op.adb:5:23: warning: loop range is null, loop will not execute [enabled␣
 ↪by default]
```

The `for` loop is more general than what we illustrated here; more on that later.

2.3.2 Bare loops

The simplest loop in Ada is the bare loop, which forms the foundation of the other kinds of Ada loops.

Listing 9: greet_5b.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Greet_5b is
   --  Variable declaration:
   I : Integer := 1;
   --  ^ Type
   --              ^ Initial value
begin
   loop
      Put_Line ("Hello, World!"
                & Integer'Image (I));

      --  Exit statement:
      exit when I = 5;
      --        ^ Boolean condition

      --  Assignment:
      I := I + 1;
      --  There is no I++ short form to
      --  increment a variable
   end loop;
end Greet_5b;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Greet_5b
MD5: 5b218a64a07f64bd97774b574883c44a
```

Runtime output

```
Hello, World! 1
Hello, World! 2
Hello, World! 3
Hello, World! 4
Hello, World! 5
```

This example has the same effect as `Greet_5a` shown earlier.

It illustrates several concepts:

- We have declared a variable named `I` between the **`is`** and the **`begin`**. This constitutes a *declarative region*. Ada clearly separates the declarative region from the statement part of a subprogram. A declaration can appear in a declarative region but is not allowed as a statement.
- The bare loop statement is introduced by the keyword **`loop`** on its own and, like every kind of loop statement, is terminated by the combination of keywords **`end loop`**. On its own, it is an infinite loop. You can break out of it with an **`exit`** statement.
- The syntax for assignment is `:=`, and the one for equality is `=`. There is no way to confuse them, because as previously noted, in Ada, statements and expressions are distinct, and expressions are not valid statements.

2.3.3 While loops

The last kind of loop in Ada is the **while** loop.

Listing 10: greet_5c.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Greet_5c is
   I : Integer := 1;
begin
   --  Condition must be a Boolean value
   --  (no Integers).
   --  Operator "<=" returns a Boolean
   while I <= 5 loop
      Put_Line ("Hello, World!"
                & Integer'Image (I));

      I := I + 1;
   end loop;
end Greet_5c;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Greet_5c
MD5: 5d1d099477795b226db43736c2810274
```

Runtime output

```
Hello, World! 1
Hello, World! 2
Hello, World! 3
Hello, World! 4
Hello, World! 5
```

The condition is evaluated before each iteration. If the result is false, then the loop is terminated.

This program has the same effect as the previous examples.

In other languages

Note that Ada has different semantics than C-based languages with respect to the condition in a while loop. In Ada the condition has to be a Boolean value or the compiler will reject the program; the condition is not an integer that is treated as either **True** or **False** depending on whether it is non-zero or zero.

2.4 Imperative language - Case statement

Ada's **case** statement is similar to the C and C++ **switch** statement, but with some important differences.

Here's an example, a variation of a program that was shown earlier with an **if** statement:

Listing 11: check_direction.adb

```
with Ada.Text_IO;         use Ada.Text_IO;
with Ada.Integer_Text_IO; use Ada.Integer_Text_IO;
```

(continues on next page)

(continued from previous page)

```
3
4  procedure Check_Direction is
5     N : Integer;
6  begin
7     loop
8        Put ("Enter an integer value: ");
9        Get (N);
10       Put (N);
11
12       case N is
13          when 0 | 360 =>
14             Put_Line
15               (" is due north");
16          when 1 .. 89 =>
17             Put_Line
18               (" is in the northeast quadrant");
19          when 90 =>
20             Put_Line
21               (" is due east");
22          when 91 .. 179 =>
23             Put_Line
24               (" is in the southeast quadrant");
25          when 180 =>
26             Put_Line
27               (" is due south");
28          when 181 .. 269 =>
29             Put_Line
30               (" is in the southwest quadrant");
31          when 270 =>
32             Put_Line
33               (" is due west");
34          when 271 .. 359 =>
35             Put_Line
36               (" is in the northwest quadrant");
37          when others =>
38             Put_Line
39               (" Au revoir");
40             exit;
41       end case;
42    end loop;
43 end Check_Direction;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Check_Direction_2
MD5: 1c758b76a2c3991cb4e2a0cf5e172ac3
```

This program repeatedly prompts for an integer value and then, if the value is in the range `0 .. 360`, displays the associated quadrant or axis. If the value is an Integer outside this range, the loop (and the program) terminate after outputting a farewell message.

The effect of the case statement is similar to the if statement in an earlier example, but the case statement can be more efficient because it does not involve multiple range tests.

Notable points about Ada's case statement:

- The case expression (here the variable `N`) must be of a discrete type, i.e. either an integer type or an enumeration type. Discrete types will be covered in more detail later *discrete types* (page 47).
- Every possible value for the case expression needs to be covered by a unique branch of the case statement. This will be checked at compile time.

- A branch can specify a single value, such as `0`; a range of values, such as `1 .. 89`; or any combination of the two (separated by a |).
- As a special case, an optional final branch can specify **`others`**, which covers all values not included in the earlier branches.
- Execution consists of the evaluation of the case expression and then a transfer of control to the statement sequence in the unique branch that covers that value.
- When execution of the statements in the selected branch has completed, control resumes after the **`end case`**. Unlike C, execution does not fall through to the next branch. So Ada doesn't need (and doesn't have) a **`break`** statement.

2.5 Imperative language - Declarative regions

As mentioned earlier, Ada draws a clear syntactic separation between declarations, which introduce names for entities that will be used in the program, and statements, which perform the processing. The areas in the program where declarations may appear are known as declarative regions.

In any subprogram, the section between the **`is`** and the **`begin`** is a declarative region. You can have variables, constants, types, inner subprograms, and other entities there.

We've briefly mentioned variable declarations in previous subsection. Let's look at a simple example, where we declare an integer variable X in the declarative region and perform an initialization and an addition on it:

Listing 12: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   X : Integer;
begin
   X := 0;
   Put_Line ("The initial value of X is "
             & Integer'Image (X));

   Put_Line ("Performing operation on X...");
   X := X + 1;

   Put_Line ("The value of X now is "
             & Integer'Image (X));
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Variable_Declaration
MD5: cbb08d5e382fbfcc28e986bea80cd253
```

Runtime output

```
The initial value of X is  0
Performing operation on X...
The value of X now is  1
```

Let's look at an example of a nested procedure:

Listing 13: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   procedure Nested is
   begin
      Put_Line ("Hello World");
   end Nested;
begin
   Nested;
   --  Call to Nested
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Nested_Procedure
MD5: 2e7fb267e31232196065febd5e35e6ef
```

Runtime output

```
Hello World
```

A declaration cannot appear as a statement. If you need to declare a local variable amidst the statements, you can introduce a new declarative region with a block statement:

Listing 14: greet.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Greet is
begin
   loop
      Put_Line ("Please enter your name: ");

      declare
         Name : String := Get_Line;
         --             ^ Call to the
         --               Get_Line function
      begin
         exit when Name = "";
         Put_Line ("Hi " & Name & "!");
      end;

      --  Name is undefined here
   end loop;

  Put_Line ("Bye!");
end Greet;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Greet_6
MD5: a9c0c14a1b3e2ebe07cd88f442787e3a
```

Attention: The `Get_Line` function allows you to receive input from the user, and get the result as a string. It is more or less equivalent to the `scanf` C function.

It returns a **`String`**, which, as we will see later, is an *Unconstrained array type* (page 78). For now we simply note that, if you wish to declare a **`String`** variable and do not know

its size in advance, then you need to initialize the variable during its declaration.

2.6 Imperative language - conditional expressions

Ada 2012 introduced an expression analog for conditional statements (**if** and **case**).

2.6.1 If expressions

Here's an alternative version of an example we saw earlier; the **if** statement has been replaced by an **if** expression:

Listing 15: check_positive.adb

```
with Ada.Text_IO;         use Ada.Text_IO;
with Ada.Integer_Text_IO; use Ada.Integer_Text_IO;

procedure Check_Positive is
   N : Integer;
begin
   Put ("Enter an integer value: ");
   Get (N);
   Put (N);

   declare
      S : constant String :=
        (if N > 0
           then " is a positive number"
           else " is not a positive number");
   begin
      Put_Line (S);
   end;
end Check_Positive;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Check_Positive
MD5: 01f23463b14774f750dbb21f6c65ea09
```

The **if** expression evaluates to one of the two Strings depending on N, and assigns that value to the local variable S.

Ada's **if** expressions are similar to **if** statements. However, there are a few differences that stem from the fact that it is an expression:

- All branches' expressions must be of the same type
- It *must* be surrounded by parentheses if the surrounding expression does not already contain them
- An **else** branch is mandatory unless the expression following **then** has a Boolean value. In that case an **else** branch is optional and, if not present, defaults to **else True**.

Here's another example:

Listing 16: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
begin
   for I in 1 .. 10 loop
      Put_Line (if I mod 2 = 0
                  then "Even"
                  else "Odd");
   end loop;
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Even_Odd
MD5: c89c3233ab8822c828f7a7bba8fd3f1c
```

Runtime output

```
Odd
Even
Odd
Even
Odd
Even
Odd
Even
Odd
Even
```

This program produces 10 lines of output, alternating between "Odd" and "Even".

2.6.2 Case expressions

Analogous to **if** expressions, Ada also has **case** expressions. They work just as you would expect.

Listing 17: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
begin
   for I in 1 .. 10 loop
      Put_Line
        (case I is
         when 1 | 3 | 5 | 7 | 9  => "Odd",
         when 2 | 4 | 6 | 8 | 10 => "Even");
   end loop;
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Imperative_Language.Case_Expression
MD5: 6ce40efc987c2665960b1f08d30d780d
```

Runtime output

```
0dd
Even
0dd
Even
0dd
Even
0dd
Even
0dd
Even
```

This program has the same effect as the preceding example.

The syntax differs from **case** statements, with branches separated by commas.

CHAPTER

THREE

SUBPROGRAMS

3.1 Subprograms

So far, we have used procedures, mostly to have a main body of code to execute. Procedures are one kind of *subprogram*.

There are two kinds of subprograms in Ada, *functions* and *procedures*. The distinction between the two is that a function returns a value, and a procedure does not.

This example shows the declaration and definition of a function:

Listing 1: increment.ads

```
function Increment (I : Integer) return Integer;
```

Listing 2: increment.adb

```
--  We declare (but don't define) a function with
--  one parameter, returning an integer value

function Increment (I : Integer) return Integer is
   --  We define the Increment function
begin
    return I + 1;
end Increment;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Subprograms.Increment
MD5: 582fe283730a130cec071c455a0ce3d4
```

Subprograms in Ada can, of course, have parameters. One syntactically important note is that a subprogram which has no parameters does not have a parameter section at all, for example:

```
procedure Proc;

function Func return Integer;
```

Here's another variation on the previous example:

Listing 3: increment_by.ads

```
function Increment_By
  (I    : Integer := 0;
   Incr : Integer := 1) return Integer;
--                ^ Default value for parameters
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Subprograms.Increment_By
MD5: 5728b915789beee0b5546ea7b36a1cc2
```

In this example, we see that parameters can have default values. When calling the subprogram, you can then omit parameters if they have a default value. Unlike C/C++, a call to a subprogram without parameters does not include parentheses.

This is the implementation of the function above:

Listing 4: increment_by.adb

```
function Increment_By
  (I    : Integer := 0;
   Incr : Integer := 1) return Integer is
begin
   return I + Incr;
end Increment_By;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Subprograms.Increment_By
MD5: 07c85e5c1272ea396bf4dbc0cefcdce7
```

In the GNAT toolchain

The Ada standard doesn't mandate in which file the specification or the implementation of a subprogram must be stored. In other words, the standard doesn't require a specific file structure or specific file name extensions. For example, we could save both the specification and the implementation of the `Increment` function above in a file called `increment.txt`. (We could even store the entire source code of a system in a single file.) From the standard's perspective, this would be completely acceptable.

The GNAT toolchain, however, requires the following file naming scheme:

- files with the *.ads* extension contain the specification, while
- files with the *.adb* extension contain the implementation.

Therefore, in the GNAT toolchain, the specification of the `Increment` function must be stored in the `increment.ads` file, while its implementation must be stored in the `increment.adb` file. This rule always applies to packages, which we discuss *later* (page 35). (Note, however, that it's possible to circumvent this rule.) For more details, you may refer to the *Introduction to GNAT Toolchain* (page 1681) course or the GPRbuild User's Guide[12].

3.1.1 Subprogram calls

We can then call our subprogram this way:

Listing 5: show_increment.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Increment_By;

procedure Show_Increment is
   A, B, C : Integer;
begin
   C := Increment_By;
```

(continues on next page)

[12] https://docs.adacore.com/gprbuild-docs/html/gprbuild_ug.html

(continued from previous page)

```
   --              ^ Parameterless call,
   --                value of I is 0
   --                and Incr is 1

   Put_Line ("Using defaults for Increment_By is "
             & Integer'Image (C));

   A := 10;
   B := 3;
   C := Increment_By (A, B);
   --                 ^ Regular parameter passing

   Put_Line ("Increment of "
             & Integer'Image (A)
             & " with "
             & Integer'Image (B)
             & " is "
             & Integer'Image (C));

   A := 20;
   B := 5;
   C := Increment_By (I    => A,
                      Incr => B);
    --                ^ Named parameter passing

   Put_Line ("Increment of "
             & Integer'Image (A)
             & " with "
             & Integer'Image (B)
             & " is "
             & Integer'Image (C));
end Show_Increment;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Subprograms.Increment_By
MD5: dcb501c8c6815b03c6841fc8b80d6911
```

Runtime output

```
Using defaults for Increment_By is  1
Increment of  10 with  3 is  13
Increment of  20 with  5 is  25
```

Ada allows you to name the parameters when you pass them, whether they have a default or not. There are some rules:

- Positional parameters come first.
- A positional parameter cannot follow a named parameter.

As a convention, people usually name parameters at the call site if the function's corresponding parameters has a default value. However, it is also perfectly acceptable to name every parameter if it makes the code clearer.

3.1.2 Nested subprograms

As briefly mentioned earlier, Ada allows you to declare one subprogram inside another.

This is useful for two reasons:

- It lets you organize your programs in a cleaner fashion. If you need a subprogram only as a "helper" for another subprogram, then the principle of localization indicates that the helper subprogram should be declared nested.
- It allows you to share state easily in a controlled fashion, because the nested subprograms have access to the parameters, as well as any local variables, declared in the outer scope.

For the previous example, we can move the duplicated code (call to `Put_Line`) to a separate procedure. This is a shortened version with the nested `Display_Result` procedure.

Listing 6: show_increment.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Increment_By;

procedure Show_Increment is
   A, B, C : Integer;

   procedure Display_Result is
   begin
      Put_Line ("Increment of "
                & Integer'Image (A)
                & " with "
                & Integer'Image (B)
                & " is "
                & Integer'Image (C));
   end Display_Result;

begin
   A := 10;
   B := 3;
   C := Increment_By (A, B);
   Display_Result;
   A := 20;
   B := 5;
   C := Increment_By (A, B);
   Display_Result;
end Show_Increment;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Subprograms.Increment_By
MD5: 23ec8ae3080c042123a9e82ee6b3d9e3
```

Runtime output

```
Increment of  10 with  3 is  13
Increment of  20 with  5 is  25
```

3.1.3 Function calls

An important feature of function calls in Ada is that the return value at a call cannot be ignored; that is, a function call cannot be used as a statement.

If you want to call a function and do not need its result, you will still need to explicitly store it in a local variable.

Listing 7: quadruple.adb

```
function Quadruple (I : Integer)
                    return Integer is

    function Double (I : Integer)
                     return Integer is
    begin
       return I * 2;
    end Double;

   Res : Integer := Double (Double (I));
   --               ^ Calling the Double
   --                 function
begin
   Double (I);
   --  ERROR: cannot use call to function
   --         "Double" as a statement

   return Res;
end Quadruple;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Subprograms.Quadruple
MD5: 44326f12a9d797ea13ffe52ea48fc36f
```

Build output

```
quadruple.adb:14:04: error: cannot use call to function "Double" as a statement
quadruple.adb:14:04: error: return value of a function call cannot be ignored
gprbuild: *** compilation phase failed
```

In the GNAT toolchain

In GNAT, with all warnings activated, it becomes even harder to ignore the result of a function, because unused variables will be flagged. For example, this code would not be valid:

```
function Read_Int
   (Stream :     Network_Stream;
    Result : out Integer) return Boolean;

procedure Main is
    Stream : Network_Stream := Get_Stream;
    My_Int : Integer;

    -- Warning: in the line below, B is
    --          never read.
    B : Boolean := Read_Int (Stream, My_Int);
begin
   null;
end Main;
```

You then have two solutions to silence this warning:

- Either annotate the variable with **pragma** *Unreferenced* , e.g.:

```
B : Boolean := Read_Int (Stream, My_Int);
pragma Unreferenced (B);
```

- Or give the variable a name that contains any of the strings `discard` `dummy` `ignore` `junk` `unused` (case insensitive)

3.2 Parameter modes

So far we have seen that Ada is a safety-focused language. There are many ways this is realized, but two important points are:

- Ada makes the user specify as much as possible about the behavior expected for the program, so that the compiler can warn or reject if there is an inconsistency.
- Ada provides a variety of techniques for achieving the generality and flexibility of pointers and dynamic memory management, but without the latter's drawbacks (such as memory leakage and dangling references).

Parameter modes are a feature that helps achieve the two design goals above. A subprogram parameter can be specified with a mode, which is one of the following:

in	Parameter can only be read, not written
out	Parameter can be written to, then read
in out	Parameter can be both read and written

The default mode for parameters is **in**; so far, most of the examples have been using **in** parameters.

Historically

Functions and procedures were originally more different in philosophy. Before Ada 2012, functions could only take **in** parameters.

3.3 Subprogram calls

3.3.1 In parameters

The first mode for parameters is the one we have been implicitly using so far. Parameters passed using this mode cannot be modified, so that the following program will cause an error:

Listing 8: swap.adb

```
1 procedure Swap (A, B : Integer) is
2    Tmp : Integer;
3 begin
4    Tmp := A;
5
6    --  Error: assignment to "in" mode
7    --         parameter not allowed
```

(continues on next page)

(continued from previous page)

```
   A := B;

   --  Error: assignment to "in" mode
   --         parameter not allowed
   B := Tmp;
end Swap;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Subprograms.Swap
MD5: 478ac23f878934aae820e4b9c056d939
```

Build output

```
swap.adb:8:04: error: assignment to "in" mode parameter not allowed
swap.adb:12:04: error: assignment to "in" mode parameter not allowed
gprbuild: *** compilation phase failed
```

The fact that **in** is the default mode is very important. It means that a parameter will not be modified unless you explicitly specify a mode in which modification is allowed.

3.3.2 In out parameters

To correct our code above, we can use an **in out** parameter.

Listing 9: in_out_params.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure In_Out_Params is
   procedure Swap (A, B : in out Integer) is
      Tmp : Integer;
   begin
      Tmp := A;
      A   := B;
      B   := Tmp;
   end Swap;

   A : Integer := 12;
   B : Integer := 44;
begin
    Swap (A, B);

    --  Prints 44
    Put_Line (Integer'Image (A));
end In_Out_Params;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Subprograms.In_Out_Params
MD5: 319358e479449c115cf2b3cbb4ff3a6b
```

Runtime output

```
 44
```

An **in out** parameter will allow read and write access to the object passed as parameter, so in the example above, we can see that A is modified after the call to Swap.

Attention: While `in out` parameters look a bit like references in C++, or regular parameters in Java that are passed by-reference, the Ada language standard does not mandate "by reference" passing for in out parameters except for certain categories of types as will be explained later.

In general, it is better to think of modes as higher level than by-value versus by-reference semantics. For the compiler, it means that an array passed as an `in` parameter might be passed by reference, because it is more efficient (which does not change anything for the user since the parameter is not assignable). However, a parameter of a discrete type will always be passed by copy, regardless of its mode (which is more efficient on most architectures).

3.3.3 Out parameters

The `out` mode applies when the subprogram needs to write to a parameter that might be uninitialized at the point of call. Reading the value of an `out` parameter is permitted, but it should only be done after the subprogram has assigned a value to the parameter. Out parameters behave a bit like return values for functions. When the subprogram returns, the actual parameter (a variable) will have the value of the out parameter at the point of return.

In other languages

Ada doesn't have a tuple construct and does not allow returning multiple values from a subprogram (except by declaring a full-fledged record type). Hence, a way to return multiple values from a subprogram is to use `out` parameters.

For example, a procedure reading integers from the network could have one of the following specifications:

```
procedure Read_Int
   (Stream  :     Network_Stream;
    Success : out Boolean;
    Result  : out Integer);

function Read_Int
   (Stream :     Network_Stream;
    Result : out Integer) return Boolean;
```

While reading an out variable before writing to it should, ideally, trigger an error, imposing that as a rule would cause either inefficient run-time checks or complex compile-time rules. So from the user's perspective an out parameter acts like an uninitialized variable when the subprogram is invoked.

In the GNAT toolchain

GNAT will detect simple cases of incorrect use of out parameters. For example, the compiler will emit a warning for the following program:

Listing 10: outp.adb

```
1  procedure Outp is
2     procedure Foo (A : out Integer) is
3        B : Integer := A;
4        --             ^ Warning on reference
5        --               to uninitialized A
```

(continues on next page)

(continued from previous page)

```
   begin
      A := B;
   end Foo;
begin
   null;
end Outp;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Subprograms.Out_Params
MD5: 36bdb4e541297d7fb0b075816cb6e73a
```

Build output

```
outp.adb:3:22: warning: "A" may be referenced before it has a value [enabled by␣
↪default]
```

3.3.4 Forward declaration of subprograms

As we saw earlier, a subprogram can be declared without being fully defined, This is possible in general, and can be useful if you need subprograms to be mutually recursive, as in the example below:

Listing 11: mutually_recursive_subprograms.adb

```
procedure Mutually_Recursive_Subprograms is
    procedure Compute_A (V : Natural);
    --  Forward declaration of Compute_A

    procedure Compute_B (V : Natural) is
    begin
       if V > 5 then
          Compute_A (V - 1);
          --  Call to Compute_A
       end if;
    end Compute_B;

    procedure Compute_A (V : Natural) is
    begin
       if V > 2 then
          Compute_B (V - 1);
          --  Call to Compute_B
       end if;
    end Compute_A;
begin
   Compute_A (15);
end Mutually_Recursive_Subprograms;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Subprograms.Mutually_Recursive_Subprograms
MD5: 5ee030cdecc6c4aea8916cbb763e8526
```

3.4 Renaming

Subprograms can be renamed by using the **renames** keyword and declaring a new name for a subprogram:

```
procedure New_Proc renames Original_Proc;
```

This can be useful, for example, to improve the readability of your application when you're using code from external sources that cannot be changed in your system. Let's look at an example:

Listing 12: a_procedure_with_very_long_name_that_cannot_be_changed.ads

```
1 procedure A_Procedure_With_Very_Long_Name_That_Cannot_Be_Changed
2    (A_Message : String);
```

Listing 13: a_procedure_with_very_long_name_that_cannot_be_changed.adb

```
1 with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure A_Procedure_With_Very_Long_Name_That_Cannot_Be_Changed
4    (A_Message : String) is
5  begin
6     Put_Line (A_Message);
7  end A_Procedure_With_Very_Long_Name_That_Cannot_Be_Changed;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Subprograms.Proc_Renaming
MD5: 6d4952e9dee8ef69a9e3c3e185c635f1
```

As the wording in the name of procedure above implies, we cannot change its name. We can, however, rename it to something like Show in our test application and use this shorter name. Note that we also have to declare all parameters of the original subprogram — we may rename them, too, in the declaration. For example:

Listing 14: show_renaming.adb

```
1 with A_Procedure_With_Very_Long_Name_That_Cannot_Be_Changed;
2
3  procedure Show_Renaming is
4
5     procedure Show (S : String) renames
6       A_Procedure_With_Very_Long_Name_That_Cannot_Be_Changed;
7
8  begin
9     Show ("Hello World!");
10 end Show_Renaming;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Subprograms.Proc_Renaming
MD5: 5b3b550f8a1cbeb7d9cfd3673f6d42b3
```

Runtime output

```
Hello World!
```

Note that the original name (`A_Procedure_With_Very_Long_Name_That_Cannot_Be_Changed`) is still visible after the declaration of the Show procedure.

We may also rename subprograms from the standard library. For example, we may rename `Integer'Image` to `Img`:

Listing 15: show_image_renaming.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Image_Renaming is

   function Img (I : Integer) return String
     renames Integer'Image;

begin
   Put_Line (Img (2));
   Put_Line (Img (3));
end Show_Image_Renaming;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Subprograms.Integer_Image_Renaming
MD5: 9843b9d5967679c4fe8bd83a5213829f
```

Runtime output

```
 2
 3
```

Renaming also allows us to introduce default expressions that were not available in the original declaration. For example, we may specify `"Hello World!"` as the default for the `String` parameter of the Show procedure:

```
with A_Procedure_With_Very_Long_Name_That_Cannot_Be_Changed;

procedure Show_Renaming_Defaults is

   procedure Show (S : String := "Hello World!")
     renames
       A_Procedure_With_Very_Long_Name_That_Cannot_Be_Changed;

begin
   Show;
end Show_Renaming_Defaults;
```

CHAPTER

FOUR

MODULAR PROGRAMMING

So far, our examples have been simple standalone subprograms. Ada is helpful in that regard, since it allows arbitrary declarations in a declarative part. We were thus able to declare our types and variables in the bodies of main procedures.

However, it is easy to see that this is not going to scale up for real-world applications. We need a better way to structure our programs into modular and distinct units.

Ada encourages the separation of programs into multiple packages and sub-packages, providing many tools to a programmer on a quest for a perfectly organized code-base.

4.1 Packages

Here is an example of a package declaration in Ada:

Listing 1: week.ads

```
package Week is

   Mon : constant String := "Monday";
   Tue : constant String := "Tuesday";
   Wed : constant String := "Wednesday";
   Thu : constant String := "Thursday";
   Fri : constant String := "Friday";
   Sat : constant String := "Saturday";
   Sun : constant String := "Sunday";

end Week;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Week
MD5: 0fa033dc8fe2b9741483de273354e7ee
```

And here is how you use it:

Listing 2: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Week;
--  References the Week package, and
--  adds a dependency from Main to Week

procedure Main is
begin
   Put_Line ("First day of the week is "
```

(continues on next page)

(continued from previous page)

```
9               & Week.Mon);
10  end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Week
MD5: 03e17a75620de6a397b1d3c5a3e22f6a
```

Runtime output

```
First day of the week is Monday
```

Packages let you make your code modular, separating your programs into semantically significant units. Additionally the separation of a package's specification from its body (which we will see below) can reduce compilation time.

While the **with** clause indicates a dependency, you can see in the example above that you still need to prefix the referencing of entities from the Week package by the name of the package. (If we had included a **use** Week clause, then such a prefix would not have been necessary.)

Accessing entities from a package uses the dot notation, `A.B`, which is the same notation as the one used to access record fields.

A **with** clause can *only* appear in the prelude of a compilation unit (i.e., before the reserved word, such as **procedure**, that marks the beginning of the unit). It is not allowed anywhere else. This rule is only needed for methodological reasons: the person reading your code should be able to see immediately which units the code depends on.

In other languages

Packages look similar to, but are semantically very different from, header files in C/C++.

- The first and most important distinction is that packages are a language-level mechanism. This is in contrast to a *#include*'d header file, which is a functionality of the C preprocessor.
- An immediate consequence is that the **with** construct is a semantic inclusion mechanism, not a text inclusion mechanism. Hence, when you **with** a package, you are saying to the compiler "I'm depending on this semantic unit", and not "include this bunch of text in place here".
- The effect of a package thus does not vary depending on where it has been **with**ed from. Contrast this with C/C++, where the meaning of the included text depends on the context in which the *#include* appears.

  This allows compilation/recompilation to be more efficient. It also allows tools like IDEs to have correct information about the semantics of a program. In turn, this allows better tooling in general, and code that is more analyzable, even by humans.

An important benefit of Ada **with** clauses when compared to *#include* is that it is stateless. The order of **with** and **use** clauses does not matter, and can be changed without side effects.

In the GNAT toolchain

The Ada language standard does not mandate any particular relationship between source files and packages; for example, in theory you can put all your code in one file, or use your own file naming conventions. In practice, however, an implementation will have specific rules. With GNAT, each top-level compilation unit needs to go into a separate file. In the

example above, the Week package will be in an .ads file (for Ada specification), and the Main procedure will be in an .adb file (for Ada body).

4.2 Using a package

As we have seen above, the **with** clause indicates a dependency on another package. However, every reference to an entity coming from the Week package had to be prefixed by the full name of the package. It is possible to make every entity of a package visible directly in the current scope, using the **use** clause.

In fact, we have been using the **use** clause since almost the beginning of this tutorial.

Listing 3: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
--                ^ Make every entity of the
--                  Ada.Text_IO package
--                  directly visible.
with Week;

procedure Main is
   use Week;
   --  Make every entity of the Week
   --  package directly visible.
begin
   Put_Line ("First day of the week is " & Mon);
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Week
MD5: ea54077d4ae165b28ae8facfe8ba2db7
```

Runtime output

```
First day of the week is Monday
```

As you can see in the example above:

- Put_Line is a subprogram that comes from the Ada.Text_IO package. We can reference it directly because we have **use**d the package at the top of the Main unit.
- Unlike **with** clauses, a **use** clause can be placed either in the prelude, or in any declarative region. In the latter case the **use** clause will have an effect in its containing lexical scope.

4.3 Package body

In the simple example above, the Week package only has declarations and no body. That's not a mistake: in a package specification, which is what is illustrated above, you cannot declare bodies. Those have to be in the package body.

Listing 4: operations.ads

```
package Operations is

   --  Declaration
   function Increment_By
     (I    : Integer;
      Incr : Integer := 0) return Integer;

   function Get_Increment_Value return Integer;

end Operations;
```

Listing 5: operations.adb

```
package body Operations is

   Last_Increment : Integer := 1;

   function Increment_By
     (I    : Integer;
      Incr : Integer := 0) return Integer is
   begin
      if Incr /= 0 then
         Last_Increment := Incr;
      end if;

      return I + Last_Increment;
   end Increment_By;

   function Get_Increment_Value return Integer is
   begin
      return Last_Increment;
   end Get_Increment_Value;

end Operations;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Operations
MD5: 2adfb64e825605c74fecf6c9d45c8437
```

Here we can see that the body of the `Increment_By` function has to be declared in the body. Coincidentally, introducing a body allows us to put the `Last_Increment` variable in the body, and make them inaccessible to the user of the `Operations` package, providing a first form of encapsulation.

This works because entities declared in the body are *only* visible in the body.

This example shows how `Last_Increment` is used indirectly:

Listing 6: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Operations;

procedure Main is
   use Operations;

   I : Integer := 0;
   R : Integer;

   procedure Display_Update_Values is
```

(continues on next page)

(continued from previous page)

```
      Incr : constant Integer :=
                Get_Increment_Value;
   begin
      Put_Line (Integer'Image (I)
                & " incremented by "
                & Integer'Image (Incr)
                & " is "
                & Integer'Image (R));
      I := R;
   end Display_Update_Values;
begin
   R := Increment_By (I);
   Display_Update_Values;
   R := Increment_By (I);
   Display_Update_Values;

   R := Increment_By (I, 5);
   Display_Update_Values;
   R := Increment_By (I);
   Display_Update_Values;

   R := Increment_By (I, 10);
   Display_Update_Values;
   R := Increment_By (I);
   Display_Update_Values;
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Operations
MD5: 76190b1261a9652cfb7986ecec191e37
```

Runtime output

```
 0 incremented by  1 is  1
 1 incremented by  1 is  2
 2 incremented by  5 is  7
 7 incremented by  5 is  12
 12 incremented by  10 is  22
 22 incremented by  10 is  32
```

4.4 Child packages

Packages can be used to create hierarchies. We achieve this by using child packages, which extend the functionality of their parent package. One example of a child package that we've been using so far is the `Ada.Text_IO` package. Here, the parent package is called Ada, while the child package is called `Text_IO`. In the previous examples, we've been using the `Put_Line` procedure from the `Text_IO` child package.

Important

Ada also supports nested packages. However, since they can be more complicated to use, the recommendation is to use child packages instead. Nested packages will be covered in the advanced course.

Let's begin our discussion on child packages by taking our previous `Week` package:

Listing 7: week.ads

```
package Week is

   Mon : constant String := "Monday";
   Tue : constant String := "Tuesday";
   Wed : constant String := "Wednesday";
   Thu : constant String := "Thursday";
   Fri : constant String := "Friday";
   Sat : constant String := "Saturday";
   Sun : constant String := "Sunday";

end Week;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Child_Packages
MD5: 0fa033dc8fe2b9741483de273354e7ee
```

If we want to create a child package for `Week`, we may write:

Listing 8: week-child.ads

```
package Week.Child is

   function Get_First_Of_Week return String;

end Week.Child;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Child_Packages
MD5: a7db38e772cf6153b5eb95069517e833
```

Here, `Week` is the parent package and `Child` is the child package. This is the corresponding package body of `Week.Child`:

Listing 9: week-child.adb

```
package body Week.Child is

   function Get_First_Of_Week return String is
   begin
      return Mon;
   end Get_First_Of_Week;

end Week.Child;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Child_Packages
MD5: 04dad82685ad9f0231c3084266b0af83
```

In the implementation of the `Get_First_Of_Week` function, we can use the `Mon` string directly, even though it was declared in the parent package `Week`. We don't write `with Week` here because all elements from the specification of the `Week` package — such as `Mon`, `Tue` and so on — are visible in the child package `Week.Child`.

Now that we've completed the implementation of the `Week.Child` package, we can use elements from this child package in a subprogram by simply writing `with Week.Child`. Similarly, if we want to use these elements directly, we write `use Week.Child` in addition. For example:

Listing 10: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Week.Child;  use Week.Child;

procedure Main is
begin
   Put_Line ("First day of the week is "
             & Get_First_Of_Week);
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Child_Packages
MD5: e2f5c6ad3a92da4cb04ee7ec12293df4
```

Runtime output

```
First day of the week is Monday
```

4.4.1 Child of a child package

So far, we've seen a two-level package hierarchy. But the hierarchy that we can potentially create isn't limited to that. For instance, we could extend the hierarchy of the previous source code example by declaring a `Week.Child.Grandchild` package. In this case, `Week.Child` would be the parent of the `Grandchild` package. Let's consider this implementation:

Listing 11: week-child-grandchild.ads

```
package Week.Child.Grandchild is

   function Get_Second_Of_Week return String;

end Week.Child.Grandchild;
```

Listing 12: week-child-grandchild.adb

```
package body Week.Child.Grandchild is

   function Get_Second_Of_Week return String is
   begin
      return Tue;
   end Get_Second_Of_Week;

end Week.Child.Grandchild;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Child_Packages
MD5: 03ee5932a68212b2e501370212508ab1
```

We can use this new `Grandchild` package in our test application in the same way as before: we can reuse the previous test application and adapt the **`with`** and **`use`**, and the function call. This is the updated code:

Listing 13: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

```

(continues on next page)

(continued from previous page)

```
with Week.Child.Grandchild;
use  Week.Child.Grandchild;

procedure Main is
begin
   Put_Line ("Second day of the week is "
             & Get_Second_Of_Week);
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Child_Packages
MD5: 29ee409c8131bd9529c6bf6e366bb390
```

Runtime output

```
Second day of the week is Tuesday
```

Again, this isn't the limit for the package hierarchy. We could continue to extend the hierarchy of the previous example by implementing a `Week.Child.Grandchild.Grand_grandchild` package.

4.4.2 Multiple children

So far, we've seen a single child package of a parent package. However, a parent package can also have multiple children. We could extend the example above and implement a `Week.Child_2` package. For example:

Listing 14: week-child_2.ads

```
package Week.Child_2 is

   function Get_Last_Of_Week return String;

end Week.Child_2;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Child_Packages
MD5: bd3f63cacd142d9885600f4000b4573b
```

Here, `Week` is still the parent package of the `Child` package, but it's also the parent of the `Child_2` package. In the same way, `Child_2` is obviously one of the child packages of `Week`.

This is the corresponding package body of `Week.Child_2`:

Listing 15: week-child_2.adb

```
package body Week.Child_2 is

   function Get_Last_Of_Week return String is
   begin
      return Sun;
   end Get_Last_Of_Week;

end Week.Child_2;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Child_Packages
MD5: c2c03e4cb1daff02dd6076c2956ef2aa
```

We can now reference both children in our test application:

Listing 16: main.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with Week.Child;   use Week.Child;
with Week.Child_2; use Week.Child_2;

procedure Main is
begin
   Put_Line ("First day of the week is "
             & Get_First_Of_Week);
   Put_Line ("Last day of the week is "
             & Get_Last_Of_Week);
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Child_Packages
MD5: 6a91f239fb2a2d8c702409c22467a424
```

Runtime output

```
First day of the week is Monday
Last day of the week is Sunday
```

4.4.3 Visibility

In the previous section, we've seen that elements declared in a parent package specification are visible in the child package. This is, however, not the case for elements declared in the package body of a parent package.

Let's consider the package Book and its child `Additional_Operations`:

Listing 17: book.ads

```
package Book is

   Title : constant String :=
     "Visible for my children";

   function Get_Title return String;

   function Get_Author return String;

end Book;
```

Listing 18: book-additional_operations.ads

```
package Book.Additional_Operations is

   function Get_Extended_Title return String;

   function Get_Extended_Author return String;

end Book.Additional_Operations;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Visibility
MD5: a0d67cff9aeff288709391d16306df00
```

This is the body of both packages:

Listing 19: book.adb

```
package body Book is

   Author : constant String :=
     "Author not visible for my children";

   function Get_Title return String is
   begin
      return Title;
   end Get_Title;

   function Get_Author return String is
   begin
      return Author;
   end Get_Author;

end Book;
```

Listing 20: book-additional_operations.adb

```
package body Book.Additional_Operations is

   function Get_Extended_Title return String is
   begin
      return "Book Title: " & Title;
   end Get_Extended_Title;

   function Get_Extended_Author return String is
   begin
      --  "Author" string declared in the body
      --  of the Book package is not visible
      --  here. Therefore, we cannot write:
      --
      --  return "Book Author: " & Author;

      return "Book Author: Unknown";
   end Get_Extended_Author;

end Book.Additional_Operations;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Visibility
MD5: 68b7490da12bafae0aa6fe0ab76c6b1c
```

In the implementation of the `Get_Extended_Title`, we're using the `Title` constant from the parent package `Book`. However, as indicated in the comments of the `Get_Extended_Author` function, the `Author` string — which we declared in the body of the `Book` package — isn't visible in the `Book.Additional_Operations` package. Therefore, we cannot use it to implement the `Get_Extended_Author` function.

We can, however, use the `Get_Author` function from `Book` in the implementation of the `Get_Extended_Author` function to retrieve this string. Likewise, we can use this strategy to implement the `Get_Extended_Title` function. This is the adapted code:

Listing 21: book-additional_operations.adb

```
package body Book.Additional_Operations is

   function Get_Extended_Title return String is
   begin
      return "Book Title: " & Get_Title;
   end Get_Extended_Title;

   function Get_Extended_Author return String is
   begin
      return "Book Author: " & Get_Author;
   end Get_Extended_Author;

end Book.Additional_Operations;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Visibility
MD5: b00c187cb54d3fcb9574726028c1efc6
```

This is a simple test application for the packages above:

Listing 22: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Book.Additional_Operations;
use  Book.Additional_Operations;

procedure Main is
begin
   Put_Line (Get_Extended_Title);
   Put_Line (Get_Extended_Author);
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Visibility
MD5: bdc75987fe61e9401b400f8704890ebe
```

Runtime output

```
Book Title: Visible for my children
Book Author: Author not visible for my children
```

By declaring elements in the body of a package, we can implement encapsulation in Ada. Those elements will only be visible in the package body, but nowhere else. This isn't, however, the only way to achieve encapsulation in Ada: we'll discuss other approaches in the *Privacy* (page 113) chapter.

4.5 Renaming

Previously, we've mentioned that *subprograms can be renamed* (page 32). We can rename packages, too. Again, we use the **renames** keyword for that. The following example renames the Ada.Text_IO package as TIO:

Listing 23: main.adb

```
with Ada.Text_IO;

procedure Main is
   package TIO renames Ada.Text_IO;
begin
   TIO.Put_Line ("Hello");
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Rename_Text_IO
MD5: 33652dd004ef33d95c168ab8893cd412
```

Runtime output

```
Hello
```

We can use renaming to improve the readability of our code by using shorter package names. In the example above, we write TIO.Put_Line instead of the longer version (Ada.Text_IO.Put_Line). This approach is especially useful when we don't **use** packages and want to avoid that the code becomes too verbose.

Note we can also rename subprograms and objects inside packages. For instance, we could have just renamed the Put_Line procedure in the source code example above:

Listing 24: main.adb

```
with Ada.Text_IO;

procedure Main is
   procedure Say (Something : String)
     renames Ada.Text_IO.Put_Line;
begin
   Say ("Hello");
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Modular_Programming.Rename_Put_Line
MD5: f30174ff29eb01f33bc95f1787f9f1dc
```

Runtime output

```
Hello
```

In this example, we rename the Put_Line procedure to Say.

CHAPTER

FIVE

STRONGLY TYPED LANGUAGE

Ada is a strongly typed language. It is interestingly modern in that respect: strong static typing has been increasing in popularity in programming language design, owing to factors such as the growth of statically typed functional programming, a big push from the research community in the typing domain, and many practical languages with strong type systems.

5.1 What is a type?

In statically typed languages, a type is mainly (but not only) a *compile time* construct. It is a construct to enforce invariants about the behavior of a program. Invariants are unchangeable properties that hold for all variables of a given type. Enforcing them ensures, for example, that variables of a data type never have invalid values.

A type is used to reason about the *objects* a program manipulates (an object is a variable or a constant). The aim is to classify objects by what you can accomplish with them (i.e., the operations that are permitted), and this way you can reason about the correctness of the objects' values.

5.2 Integers

A nice feature of Ada is that you can define your own integer types, based on the requirements of your program (i.e., the range of values that makes sense). In fact, the definitional mechanism that Ada provides forms the semantic basis for the predefined integer types. There is no "magical" built-in type in that regard, which is unlike most languages, and arguably very elegant.

Listing 1: integer_type_example.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Integer_Type_Example is
4     --  Declare a signed integer type,
5     --  and give the bounds
6     type My_Int is range -1 .. 20;
7     --                         ^ High bound
8     --                   ^ Low bound
9
10    --  Like variables, type declarations can
11    --  only appear in declarative regions.
12 begin
13    for I in My_Int loop
14       Put_Line (My_Int'Image (I));
15       --              ^ 'Image attribute
```

(continues on next page)

(continued from previous page)

```
16       --                converts a value
17       --                to a String.
18    end loop;
19 end Integer_Type_Example;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Integer_Type_Example
MD5: 1d82fa54b604944fdd8652cbf84f4ff2
```

Runtime output

```
-1
 0
 1
 2
 3
 4
 5

 7
 8
 9
 10
 11
 12
 13
 14
 15
 16
 17
 18
 19
 20
```

This example illustrates the declaration of a signed integer type, and several things we can do with them.

Every type declaration in Ada starts with the **type** keyword (except for *task types* (page 161)). After the type, we can see a range that looks a lot like the ranges that we use in **for** loops, that defines the low and high bound of the type. Every integer in the inclusive range of the bounds is a valid value for the type.

Ada integer types

In Ada, an integer type is not specified in terms of its machine representation, but rather by its range. The compiler will then choose the most appropriate representation.

Another point to note in the above example is the `My_Int'Image (I)` expression. The `Name'Attribute (optional params)` notation is used for what is called an attribute in Ada. An attribute is a built-in operation on a type, a value, or some other program entity. It is accessed by using a ' symbol (the ASCII apostrophe).

Ada has several types available as "built-ins"; **Integer** is one of them. Here is how **Integer** might be defined for a typical processor:

```
type Integer is
  range -(2 ** 31) .. +(2 ** 31 - 1);
```

** is the exponent operator, which means that the first valid value for **Integer** is -2^{31}, and the last valid value is $2^{31} - 1$.

Ada does not mandate the range of the built-in type **Integer**. An implementation for a 16-bit target would likely choose the range -2^{15} through $2^{15} - 1$.

5.2.1 Operational semantics

Unlike some other languages, Ada requires that operations on integers should be checked for overflow.

Listing 2: main.adb

```
procedure Main is
   A : Integer := Integer'Last;
   B : Integer;
begin
   B := A + 5;
   --  This operation will overflow, eg. it
   --  will raise an exception at run time.
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Overflow_Check
MD5: bddd15b394f043442024899d12b982fb
```

Build output

```
main.adb:5:11: warning: value not in range of type "Standard.Integer" [enabled by␣
 ↪default]
main.adb:5:11: warning: Constraint_Error will be raised at run time [enabled by␣
 ↪default]
```

Runtime output

```

raised CONSTRAINT_ERROR : main.adb:5 overflow check failed
```

There are two types of overflow checks:

- Machine-level overflow, when the result of an operation exceeds the maximum value (or is less than the minimum value) that can be represented in the storage reserved for an object of the type, and
- Type-level overflow, when the result of an operation is outside the range defined for the type.

Mainly for efficiency reasons, while machine-level overflow always results in an exception, type-level overflows will only be checked at specific boundaries, like assignment:

Listing 3: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   type My_Int is range 1 .. 20;
   A : My_Int := 12;
   B : My_Int := 15;
   M : My_Int := (A + B) / 2;
   --  No overflow here, overflow checks
   --  are done at specific boundaries.
begin
   for I in 1 .. M loop
```

(continues on next page)

(continued from previous page)

```
12       Put_Line ("Hello, World!");
13    end loop;
14    --  Loop body executed 13 times
15 end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Overflow_Check_2
MD5: d24283cbb42c0be5b5fa215eb16ad2e7
```

Runtime output

```
Hello, World!
Hello, World!
Hello, World!
Hello, World!
Hello, World!
Hello, World!
Hello, World!
Hello, World!
Hello, World!
Hello, World!
Hello, World!
Hello, World!
Hello, World!
```

Type-level overflow will only be checked at specific points in the execution. The result, as we see above, is that you might have an operation that overflows in an intermediate computation, but no exception will be raised because the final result does not overflow.

5.3 Unsigned types

Ada also features unsigned Integer types. They're called *modular* types in Ada parlance. The reason for this designation is due to their behavior in case of overflow: They simply "wrap around", as if a modulo operation was applied.

For machine sized modular types, for example a modulus of 2^{32}, this mimics the most common implementation behavior of unsigned types. However, an advantage of Ada is that the modulus is more general:

Listing 4: main.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Main is
4     type Mod_Int is mod 2 ** 5;
5     --              ^ Range is 0 .. 31
6
7     A : constant Mod_Int := 20;
8     B : constant Mod_Int := 15;
9
10    M : constant Mod_Int := A + B;
11    --  No overflow here,
12    --  M = (20 + 15) mod 32 = 3
13 begin
14    for I in 1 .. M loop
15       Put_Line ("Hello, World!");
```

(continues on next page)

(continued from previous page)

```
16    end loop;
17 end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Unsigned_Types
MD5: df4efee4eb29e7ea15a0cf961b600dd5
```

Runtime output

```
Hello, World!
Hello, World!
Hello, World!
```

Unlike in C/C++, since this wraparound behavior is guaranteed by the Ada specification, you can rely on it to implement portable code. Also, being able to leverage the wrapping on arbitrary bounds is very useful — the modulus does not need to be a power of 2 — to implement certain algorithms and data structures, such as ring buffers[13].

5.4 Enumerations

Enumeration types are another nicety of Ada's type system. Unlike C's enums, they are *not* integers, and each new enumeration type is incompatible with other enumeration types. Enumeration types are part of the bigger family of discrete types, which makes them usable in certain situations that we will describe later but one context that we have already seen is a case statement.

Listing 5: enumeration_example.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Enumeration_Example is
4     type Days is (Monday, Tuesday, Wednesday,
5                   Thursday, Friday,
6                   Saturday, Sunday);
7     --  An enumeration type
8  begin
9     for I in Days loop
10       case I is
11          when Saturday .. Sunday =>
12             Put_Line ("Week end!");
13
14          when Monday .. Friday =>
15             Put_Line ("Hello on "
16                       & Days'Image (I));
17             --  'Image attribute, works on
18             --  enums too
19       end case;
20    end loop;
21 end Enumeration_Example;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Enumeration_Example
MD5: 45d6c83992af4fb6d5015d5f22cb7113
```

Runtime output

[13] https://en.wikipedia.org/wiki/Circular_buffer

```
Hello on MONDAY
Hello on TUESDAY
Hello on WEDNESDAY
Hello on THURSDAY
Hello on FRIDAY
Week end!
Week end!
```

Enumeration types are powerful enough that, unlike in most languages, they're used to define the standard Boolean type:

```
type Boolean is (False, True);
```

As mentioned previously, every "built-in" type in Ada is defined with facilities generally available to the user.

5.5 Floating-point types

5.5.1 Basic properties

Like most languages, Ada supports floating-point types. The most commonly used floating-point type is **Float**:

Listing 6: floating_point_demo.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Floating_Point_Demo is
   A : constant Float := 2.5;
begin
   Put_Line ("The value of A is "
             & Float'Image (A));
end Floating_Point_Demo;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Floating_Point_Demo
MD5: 06998775497b68b742700138faecbb6a
```

Runtime output

```
The value of A is  2.50000E+00
```

The application will display 2.5 as the value of A.

The Ada language does not specify the precision (number of decimal digits in the mantissa) for Float; on a typical 32-bit machine the precision will be 6.

All common operations that could be expected for floating-point types are available, including absolute value and exponentiation. For example:

Listing 7: floating_point_operations.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Floating_Point_Operations is
   A : Float := 2.5;
begin
```

(continues on next page)

(continued from previous page)

```
   A := abs (A - 4.5);
   Put_Line ("The value of A is "
             & Float'Image (A));

   A := A ** 2 + 1.0;
   Put_Line ("The value of A is "
             & Float'Image (A));
end Floating_Point_Operations;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Floating_Point_Operations
MD5: c280e0f23e020aaee1a8777e7fb4c242
```

Runtime output

```
The value of A is  2.00000E+00
The value of A is  5.00000E+00
```

The value of A is `2.0` after the first operation and `5.0` after the second operation.

In addition to **`Float`**, an Ada implementation may offer data types with higher precision such as **`Long_Float`** and **`Long_Long_Float`**. Like **`Float`**, the standard does not indicate the exact precision of these types: it only guarantees that the type **`Long_Float`**, for example, has at least the precision of **`Float`**. In order to guarantee that a certain precision requirement is met, we can define custom floating-point types, as we will see in the next section.

5.5.2 Precision of floating-point types

Ada allows the user to specify the precision for a floating-point type, expressed in terms of decimal digits. Operations on these custom types will then have at least the specified precision. The syntax for a simple floating-point type declaration is:

```
type T is digits <number_of_decimal_digits>;
```

The compiler will choose a floating-point representation that supports the required precision. For example:

Listing 8: custom_floating_types.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Custom_Floating_Types is
   type T3  is digits 3;
   type T15 is digits 15;
   type T18 is digits 18;
begin
   Put_Line ("T3  requires "
             & Integer'Image (T3'Size)
             & " bits");
   Put_Line ("T15 requires "
             & Integer'Image (T15'Size)
             & " bits");
   Put_Line ("T18 requires "
             & Integer'Image (T18'Size)
             & " bits");
end Custom_Floating_Types;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Custom_Floating_Types
MD5: 3c23738f13e081038996c533da8fb723
```

Runtime output

```
T3  requires  32 bits
T15 requires  64 bits
T18 requires  128 bits
```

In this example, the attribute `'Size` is used to retrieve the number of bits used for the specified data type. As we can see by running this example, the compiler allocates 32 bits for T3, 64 bits for T15 and 128 bits for T18. This includes both the mantissa and the exponent.

The number of digits specified in the data type is also used in the format when displaying floating-point variables. For example:

Listing 9: display_custom_floating_types.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Display_Custom_Floating_Types is
   type T3  is digits 3;
   type T18 is digits 18;

   C1 : constant := 1.0e-4;

   A : constant T3  := 1.0 + C1;
   B : constant T18 := 1.0 + C1;
begin
   Put_Line ("The value of A is "
             & T3'Image (A));
   Put_Line ("The value of B is "
             & T18'Image (B));
end Display_Custom_Floating_Types;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Display_Custom_Floating_Types
MD5: 58ec2660388a7f05e139f73e94303cf1
```

Runtime output

```
The value of A is  1.00E+00
The value of B is  1.00010000000000000E+00
```

As expected, the application will display the variables according to specified precision (1.00E+00 and 1.00010000000000000E+00).

5.5.3 Range of floating-point types

In addition to the precision, a range can also be specified for a floating-point type. The syntax is similar to the one used for integer data types — using the **range** keyword. This simple example creates a new floating-point type based on the type **Float**, for a normalized range between `-1.0` and `1.0`:

Listing 10: floating_point_range.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Floating_Point_Range is
   type T_Norm  is new Float range -1.0 .. 1.0;
   A  : T_Norm;
begin
   A := 1.0;
   Put_Line ("The value of A is "
             & T_Norm'Image (A));
end Floating_Point_Range;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Floating_Point_Range
MD5: b43d596682aa0fa11124a3a3d0596abc
```

Runtime output

```
The value of A is  1.00000E+00
```

The application is responsible for ensuring that variables of this type stay within this range; otherwise an exception is raised. In this example, the exception `Constraint_Error` is raised when assigning `2.0` to the variable `A`:

Listing 11: floating_point_range_exception.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Floating_Point_Range_Exception is
   type T_Norm  is new Float range -1.0 .. 1.0;
   A  : T_Norm;
begin
   A := 2.0;
   Put_Line ("The value of A is "
             & T_Norm'Image (A));
end Floating_Point_Range_Exception;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Floating_Point_Range_
 ↪Exception
MD5: ecda66589ba28e453956dca159ea5f0d
```

Build output

```
floating_point_range_exception.adb:7:09: warning: value not in range of type "T_
 ↪Norm" defined at line 4 [enabled by default]
floating_point_range_exception.adb:7:09: warning: Constraint_Error will be raised␣
 ↪at run time [enabled by default]
```

Runtime output

```

raised CONSTRAINT_ERROR : floating_point_range_exception.adb:7 range check failed
```

Ranges can also be specified for custom floating-point types. For example:

Listing 12: custom_range_types.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with Ada.Numerics; use Ada.Numerics;

procedure Custom_Range_Types is
   type T6_Inv_Trig  is
     digits 6 range -Pi / 2.0 .. Pi / 2.0;
begin
   null;
end Custom_Range_Types;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Custom_Range_Types
MD5: 7b62abc869290a30e351163f670059e0
```

In this example, we are defining a type called `T6_Inv_Trig`, which has a range from -π / 2 to π / 2 with a minimum precision of 6 digits. (`Pi` is defined in the predefined package `Ada.Numerics`.)

5.6 Strong typing

As noted earlier, Ada is strongly typed. As a result, different types of the same family are incompatible with each other; a value of one type cannot be assigned to a variable from the other type. For example:

Listing 13: illegal_example.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Illegal_Example is
   --  Declare two different floating point types
   type Meters is new Float;
   type Miles  is new Float;

   Dist_Imperial : Miles;

   --  Declare a constant
   Dist_Metric : constant Meters := 1000.0;
begin
   --  Not correct: types mismatch
   Dist_Imperial := Dist_Metric * 621.371e-6;
   Put_Line (Miles'Image (Dist_Imperial));
end Illegal_Example;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Imperial_Metric_Error
MD5: e28e341c5eda9b3b4cef691fa24b7f7e
```

Build output

```
illegal_example.adb:14:33: error: expected type "Miles" defined at line 6
illegal_example.adb:14:33: error: found type "Meters" defined at line 5
gprbuild: *** compilation phase failed
```

A consequence of these rules is that, in the general case, a "mixed mode" expression like `2 * 3.0` will trigger a compilation error. In a language like C or Python, such expressions are made valid by implicit conversions. In Ada, such conversions must be made explicit:

Listing 14: conv.adb

```
with Ada.Text_IO; use Ada.Text_IO;
procedure Conv is
   type Meters is new Float;
   type Miles is new Float;
   Dist_Imperial : Miles;
   Dist_Metric : constant Meters := 1000.0;
begin
   Dist_Imperial :=
     Miles (Dist_Metric) * 621.371e-6;
   --  ^^^^^^^^^^^^^^^^^
   --    Type conversion, from Meters to Miles
   --    Now the code is correct

   Put_Line (Miles'Image (Dist_Imperial));
end Conv;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Imperial_Metric
MD5: e455641e86227e80e5f920b5af6315d4
```

Runtime output

```
 6.21371E-01
```

Of course, we probably do not want to write the conversion code every time we convert from meters to miles. The idiomatic Ada way in that case would be to introduce conversion functions along with the types.

Listing 15: conv.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Conv is
   type Meters is new Float;
   type Miles  is new Float;

   --  Function declaration, like procedure
   --  but returns a value.
   function To_Miles (M : Meters) return Miles is
   --                              ^ Return type
   begin
      return Miles (M) * 621.371e-6;
   end To_Miles;

   Dist_Imperial : Miles;
   Dist_Metric   : constant Meters := 1000.0;
begin
   Dist_Imperial := To_Miles (Dist_Metric);
   Put_Line (Miles'Image (Dist_Imperial));
end Conv;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Imperial_Metric_Func
MD5: 661737fa9f130ac3070210bbf6f08214
```

Runtime output

```
6.21371E-01
```

If you write a lot of numeric code, having to explicitly provide such conversions might seem painful at first. However, this approach brings some advantages. Notably, you can rely on the absence of implicit conversions, which will in turn prevent some subtle errors.

In other languages

In C, for example, the rules for implicit conversions may not always be completely obvious. In Ada, however, the code will always do exactly what it seems to do. For example:

```
int a = 3, b = 2;
float f = a / b;
```

This code will compile fine, but the result of f will be 1.0 instead of 1.5, because the compiler will generate an integer division (three divided by two) that results in one. The software developer must be aware of data conversion issues and use an appropriate casting:

```
int a = 3, b = 2;
float f = (float)a / b;
```

In the corrected example, the compiler will convert both variables to their corresponding floating-point representation before performing the division. This will produce the expected result.

This example is very simple, and experienced C developers will probably notice and correct it before it creates bigger problems. However, in more complex applications where the type declaration is not always visible — e.g. when referring to elements of a **struct** — this situation might not always be evident and quickly lead to software defects that can be harder to find.

The Ada compiler, in contrast, will always reject code that mixes floating-point and integer variables without explicit conversion. The following Ada code, based on the erroneous example in C, will not compile:

Listing 16: main.adb

```
1 procedure Main is
2    A : Integer := 3;
3    B : Integer := 2;
4    F : Float;
5 begin
6    F := A / B;
7 end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Implicit_Cast
MD5: 38a8fcc6608c22e22940052ab8dd62f4
```

Build output

```
main.adb:6:11: error: expected type "Standard.Float"
main.adb:6:11: error: found type "Standard.Integer"
gprbuild: *** compilation phase failed
```

The offending line must be changed to `F := Float (A) / Float (B);` in order to be accepted by the compiler.

You can use Ada's strong typing to help enforce invariants in your code, as in the example above: Since Miles and Meters are two different types, you cannot mistakenly convert an instance of one to an instance of the other.

5.7 Derived types

In Ada you can create new types based on existing ones. This is very useful: you get a type that has the same properties as some existing type but is treated as a distinct type in the interest of strong typing.

Listing 17: main.adb

```
procedure Main is
   --  ID card number type,
   --  incompatible with Integer.
   type Social_Security_Number is new Integer
     range 0 .. 999_99_9999;
   --       ^ Since a SSN has 9 digits
   --         max., and cannot be
   --         negative, we enforce
   --         a validity constraint.

   SSN : Social_Security_Number :=
     555_55_5555;
   --    ^ You can put underscores as
   --      formatting in any number.

   I   : Integer;

   --  The value -1 below will cause a
   --  runtime error and a compile time
   --  warning with GNAT.
   Invalid : Social_Security_Number := -1;
begin
   --  Illegal, they have different types:
   I := SSN;

   --  Likewise illegal:
   SSN := I;

   --  OK with explicit conversion:
   I := Integer (SSN);

   --  Likewise OK:
   SSN := Social_Security_Number (I);
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Derived_Types
MD5: 63445601ddb5e52dceab095d3305623a
```

Build output

```
main.adb:21:40: warning: value not in range of type "Social_Security_Number"␣
 ↪defined at line 4 [enabled by default]
main.adb:21:40: warning: Constraint_Error will be raised at run time [enabled by␣
 ↪default]
```

(continues on next page)

(continued from previous page)

```
main.adb:24:09: error: expected type "Standard.Integer"
main.adb:24:09: error: found type "Social_Security_Number" defined at line 4
main.adb:27:11: error: expected type "Social_Security_Number" defined at line 4
main.adb:27:11: error: found type "Standard.Integer"
gprbuild: *** compilation phase failed
```

The type `Social_Security` is said to be a *derived type*; its *parent type* is **`Integer`**.

As illustrated in this example, you can refine the valid range when defining a derived scalar type (such as integer, floating-point and enumeration).

The syntax for enumerations uses the **`range`** <**`range`**> syntax:

Listing 18: greet.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Greet is
   type Days is (Monday, Tuesday, Wednesday,
                 Thursday, Friday,
                 Saturday, Sunday);

   type Weekend_Days is new
     Days range Saturday .. Sunday;
   --  New type, where only Saturday and Sunday
   --  are valid literals.
begin
   null;
end Greet;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Days
MD5: 853b5c1576961c7c20d4306275122364
```

5.8 Subtypes

As we are starting to see, types may be used in Ada to enforce constraints on the valid range of values. However, we sometimes want to enforce constraints on some values while staying within a single type. This is where subtypes come into play. A subtype does not introduce a new type.

Listing 19: greet.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Greet is
   type Days is (Monday, Tuesday, Wednesday,
                 Thursday, Friday,
                 Saturday, Sunday);

   --  Declaration of a subtype
   subtype Weekend_Days is
     Days range Saturday .. Sunday;
   --      ^ Constraint of the subtype

   M : Days := Sunday;

```

(continues on next page)

(continued from previous page)

```
   S : Weekend_Days := M;
   --  No error here, Days and Weekend_Days
   --  are of the same type.
begin
   for I in Days loop
      case I is
         --  Just like a type, a subtype can
         --  be used as a range
         when Weekend_Days =>
            Put_Line ("Week end!");
         when others =>
            Put_Line ("Hello on "
                      & Days'Image (I));
      end case;
   end loop;
end Greet;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Days_Subtype
MD5: 8ee7127d152a8b2c9d0ac74d05fc2fc2
```

Runtime output

```
Hello on MONDAY
Hello on TUESDAY
Hello on WEDNESDAY
Hello on THURSDAY
Hello on FRIDAY
Week end!
Week end!
```

Several subtypes are predefined in the standard package in Ada, and are automatically available to you:

```
subtype Natural  is Integer range 0 .. Integer'Last;
subtype Positive is Integer range 1 .. Integer'Last;
```

While subtypes of a type are statically compatible with each other, constraints are enforced at run time: if you violate a subtype constraint, an exception will be raised.

Listing 20: greet.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Greet is
   type Days is (Monday, Tuesday, Wednesday,
                 Thursday, Friday,
                 Saturday, Sunday);

   subtype Weekend_Days is
     Days range Saturday .. Sunday;

   Day     : Days := Saturday;
   Weekend : Weekend_Days;
begin
   Weekend := Day;
   --         ^ Correct: Same type, subtype
   --           constraints are respected
   Weekend := Monday;
   --         ^ Wrong value for the subtype
```

(continues on next page)

(continued from previous page)

```
   --           Compiles, but exception at runtime
end Greet;
```

greet.adb:17:15: warning: Constraint_Error will be raised at run time [enabled by␣
 ↪default]
```

Runtime output

```

raised CONSTRAINT_ERROR : greet.adb:17 range check failed
```

5.8.1 Subtypes as type aliases

Previously, we've seen that we can create new types by declaring e.g. **type Miles is new Float**. We could also create type aliases, which generate alternative names — *aliases* — for known types. Note that type aliases are sometimes called *type synonyms*.

We achieve this in Ada by using subtypes without new constraints. In this case, however, we don't get all of the benefits of Ada's strong type checking. Let's rewrite an example using type aliases:

Listing 21: undetected_imperial_metric_error.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Undetected_Imperial_Metric_Error is
   --  Declare two type aliases
   subtype Meters is Float;
   subtype Miles is Float;

   Dist_Imperial : Miles;

   --  Declare a constant
   Dist_Metric : constant Meters := 100.0;
begin
   --  No conversion to Miles type required:
   Dist_Imperial := (Dist_Metric * 1609.0)
                     / 1000.0;

   --  Not correct, but undetected:
   Dist_Imperial := Dist_Metric;

   Put_Line (Miles'Image (Dist_Imperial));
end Undetected_Imperial_Metric_Error;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Strongly_Typed_Language.Undetected_Imperial_Metric_
 ↪Error
MD5: cdb8f949c69f3c480502b859dac298ee
```

Runtime output

```
 1.00000E+02
```

In the example above, the fact that both `Meters` and `Miles` are subtypes of **`Float`** allows us to mix variables of both types without type conversion. This, however, can lead to all sorts of programming mistakes that we'd like to avoid, as we can see in the undetected error highlighted in the code above. In that example, the error in the assignment of a value in meters to a variable meant to store values in miles remains undetected because both `Meters` and `Miles` are subtypes of **`Float`**. Therefore, the recommendation is to use strong typing — via **`type X is new`** Y — for cases such as the one above.

There are, however, many situations where type aliases are useful. For example, in an application that uses floating-point types in multiple contexts, we could use type aliases to indicate additional meaning to the types or to avoid long variable names. For example, instead of writing:

```
Paid_Amount, Due_Amount : Float;
```

We could write:

```
subtype Amount is Float;

Paid, Due : Amount;
```

In other languages

In C, for example, we can use a **`typedef`** declaration to create a type alias. For example:

```
typedef float meters;
```

This corresponds to the declaration that we've seen above using subtypes. Other programming languages include this concept in similar ways. For example:

- C++: `using meters = float;`
- Swift: `typealias Meters = Double`
- Kotlin: `typealias Meters = Double`
- Haskell: `type Meters = Float`

Note, however, that subtypes in Ada correspond to type aliases if, and only if, they don't have new constraints. Thus, if we add a new constraint to a subtype declaration, we don't have a type alias anymore. For example, the following declaration *can't* be considered a type alias of **`Float`**:

```
subtype Meters is Float range 0.0 .. 1_000_000.0;
```

Let's look at another example:

```
subtype Degree_Celsius is Float;

subtype Liquid_Water_Temperature is
  Degree_Celsius range 0.0 .. 100.0;

subtype Running_Water_Temperature is
  Liquid_Water_Temperature;
```

In this example, `Liquid_Water_Temperature` isn't an alias of `Degree_Celsius`, since it adds a new constraint that wasn't part of the declaration of the `Degree_Celsius`. However, we do have two type aliases here:

- `Degree_Celsius` is an alias of **`Float`**;
- `Running_Water_Temperature` is an alias of `Liquid_Water_Temperature`, even if `Liquid_Water_Temperature` itself has a constrained range.

CHAPTER

SIX

RECORDS

So far, all the types we have encountered have values that are not decomposable: each instance represents a single piece of data. Now we are going to see our first class of composite types: records.

Records allow composing a value out of instances of other types. Each of those instances will be given a name. The pair consisting of a name and an instance of a specific type is called a field, or a component.

6.1 Record type declaration

Here is an example of a simple record declaration:

```
type Date is record
   --  The following declarations are
   --  components of the record
   Day   : Integer range 1 .. 31;
   Month : Months;
   --  You can add custom constraints
   --  on fields
   Year  : Integer range 1 .. 3000;
end record;
```

Fields look a lot like variable declarations, except that they are inside of a record definition. And as with variable declarations, you can specify additional constraints when supplying the subtype of the field.

```
type Date is record
   Day   : Integer range 1 .. 31;
   Month : Months := January;
   --  This component has a default value
   Year  : Integer range 1 .. 3000 := 2012;
   --                                 ^^^^
   --                              Default value
end record;
```

Record components can have default values. When a variable having the record type is declared, a field with a default initialization will be automatically set to this value. The value can be any expression of the component type, and may be run-time computable.

In the remaining sections of this chapter, we see how to use record types. In addition to that, we discuss more about records in *another chapter* (page 101).

6.2 Aggregates

```
--  Positional components
Ada_Birthday    : Date := (10, December, 1815);

--  Named components
Leap_Day_2020   : Date := (Day   => 29,
                           Month => February,
                           Year  => 2020);
--                         ^ By name
```

Records have a convenient notation for expressing values, illustrated above. This notation is called aggregate notation, and the literals are called aggregates. They can be used in a variety of contexts that we will see throughout the course, one of which is to initialize records.

An aggregate is a list of values separated by commas and enclosed in parentheses. It is allowed in any context where a value of the record is expected.

Values for the components can be specified positionally, as in `Ada_Birthday` example, or by name, as in `Leap_Day_2020`. A mixture of positional and named values is permitted, but you cannot use a positional notation after a named one.

6.3 Component selection

To access components of a record instance, you use an operation that is called component selection. This is achieved by using the dot notation. For example, if we declare a variable `Some_Day` of the `Date` record type mentioned above, we can access the `Year` component by writing `Some_Day.Year`.

Let's look at an example:

Listing 1: record_selection.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Record_Selection is
4
5     type Months is
6       (January, February, March, April,
7        May, June, July, August, September,
8        October, November, December);
9
10    type Date is record
11       Day   : Integer range 1 .. 31;
12       Month : Months;
13       Year  : Integer range 1 .. 3000 := 2032;
14    end record;
15
16    procedure Display_Date (D : Date) is
17    begin
18       Put_Line ("Day:" & Integer'Image (D.Day)
19                 & ", Month: "
20                 & Months'Image (D.Month)
21                 & ", Year:"
22                 & Integer'Image (D.Year));
23    end Display_Date;
24
25    Some_Day : Date := (1, January, 2000);
```

(continues on next page)

(continued from previous page)

```
26
27 begin
28    Display_Date (Some_Day);
29
30    Put_Line ("Changing year...");
31    Some_Day.Year := 2001;
32
33    Display_Date (Some_Day);
34 end Record_Selection;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Records.Record_Selection
MD5: 79602cf4d011ba7423d07772b13e2b5a
```

Runtime output

```
Day: 1, Month: JANUARY, Year: 2000
Changing year...
Day: 1, Month: JANUARY, Year: 2001
```

As you can see in this example, we can use the dot notation in the expression `D.Year` or `Some_Day.Year` to access the information stored in that component, as well as to modify this information in assignments. To be more specific, when we use `D.Year` in the call to `Put_Line`, we're retrieving the information stored in that component. When we write `Some_Day.Year := 2001`, we're overwriting the information that was previously stored in the `Year` component of `Some_Day`.

6.4 Renaming

In previous chapters, we've discussed *subprogram* (page 32) and *package* (page 46) renaming. We can rename record components as well. Instead of writing the full component selection using the dot notation, we can declare an alias that allows us to access the same component. This is useful to simplify the implementation of a subprogram, for example.

We can rename record components by using the **renames** keyword in a variable declaration. For example:

```
Some_Day : Date;
Y        : Integer renames Some_Day.Year;
```

Here, Y is an alias, so that every time we using Y, we are really using the `Year` component of `Some_Day`.

Let's look at a complete example:

Listing 2: dates.ads

```
1  package Dates is
2
3     type Months is
4       (January, February, March, April,
5        May, June, July, August, September,
6        October, November, December);
7
8     type Date is record
9        Day   : Integer range 1 .. 31;
10       Month : Months;
```

(continues on next page)

(continued from previous page)

```
      Year  : Integer range 1 .. 3000 := 2032;
   end record;

   procedure Increase_Month
    (Some_Day : in out Date);

   procedure Display_Month
     (Some_Day : Date);

end Dates;
```

Listing 3: dates.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Dates is

   procedure Increase_Month
     (Some_Day : in out Date)
   is
      --  Renaming components from
      --  the Date record
      M : Months  renames Some_Day.Month;
      Y : Integer renames Some_Day.Year;

      --  Renaming function (for Months
      --  enumeration)
      function Next (M : Months)
                     return Months
        renames Months'Succ;
   begin
      if M = December then
         M := January;
         Y := Y + 1;
      else
         M := Next (M);
      end if;
   end Increase_Month;

   procedure Display_Month
     (Some_Day : Date)
   is
      --  Renaming components from
      --  the Date record
      M : Months  renames Some_Day.Month;
      Y : Integer renames Some_Day.Year;
   begin
      Put_Line ("Month: "
                & Months'Image (M)
                & ", Year:"
                & Integer'Image (Y));
   end Display_Month;

end Dates;
```

Listing 4: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Dates;       use Dates;

```

(continues on next page)

(continued from previous page)

```
4  procedure Main is
5     D : Date := (1, January, 2000);
6  begin
7     Display_Month (D);
8
9     Put_Line ("Increasing month...");
10    Increase_Month (D);
11
12    Display_Month (D);
13 end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Arrays.Record_Component_Renaming
MD5: 905390bd02b84170390522l8800975a3
```

Runtime output

```
Month: JANUARY, Year: 2000
Increasing month...
Month: FEBRUARY, Year: 2000
```

We apply renaming to two components of the `Date` record in the implementation of the `Increase_Month` procedure. Then, instead of directly using `Some_Day.Month` and `Some_Day.Year` in the next operations, we simply use the renamed versions `M` and `Y`.

Note that, in the example above, we also rename `Months'Succ` — which is the function that gives us the next month — to `Next`.

CHAPTER

SEVEN

ARRAYS

Arrays provide another fundamental family of composite types in Ada.

7.1 Array type declaration

Arrays in Ada are used to define contiguous collections of elements that can be selected by indexing. Here's a simple example:

Listing 1: greet.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Greet is
   type My_Int is range 0 .. 1000;
   type Index is range 1 .. 5;

   type My_Int_Array is
     array (Index) of My_Int;
   --                  ^ Type of elements
   --       ^ Bounds of the array
   Arr : My_Int_Array := (2, 3, 5, 7, 11);
   --                    ^ Array literal
   --                      (aggregate)

   V : My_Int;
begin
   for I in Index loop
      V := Arr (I);
      --        ^ Take the Ith element
      Put (My_Int'Image (V));
   end loop;
   New_Line;
end Greet;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Arrays.Greet
MD5: ffdd2ba2322b0946dfcac3a55bce5270
```

Runtime output

```
 2 3 5 7 11
```

The first point to note is that we specify the index type for the array, rather than its size. Here we declared an integer type named Index ranging from 1 to 5, so each array instance will have 5 elements, with the initial element at index 1 and the last element at index 5.

Although this example used an integer type for the index, Ada is more general: any discrete type is permitted to index an array, including *Enum types* (page 51). We will soon see what that means.

Another point to note is that querying an element of the array at a given index uses the same syntax as for function calls: that is, the array object followed by the index in parentheses.

Thus when you see an expression such as `A (B)`, whether it is a function call or an array subscript depends on what `A` refers to.

Finally, notice how we initialize the array with the `(2, 3, 5, 7, 11)` expression. This is another kind of aggregate in Ada, and is in a sense a literal expression for an array, in the same way that `3` is a literal expression for an integer. The notation is very powerful, with a number of properties that we will introduce later. A detailed overview appears in the notation of *aggregate types* (page 89).

Unrelated to arrays, the example also illustrated two procedures from `Ada.Text_IO`:

- `Put`, which displays a string without a terminating end of line
- `New_Line`, which outputs an end of line

Let's now delve into what it means to be able to use any discrete type to index into the array.

In other languages

Semantically, an array object in Ada is the entire data structure, and not simply a handle or pointer. Unlike C and C++, there is no implicit equivalence between an array and a pointer to its initial element.

Listing 2: array_bounds_example.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Array_Bounds_Example is
   type My_Int is range 0 .. 1000;

   type Index is range 11 .. 15;
   --                  ^ Low bound can
   --                    be any value

   type My_Int_Array is
     array (Index) of My_Int;

   Tab : constant My_Int_Array :=
           (2, 3, 5, 7, 11);
begin
   for I in Index loop
      Put (My_Int'Image (Tab (I)));
   end loop;
   New_Line;
end Array_Bounds_Example;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Arrays.Array_Bounds_Example
MD5: e5fe9e7b83055f3ae23dd890e29c22de
```

Runtime output

```
 2 3 5 7 11
```

One effect is that the bounds of an array can be any values. In the first example we constructed an array type whose first index is 1, but in the example above we declare an array type whose first index is 11.

That's perfectly fine in Ada, and moreover since we use the index type as a range to iterate over the array indices, the code using the array does not need to change.

That leads us to an important consequence with regard to code dealing with arrays. Since the bounds can vary, you should not assume / hard-code specific bounds when iterating / using arrays. That means the code above is good, because it uses the index type, but a for loop as shown below is bad practice even though it works correctly:

```
for I in 11 .. 15 loop
   Tab (I) := Tab (I) * 2;
end loop;
```

Since you can use any discrete type to index an array, enumeration types are permitted.

Listing 3: month_example.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Month_Example is
   type Month_Duration is range 1 .. 31;
   type Month is (Jan, Feb, Mar, Apr,
                  May, Jun, Jul, Aug,
                  Sep, Oct, Nov, Dec);

   type My_Int_Array is
     array (Month) of Month_Duration;
   --       ^ Can use an enumeration type
   --         as the index

   Tab : constant My_Int_Array :=
   --    ^ constant is like a variable but
   --      cannot be modified
     (31, 28, 31, 30, 31, 30,
      31, 31, 30, 31, 30, 31);
   --  Maps months to number of days
   --  (ignoring leap years)

   Feb_Days : Month_Duration := Tab (Feb);
   --  Number of days in February
begin
   for M in Month loop
      Put_Line
        (Month'Image (M) & " has "
         & Month_Duration'Image (Tab (M))
         & " days.");
   --    ^ Concatenation operator
   end loop;
end Month_Example;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Arrays.Month_Example
MD5: 420bb8faa36d0efd3d071c76c2033d21
```

Runtime output

```
JAN has  31 days.
FEB has  28 days.
MAR has  31 days.
```

(continues on next page)

(continued from previous page)

```
APR has  30 days.
MAY has  31 days.
JUN has  30 days.
JUL has  31 days.
AUG has  31 days.
SEP has  30 days.
OCT has  31 days.
NOV has  30 days.
DEC has  31 days.
```

In the example above, we are:

- Creating an array type mapping months to month durations in days.
- Creating an array, and instantiating it with an aggregate mapping months to their actual durations in days.
- Iterating over the array, printing out the months, and the number of days for each.

Being able to use enumeration values as indices is very helpful in creating mappings such as shown above one, and is an often used feature in Ada.

7.2 Indexing

We have already seen the syntax for selecting elements of an array. There are however a few more points to note.

First, as is true in general in Ada, the indexing operation is strongly typed. If you use a value of the wrong type to index the array, you will get a compile-time error.

Listing 4: greet.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Greet is
   type My_Int is range 0 .. 1000;

   type My_Index   is range 1 .. 5;
   type Your_Index is range 1 .. 5;

   type My_Int_Array is
     array (My_Index) of My_Int;

   Tab : My_Int_Array := (2, 3, 5, 7, 11);
begin
   for I in Your_Index loop
      Put (My_Int'Image (Tab (I)));
   --                          ^ Compile time error
   end loop;
   New_Line;
end Greet;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Arrays.Greet_2
MD5: 54543017e4ec69d24bf9e43d507b50e6
```

Build output

```
greet.adb:15:31: error: expected type "My_Index" defined at line 6
greet.adb:15:31: error: found type "Your_Index" defined at line 7
gprbuild: *** compilation phase failed
```

Second, arrays in Ada are bounds checked. This means that if you try to access an element outside of the bounds of the array, you will get a run-time error instead of accessing random memory as in unsafe languages.

Listing 5: greet.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Greet is
   type My_Int is range 0 .. 1000;
   type Index  is range 1 .. 5;

   type My_Int_Array is
     array (Index) of My_Int;

   Tab : My_Int_Array := (2, 3, 5, 7, 11);
begin
   for I in Index range 2 .. 6 loop
      Put (My_Int'Image (Tab (I)));
      --                      ^ Will raise an
      --                        exception when
      --                        I = 6
   end loop;
   New_Line;
end Greet;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Arrays.Greet_3
MD5: 0102674d089be838f1dfbf0791d99fce
```

Build output

```
greet.adb:12:30: warning: static value out of range of type "Index" defined at␣
 ↪line 5 [enabled by default]
greet.adb:12:30: warning: Constraint_Error will be raised at run time [enabled by␣
 ↪default]
greet.adb:12:30: warning: suspicious loop bound out of range of loop subtype␣
 ↪[enabled by default]
greet.adb:12:30: warning: loop executes zero times or raises Constraint_Error␣
 ↪[enabled by default]
```

Runtime output

```

raised CONSTRAINT_ERROR : greet.adb:12 range check failed
```

7.3 Simpler array declarations

In the previous examples, we have always explicitly created an index type for the array. While this can be useful for typing and readability purposes, sometimes you simply want to express a range of values. Ada allows you to do that, too.

Listing 6: simple_array_bounds.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Simple_Array_Bounds is
   type My_Int is range 0 .. 1000;

   type My_Int_Array is
     array (1 .. 5) of My_Int;
   --       ^ Subtype of Integer

   Tab : constant My_Int_Array :=
           (2, 3, 5, 7, 11);
begin
   for I in 1 .. 5 loop
   --       ^ Subtype of Integer
      Put (My_Int'Image (Tab (I)));
   end loop;
   New_Line;
end Simple_Array_Bounds;
```

Code block metadata

```

```

Runtime output

```
 2 3 5 7 11
```

This example defines the range of the array via the range syntax, which specifies an anonymous subtype of Integer and uses it to index the array.

This means that the type of the index is **Integer**. Similarly, when you use an anonymous range in a for loop as in the example above, the type of the iteration variable is also **Integer**, so you can use I to index Tab.

You can also use a named subtype for the bounds for an array.

7.4 Range attribute

We noted earlier that hard coding bounds when iterating over an array is a bad idea, and showed how to use the array's index type/subtype to iterate over its range in a **for** loop. That raises the question of how to write an iteration when the array has an anonymous range for its bounds, since there is no name to refer to the range. Ada solves that via several attributes of array objects:

Listing 7: range_example.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Range_Example is
```

(continues on next page)

(continued from previous page)

```
   type My_Int is range 0 .. 1000;

   type My_Int_Array is
     array (1 .. 5) of My_Int;

   Tab : constant My_Int_Array :=
           (2, 3, 5, 7, 11);
begin
   for I in Tab'Range loop
   --          ^ Gets the range of Tab
      Put (My_Int'Image (Tab (I)));
   end loop;
   New_Line;
end Range_Example;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Arrays.Range_Example
MD5: 8b0d7bf346cb59999dfd12dbaaf3e2a6
```

Runtime output

```
 2 3 5 7 11
```

If you want more fine grained control, you can use the separate attributes `'First` and `'Last`.

Listing 8: array_attributes_example.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Array_Attributes_Example is
   type My_Int is range 0 .. 1000;

   type My_Int_Array is
     array (1 .. 5) of My_Int;

   Tab : My_Int_Array :=
           (2, 3, 5, 7, 11);
begin
   for I in Tab'First .. Tab'Last - 1 loop
   --          ^ Iterate on every index
   --            except the last
      Put (My_Int'Image (Tab (I)));
   end loop;
   New_Line;
end Array_Attributes_Example;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Arrays.Array_Attributes_Example
MD5: 95cc407c8aadd936e050fe3505e8fb46
```

Runtime output

```
 2 3 5 7
```

The `'Range`, `'First` and `'Last` attributes in these examples could also have been applied to the array type name, and not just the array instances.

Although not illustrated in the above examples, another useful attribute for an array instance A is `A'Length`, which is the number of elements that A contains.

It is legal and sometimes useful to have a "null array", which contains no elements. To get this effect, define an index range whose upper bound is less than the lower bound.

7.5 Unconstrained arrays

Let's now consider one of the most powerful aspects of Ada's array facility.

Every array type we have defined so far has a fixed size: every instance of this type will have the same bounds and therefore the same number of elements and the same size.

However, Ada also allows you to declare array types whose bounds are not fixed: in that case, the bounds will need to be provided when creating instances of the type.

Listing 9: unconstrained_array_example.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Unconstrained_Array_Example is
   type Days is (Monday, Tuesday, Wednesday,
                 Thursday, Friday,
                 Saturday, Sunday);

   type Workload_Type is
     array (Days range <>) of Natural;
   --  Indefinite array type
   --        ^ Bounds are of type Days,
   --          but not known

   Workload : constant
     Workload_Type (Monday .. Friday) :=
   --               ^ Specify the bounds
   --                 when declaring
      (Friday => 7, others => 8);
   --               ^ Default value
   --  ^ Specify element by name of index
begin
   for I in Workload'Range loop
      Put_Line (Integer'Image (Workload (I)));
   end loop;
end Unconstrained_Array_Example;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Arrays.Unconstrained_Array_Example

```

Runtime output

```
 8
 8
 8
 8
 7
```

The fact that the bounds of the array are not known is indicated by the `Days range <>` syntax. Given a discrete type `Discrete_Type`, if we use `Discrete_Type` for the index in an array type then `Discrete_Type` serves as the type of the index and comprises the range of index values for each array instance.

If we define the index as `Discrete_Type range <>` then `Discrete_Type` serves as the type of the index, but different array instances may have different bounds from this type.

An array type that is defined with the `Discrete_Type range <>` syntax for its index is referred to as an unconstrained array type, and, as illustrated above, the bounds need to be provided when an instance is created.

The above example also shows other forms of the aggregate syntax. You can specify associations by name, by giving the value of the index on the left side of an arrow association. `1 => 2` thus means "assign value 2 to the element at index 1 in my array". `others => 8` means "assign value 8 to every element that wasn't previously assigned in this aggregate".

> **Attention:** The so-called "box" notation (<>) is commonly used as a wildcard or placeholder in Ada. You will often see it when the meaning is "what is expected here can be anything".

In other languages

While unconstrained arrays in Ada might seem similar to variable length arrays in C, they are in reality much more powerful, because they're truly first-class values in the language. You can pass them as parameters to subprograms or return them from functions, and they implicitly contain their bounds as part of their value. This means that it is useless to pass the bounds or length of an array explicitly along with the array, because they are accessible via the `'First`, `'Last`, `'Range` and `'Length` attributes explained earlier.

Although different instances of the same unconstrained array type can have different bounds, a specific instance has the same bounds throughout its lifetime. This allows Ada to implement unconstrained arrays efficiently; instances can be stored on the stack and do not require heap allocation as in languages like Java.

7.6 Predefined array type: String

A recurring theme in our introduction to Ada types has been the way important built-in types like **Boolean** or **Integer** are defined through the same facilities that are available to the user. This is also true for strings: The **String** type in Ada is a simple array.

Here is how the string type is defined in Ada:

```
type String is
  array (Positive range <>) of Character;
```

The only built-in feature Ada adds to make strings more ergonomic is custom literals, as we can see in the example below.

Hint: String literals are a syntactic sugar for aggregates, so that in the following example, A and B have the same value.

Listing 10: string_literals.ads

```
1 package String_Literals is
2     --  Those two declarations are equivalent
3     A : String (1 .. 11) := "Hello World";
4     B : String (1 .. 11) :=
5         ('H', 'e', 'l', 'l', 'o', ' ',
6          'W', 'o', 'r', 'l', 'd');
7 end String_Literals;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Arrays.String_Literals
MD5: 8e5871c8ead4ff8da643539857e23b30
```

Listing 11: greet.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Greet is
   Message : String (1 .. 11) := "dlroW olleH";
   --        ^ Pre-defined array type.
   --          Component type is Character
begin
   for I in reverse Message'Range loop
      --    ^ Iterate in reverse order
      Put (Message (I));
   end loop;
   New_Line;
end Greet;
```

However, specifying the bounds of the object explicitly is a bit of a hassle; you have to manually count the number of characters in the literal. Fortunately, Ada gives you an easier way.

You can omit the bounds when creating an instance of an unconstrained array type if you supply an initialization, since the bounds can be deduced from the initialization expression.

Listing 12: greet.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Greet is
   Message : constant String := "dlroW olleH";
   --                ^ Bounds are automatically
   --                  computed from
   --                  initialization value
begin
   for I in reverse Message'Range loop
      Put (Message (I));
   end loop;
   New_Line;
end Greet;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Arrays.Greet_5
MD5: 21448a1007a07ec9d434880628625c3f
```

Runtime output

```
Hello World
```

Listing 13: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   type Integer_Array is
     array (Natural range <>) of Integer;

   My_Array : constant Integer_Array :=
```

(continues on next page)

(continued from previous page)

```
                (1, 2, 3, 4);
   --          ^^^^^^^^^^^^^^^^^^^^
   --           Bounds are automatically
   --           computed from
   --           initialization value
begin
    null;
end Main;
```

Attention: As you can see above, the standard `String` type in Ada is an array. As such, it shares the advantages and drawbacks of arrays: a `String` value is stack allocated, it is accessed efficiently, and its bounds are immutable.

If you want something akin to C++'s `std::string`, you can use *Unbounded Strings* (page 246) from Ada's standard library. This type is more like a mutable, automatically managed string buffer to which you can add content.

7.7 Restrictions

A very important point about arrays: bounds *have* to be known when instances are created. It is for example illegal to do the following.

```
declare
   A : String;
begin
   A := "World";
end;
```

Also, while you of course can change the values of elements in an array, you cannot change the array's bounds (and therefore its size) after it has been initialized. So this is also illegal:

```
declare
   A : String := "Hello";
begin
   A := "World";       --  OK: Same size
   A := "Hello World"; --  Not OK: Different size
end;
```

Also, while you can expect a warning for this kind of error in very simple cases like this one, it is impossible for a compiler to know in the general case if you are assigning a value of the correct length, so this violation will generally result in a run-time error.

Attention

While we will learn more about this later, it is important to know that arrays are not the only types whose instances might be of unknown size at compile-time.

Such objects are said to be of an *indefinite subtype*, which means that the subtype size is not known at compile time, but is dynamically computed (at run time).

Listing 14: indefinite_subtypes.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Indefinite_Subtypes is
```

(continues on next page)

(continued from previous page)

```
    function Get_Number return Integer is
    begin
        return Integer'Value (Get_Line);
    end Get_Number;

   A : String := "Hello";
   --  Indefinite subtype

   B : String (1 .. 5) := "Hello";
   --  Definite subtype

   C : String (1 .. Get_Number);
   --  Indefinite subtype
   --  (Get_Number's value is computed at
   --  run-time)
begin
   null;
end Indefinite_Subtypes;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Arrays.Indefinite_Subtypes
MD5: a24235838511a94879f74757421a28f0
```

Here, the `'Value` attribute converts the string to an integer.

7.8 Returning unconstrained arrays

The return type of a function can be any type; a function can return a value whose size is unknown at compile time. Likewise, the parameters can be of any type.

For example, this is a function that returns an unconstrained `String`:

Listing 15: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is

   type Days is (Monday, Tuesday, Wednesday,
                 Thursday, Friday,
                 Saturday, Sunday);

   function Get_Day_Name (Day : Days := Monday)
                          return String is
   begin
      return
        (case Day is
         when Monday    => "Monday",
         when Tuesday   => "Tuesday",
         when Wednesday => "Wednesday",
         when Thursday  => "Thursday",
         when Friday    => "Friday",
         when Saturday  => "Saturday",
         when Sunday    => "Sunday");
   end Get_Day_Name;

```

(continues on next page)

(continued from previous page)

```
begin
   Put_Line ("First day is "
             & Get_Day_Name (Days'First));
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Arrays.Day_Name_1
MD5: 0b7c567c723ded52d8e95c4ef46bcecc
```

Runtime output

```
First day is Monday
```

(This example is for illustrative purposes only. There is a built-in mechanism, the 'Image attribute for scalar types, that returns the name (as a **String**) of any element of an enumeration type. For example Days'Image(Monday) is "MONDAY".)

In other languages

Returning variable size objects in languages lacking a garbage collector is a bit complicated implementation-wise, which is why C and C++ don't allow it, preferring to depend on explicit dynamic allocation / free from the user.

The problem is that explicit storage management is unsafe as soon as you want to collect unused memory. Ada's ability to return variable size objects will remove one use case for dynamic allocation, and hence, remove one potential source of bugs from your programs.

Rust follows the C/C++ model, but with safe pointer semantics. However, dynamic allocation is still used. Ada can benefit from a possible performance edge because it can use any model.

7.9 Declaring arrays (2)

While we can have array types whose size and bounds are determined at run time, the array's component type needs to be of a definite and constrained type.

Thus, if you need to declare, for example, an array of strings, the **String** subtype used as component will need to have a fixed size.

Listing 16: show_days.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Days is
   type Days is (Monday, Tuesday, Wednesday,
                 Thursday, Friday,
                 Saturday, Sunday);

   subtype Day_Name is String (1 .. 2);
   --  Subtype of string with known size

   type Days_Name_Type is
     array (Days) of Day_Name;
   --       ^ Type of the index
   --                 ^ Type of the element.
   --                   Must be definite
```

(continues on next page)

(continued from previous page)

```
16
17    Names : constant Days_Name_Type :=
18      ("Mo", "Tu", "We", "Th", "Fr", "Sa", "Su");
19    --  Initial value given by aggregate
20 begin
21    for I in Names'Range loop
22       Put_Line (Names (I));
23    end loop;
24 end Show_Days;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Arrays.Day_Name_2
MD5: bc66303091c084f66abde72ae59f55a9
```

Runtime output

```
Mo
Tu
We
Th
Fr
Sa
Su
```

7.10 Array slices

One last feature of Ada arrays that we're going to cover is array slices. It is possible to take and use a slice of an array (a contiguous sequence of elements) as a name or a value.

Listing 17: main.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Main is
4      Buf : String := "Hello ...";
5
6      Full_Name : String := "John Smith";
7  begin
8      Buf (7 .. 9) := "Bob";
9      --  Careful! This works because the string
10     --  on the right side is the same length as
11     --  the replaced slice!
12
13     --  Prints "Hello Bob"
14     Put_Line (Buf);
15
16      --  Prints "Hi John"
17     Put_Line ("Hi " & Full_Name (1 .. 4));
18 end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Arrays.Slices
MD5: cdf582c6c9089658236f5c79b7be4c3f
```

Runtime output

```
Hello Bob
Hi John
```

As we can see above, you can use a slice on the left side of an assignment, to replace only part of an array.

A slice of an array is of the same type as the array, but has a different subtype, constrained by the bounds of the slice.

Attention: Ada has multidimensional arrays[14], which are not covered in this course. Slices will only work on one dimensional arrays.

7.11 Renaming

So far, we've seen that the following elements can be renamed: *subprograms* (page 32), *packages* (page 46), and *record components* (page 67). We can also rename objects by using the **renames** keyword. This allows for creating alternative names for these objects. Let's look at an example:

Listing 18: measurements.ads

```
1  package Measurements is
2
3     subtype Degree_Celsius is Float;
4
5     Current_Temperature : Degree_Celsius;
6
7  end Measurements;
```

Listing 19: main.adb

```
1  with Ada.Text_IO;  use Ada.Text_IO;
2  with Measurements;
3
4  procedure Main is
5     subtype Degrees is
6       Measurements.Degree_Celsius;
7
8     T : Degrees
9           renames Measurements.Current_Temperature;
10 begin
11     T := 5.0;
12
13     Put_Line (Degrees'Image (T));
14     Put_Line (Degrees'Image
15       (Measurements.Current_Temperature));
16
17     T := T + 2.5;
18
19     Put_Line (Degrees'Image (T));
20     Put_Line (Degrees'Image
21       (Measurements.Current_Temperature));
22 end Main;
```

Code block metadata

[14] http://www.ada-auth.org/standards/12rm/html/RM-3-6.html

```
Project: Courses.Intro_To_Ada.Arrays.Variable_Renaming
MD5: 4426aeaa364cb5cf10ff40e1bccb9757
```

Runtime output

```
 5.00000E+00
 5.00000E+00
 7.50000E+00
 7.50000E+00
```

In the example above, we declare a variable T by renaming the `Current_Temperature` object from the `Measurements` package. As you can see by running this example, both `Current_Temperature` and its alternative name T have the same values:

- first, they show the value 5.0
- after the addition, they show the value 7.5.

This is because they are essentially referring to the same object, but with two different names.

Note that, in the example above, we're using `Degrees` as an alias of `Degree_Celsius`. We discussed this method *earlier in the course* (page 62).

Renaming can be useful for improving the readability of more complicated array indexing. Instead of explicitly using indices every time we're accessing certain positions of the array, we can create shorter names for these positions by renaming them. Let's look at the following example:

Listing 20: colors.ads

```
1  package Colors is
2
3     type Color is (Black,
4                    Red,
5                    Green,
6                    Blue,
7                    White);
8
9     type Color_Array is
10      array (Positive range <>) of Color;
11
12    procedure Reverse_It (X : in out Color_Array);
13
14 end Colors;
```

Listing 21: colors.adb

```
1  package body Colors is
2
3     procedure Reverse_It (X : in out Color_Array)
4     is
5     begin
6        for I in X'First ..
7                 (X'Last + X'First) / 2
8        loop
9           declare
10             Tmp     : Color;
11             X_Left  : Color
12               renames X (I);
13             X_Right : Color
14               renames X (X'Last + X'First - I);
15          begin
```

(continues on next page)

(continued from previous page)

```
            Tmp     := X_Left;
            X_Left  := X_Right;
            X_Right := Tmp;
         end;
      end loop;
   end Reverse_It;

end Colors;
```

Listing 22: test_reverse_colors.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Colors; use Colors;

procedure Test_Reverse_Colors is

   My_Colors : Color_Array (1 .. 5) :=
     (Black, Red, Green, Blue, White);

begin
   for C of My_Colors loop
      Put_Line ("My_Color: "
                & Color'Image (C));
   end loop;

   New_Line;
   Put_Line ("Reversing My_Color...");
   New_Line;
   Reverse_It (My_Colors);

   for C of My_Colors loop
      Put_Line ("My_Color: "
                & Color'Image (C));
   end loop;

end Test_Reverse_Colors;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Arrays.Reverse_Colors
MD5: cd9fd7f64d1ec8967e340d57fd7afc0a
```

Runtime output

```
My_Color: BLACK
My_Color: RED
My_Color: GREEN
My_Color: BLUE
My_Color: WHITE

Reversing My_Color...

My_Color: WHITE
My_Color: BLUE
My_Color: GREEN
My_Color: RED
My_Color: BLACK
```

In the example above, package `Colors` implements the procedure `Reverse_It` by declaring new names for two positions of the array. The actual implementation becomes easy to read:

```
begin
   Tmp     := X_Left;
   X_Left  := X_Right;
   X_Right := Tmp;
end;
```

Compare this to the alternative version without renaming:

```
begin
   Tmp                      := X (I);
   X (I)                    := X (X'Last +
                               X'First - I);
   X (X'Last + X'First - I) := Tmp;
end;
```

CHAPTER

EIGHT

MORE ABOUT TYPES

8.1 Aggregates: A primer

So far, we have talked about aggregates quite a bit and have seen a number of examples. Now we will revisit this feature in some more detail.

An Ada aggregate is, in effect, a literal value for a composite type. It's a very powerful notation that helps you to avoid writing procedural code for the initialization of your data structures in many cases.

A basic rule when writing aggregates is that *every component* of the array or record has to be specified, even components that have a default value.

This means that the following code is incorrect:

Listing 1: incorrect.ads

```
package Incorrect is
   type Point is record
      X, Y : Integer := 0;
   end record;

   Origin : Point := (X => 0);
end Incorrect;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.More_About_Types.Incorrect_Aggregate
MD5: 80a3475dece1c42cfb67b1d57b5bd464
```

Build output

```
incorrect.ads:6:22: error: no value supplied for component "Y"
gprbuild: *** compilation phase failed
```

There are a few shortcuts that you can use to make the notation more convenient:

- To specify the default value for a component, you can use the <> notation.
- You can use the | symbol to give several components the same value.
- You can use the **others** choice to refer to every component that has not yet been specified, provided all those fields have the same type.
- You can use the range notation `..` to refer to specify a contiguous sequence of indices in an array.

However, note that as soon as you used a named association, all subsequent components likewise need to be specified with named associations.

Listing 2: points.ads

```
package Points is
   type Point is record
      X, Y : Integer := 0;
   end record;

   type Point_Array is
     array (Positive range <>) of Point;

   --  use the default values
   Origin   : Point := (X | Y => <>);

   --  likewise, use the defaults
   Origin_2 : Point := (others => <>);

   Points_1 : Point_Array := ((1, 2), (3, 4));
   Points_2 : Point_Array := (1       => (1, 2),
                              2       => (3, 4),
                              3 .. 20 => <>);
end Points;
```

Code block metadata

MD5: 48ea183a42f203325ed6190fbd8493d9
```

8.2 Overloading and qualified expressions

Ada has a general concept of name overloading, which we saw earlier in the section on *enumeration types* (page 51).

Let's take a simple example: it is possible in Ada to have functions that have the same name, but different types for their parameters.

Listing 3: pkg.ads

```
package Pkg is
   function F (A : Integer) return Integer;
   function F (A : Character) return Integer;
end Pkg;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.More_About_Types.Overloading
MD5: defae85228ee183b536af395d077e71e
```

This is a common concept in programming languages, called overloading[15], or name overloading.

One of the novel aspects of Ada's overloading facility is the ability to resolve overloading based on the return type of a function.

Listing 4: pkg.ads

```
package Pkg is
   type SSID is new Integer;
```

(continues on next page)

[15] https://en.wikipedia.org/wiki/Function_overloading

(continued from previous page)

```
3
4     function Convert (Self : SSID)
5                       return Integer;
6     function Convert (Self : SSID)
7                       return String;
8  end Pkg;
```

Listing 5: main.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2  with Pkg;         use Pkg;
3
4  procedure Main is
5     S : String := Convert (123_145_299);
6     --             ^ Valid, will choose the
7     --               proper Convert
8  begin
9     Put_Line (S);
10 end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.More_About_Types.Overloading
MD5: aa556b55ee89f9c5f8f7e138d84c27b8
```

Attention: Note that overload resolution based on the type is allowed for both functions and enumeration literals in Ada - which is why you can have multiple enumeration literals with the same name. Semantically, an enumeration literal is treated like a function that has no parameters.

However, sometimes an ambiguity makes it impossible to resolve which declaration of an overloaded name a given occurrence of the name refers to. This is where a qualified expression becomes useful.

Listing 6: pkg.ads

```
1  package Pkg is
2     type SSID is new Integer;
3
4     function Convert (Self : SSID)
5                       return Integer;
6     function Convert (Self : SSID)
7                       return String;
8     function Convert (Self : Integer)
9                       return String;
10 end Pkg;
```

Listing 7: main.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2  with Pkg;         use Pkg;
3
4  procedure Main is
5     S : String := Convert (123_145_299);
6     --             ^ Invalid, which convert
7     --               should we call?
8
9     S2 : String := Convert (SSID'(123_145_299));
```

(continues on next page)

(continued from previous page)

```
   --                       ^ We specify that the
   --                         type of the
   --                         expression is SSID.

   --  We could also have declared a temporary

   I : SSID := 123_145_299;

   S3 : String := Convert (I);
begin
   Put_Line (S);
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.More_About_Types.Overloading_Error
MD5: 722660d8b692cde65a1c2b7800dd78c4
```

Syntactically the target of a qualified expression can be either any expression in parentheses, or an aggregate:

Listing 8: qual_expr.ads

```
package Qual_Expr is
   type Point is record
      A, B : Integer;
   end record;

   P : Point := Point'(12, 15);

   A : Integer := Integer'(12);
end Qual_Expr;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.More_About_Types.Qual_Expr
MD5: e71523eb441a28a4f6549d5f0418620a
```

This illustrates that qualified expressions are a convenient (and sometimes necessary) way for the programmer to make the type of an expression explicit, for the compiler of course, but also for other programmers.

Attention: While they look and feel similar, type conversions and qualified expressions are *not* the same.

A qualified expression specifies the exact type that the target expression will be resolved to, whereas a type conversion will try to convert the target and issue a run-time error if the target value cannot be so converted.

Note that you can use a qualified expression to convert from one subtype to another, with an exception raised if a constraint is violated.

```
X : Integer := Natural'(1);
```

8.3 Character types

As noted earlier, each enumeration type is distinct and incompatible with every other enumeration type. However, what we did not mention previously is that character literals are permitted as enumeration literals. This means that in addition to the language's strongly typed character types, user-defined character types are also permitted:

Listing 9: character_example.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Character_Example is
   type My_Char is ('a', 'b', 'c');
   --  Our custom character type, an
   --  enumeration type with 3 valid values.

   C : Character;
   --  ^ Built-in character type
   --    (it's an enumeration type)

   M : My_Char;
begin
   C := '?';
   --   ^ Character literal
   --     (enumeration literal)

   M := 'a';

   C := 65;
   --   ^ Invalid: 65 is not a
   --     Character value

   C := Character'Val (65);
   --  Assign the character at
   --  position 65 in the
   --  enumeration (which is 'A')

   M := C;
   --   ^ Invalid: C is of type Character,
   --     and M is a My_Char

   M := 'd';
   --   ^ Invalid: 'd' is not a valid
   --     literal for type My_Char
end Character_Example;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.More_About_Types.Character_Example
MD5: e4c5a07dbe8745749056f8c110d69fa3
```

Build output

```
character_example.adb:20:09: error: expected type "Standard.Character"
character_example.adb:20:09: error: found type universal integer
character_example.adb:29:09: error: expected type "My_Char" defined at line 4
character_example.adb:29:09: error: found type "Standard.Character"
character_example.adb:33:09: error: character not defined for type "My_Char"␣
 ↪defined at line 4
gprbuild: *** compilation phase failed
```

In this example, we're using characters in the definition of `My_Char`.

CHAPTER

NINE

ACCESS TYPES (POINTERS)

9.1 Overview

Pointers are a potentially dangerous construct, which conflicts with Ada's underlying philosophy.

There are two ways in which Ada helps shield programmers from the dangers of pointers:

1. One approach, which we have already seen, is to provide alternative features so that the programmer does not need to use pointers. Parameter modes, arrays, and varying size types are all constructs that can replace typical pointer usages in C.
2. Second, Ada has made pointers as safe and restricted as possible, but allows "escape hatches" when the programmer explicitly requests them and presumably will be exercising such features with appropriate care.

Here is how you declare a simple pointer type, or access type, in Ada:

Listing 1: dates.ads

```
package Dates is
   type Months is
     (January, February, March, April,
      May, June, July, August, September,
      October, November, December);

   type Date is record
      Day   : Integer range 1 .. 31;
      Month : Months;
      Year  : Integer;
   end record;
end Dates;
```

Listing 2: access_types.ads

```
with Dates; use Dates;

package Access_Types is
    --  Declare an access type
    type Date_Acc is access Date;
    --                      ^ "Designated type"
    --                      ^ Date_Acc values
    --                        point to Date
    --                        objects

    D : Date_Acc := null;
    --             ^ Literal for
    --               "access to nothing"
```

(continues on next page)

(continued from previous page)

```
14      --  ^ Access to date
15  end Access_Types;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Access_Types.Access_Types
MD5: d3421918c48c221836bdf03b9e68bfb5
```

This illustrates how to:

- Declare an access type whose values point to ("designate") objects from a specific type
- Declare a variable (access value) from this access type
- Give it a value of **null**

In line with Ada's strong typing philosophy, if you declare a second access type whose designated type is Date, the two access types will be incompatible with each other:

Listing 3: access_types.ads

```
1   with Dates; use Dates;
2
3   package Access_Types is
4       --  Declare an access type
5       type Date_Acc   is access Date;
6       type Date_Acc_2 is access Date;
7
8       D  : Date_Acc   := null;
9       D2 : Date_Acc_2 := D;
10      --                 ^ Invalid! Different types
11  end Access_Types;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Access_Types.Access_Types
MD5: af0dff5a26cb16f0fe15c84286557a44
```

Build output

```
access_types.ads:9:24: error: expected type "Date_Acc_2" defined at line 6
access_types.ads:9:24: error: found type "Date_Acc" defined at line 5
gprbuild: *** compilation phase failed
```

In other languages

In most other languages, pointer types are structurally, not nominally typed, like they are in Ada, which means that two pointer types will be the same as long as they share the same target type and accessibility rules.

Not so in Ada, which takes some time getting used to. A seemingly simple problem is, if you want to have a canonical access to a type, where should it be declared? A commonly used pattern is that if you need an access type to a specific type you "own", you will declare it along with the type:

```
package Access_Types is
   type Point is record
      X, Y : Natural;
   end record;
```

(continues on next page)

(continued from previous page)

```
   type Point_Access is access Point;
end Access_Types;
```

9.2 Allocation (by type)

Once we have declared an access type, we need a way to give variables of the types a meaningful value! You can allocate a value of an access type with the **new** keyword in Ada.

Listing 4: access_types.ads

```
with Dates; use Dates;

package Access_Types is
    type Date_Acc is access Date;

    D : Date_Acc := new Date;
    --              ^ Allocate a new Date record
end Access_Types;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Access_Types.Access_Types
MD5: e0be95b966e4aebaaf25db646d60c35c
```

If the type you want to allocate needs constraints, you can put them in the subtype indication, just as you would do in a variable declaration:

Listing 5: access_types.ads

```
with Dates; use Dates;

package Access_Types is
   type String_Acc is access String;
   --                        ^
   --  Access to unconstrained array type
   Msg : String_Acc;
   --    ^ Default value is null

   Buffer : String_Acc :=
     new String (1 .. 10);
   --            ^ Constraint required
end Access_Types;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Access_Types.Access_Types
MD5: 83cf7a1074ff1b739658508098aa8208
```

In some cases, though, allocating just by specifying the type is not ideal, so Ada also allows you to initialize along with the allocation. This is done via the qualified expression syntax:

Listing 6: access_types.ads

```
with Dates; use Dates;

package Access_Types is
```

(continues on next page)

(continued from previous page)

```
   type Date_Acc is access Date;
   type String_Acc is access String;

   D   : Date_Acc   :=
           new Date'(30, November, 2011);
   Msg : String_Acc := new String'("Hello");
end Access_Types;
```

9.3 Dereferencing

The last important piece of Ada's access type facility is how to get from an access value to the object that is pointed to, that is, how to dereference the pointer. Dereferencing a pointer uses the `.all` syntax in Ada, but is often not needed — in many cases, the access value will be implicitly dereferenced for you:

Listing 7: access_types.ads

```
with Dates; use Dates;

package Access_Types is
   type Date_Acc is access Date;

   D     : Date_Acc :=
             new Date'(30, November, 2011);

   Today : Date := D.all;
   --              ^ Access value dereference
   J     : Integer := D.Day;
   --                 ^ Implicit dereference
   --                   for record and array
   --                   components
   --                   Equivalent to D.all.day
end Access_Types;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Access_Types.Access_Types
MD5: 5cd1c259da04010b0dc1b43e9bd93b55
```

9.4 Other features

As you might know if you have used pointers in C or C++, we are still missing features that are considered fundamental to the use of pointers, such as:

- Pointer arithmetic (being able to increment or decrement a pointer in order to point to the next or previous object)
- Manual deallocation - what is called `free` or `delete` in C. This is a potentially unsafe operation. To keep within the realm of safe Ada, you need to never deallocate manually.

Those features exist in Ada, but are only available through specific standard library APIs.

> **Attention:** The guideline in Ada is that most of the time you can avoid manual allocation, and you should.

There are many ways to avoid manual allocation, some of which have been covered (such as parameter modes). The language also provides library abstractions to avoid pointers:

1. One is the use of *containers* (page 203). Containers help users avoid pointers, because container memory is automatically managed.
2. A container to note in this context is the Indefinite holder[16]. This container allows you to store a value of an indefinite type such as String.
3. GNATCOLL has a library for smart pointers, called Refcount[17] Those pointers' memory is automatically managed, so that when an allocated object has no more references to it, the memory is automatically deallocated.

9.5 Mutually recursive types

The linked list is a common idiom in data structures; in Ada this would be most naturally defined through two types, a record type and an access type, that are mutually dependent. To declare mutually dependent types, you can use an incomplete type declaration:

Listing 8: simple_list.ads

```
1  package Simple_List is
2     type Node;
3     --  This is an incomplete type declaration,
4     --  which is completed in the same
5     --  declarative region.
6
7     type Node_Acc is access Node;
8
9     type Node is record
10       Content    : Natural;
11       Prev, Next : Node_Acc;
12    end record;
13 end Simple_List;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Access_Types.Simple_List
MD5: 4929b89c1fc913da635fa02e48248271
```

In this example, the Node and Node_Acc types are mutually dependent.

CHAPTER

TEN

MORE ABOUT RECORDS

10.1 Dynamically sized record types

We have previously seen *some simple examples of record types* (page 65). Let's now look at some of the more advanced properties of this fundamental language feature.

One point to note is that object size for a record type does not need to be known at compile time. This is illustrated in the example below:

Listing 1: runtime_length.ads

```
package Runtime_Length is
   function Compute_Max_Len return Natural;
end Runtime_Length;
```

Listing 2: var_size_record.ads

```
with Runtime_Length; use Runtime_Length;

package Var_Size_Record is
    Max_Len : constant Natural :=
                Compute_Max_Len;
    --          ^ Not known at compile time

    type Items_Array is
      array (Positive range <>) of Integer;

    type Growable_Stack is record
       Items : Items_Array (1 .. Max_Len);
       Len   : Natural;
    end record;
    --  Growable_Stack is a definite type, but
    --  size is not known at compile time.

    G : Growable_Stack;
end Var_Size_Record;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.More_About_Records.Var_Size_Record
MD5: 6fb0b3f2b685a72ec694640ce378f77c
```

It is completely fine to determine the size of your records at run time, but note that all objects of this type will have the same size.

10.2 Records with discriminant

In the example above, the size of the Items field is determined once, at run-time, but every `Growable_Stack` instance will be exactly the same size. But maybe that's not what you want to do. We saw that arrays in general offer this flexibility: for an unconstrained array type, different objects can have different sizes.

You can get analogous functionality for records, too, using a special kind of field that is called a discriminant:

Listing 3: var_size_record_2.ads

```
package Var_Size_Record_2 is
    type Items_Array is
      array (Positive range <>) of Integer;

    type Growable_Stack (Max_Len : Natural) is
    record
    --                    ^ Discriminant. Cannot be
    --                      modified once
    --                      initialized.
       Items : Items_Array (1 .. Max_Len);
       Len   : Natural := 0;
    end record;
    --  Growable_Stack is an indefinite type
    --  (like an array)
end Var_Size_Record_2;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.More_About_Records.Var_Size_Record_2
MD5: 0c2ffe41b7553984e1ef48a50386559f
```

Discriminants, in their simple forms, are constant: You cannot modify them once you have initialized the object. This intuitively makes sense since they determine the size of the object.

Also, they make a type indefinite: Whether or not the discriminant is used to specify the size of an object, a type with a discriminant will be indefinite if the discriminant is not declared with an initialization:

Listing 4: test_discriminants.ads

```
package Test_Discriminants is
   type Point (X, Y : Natural) is record
      null;
   end record;

   P : Point;
   --  ERROR: Point is indefinite, so you
   --  need to specify the discriminants
   --  or give a default value

   P2 : Point (1, 2);
   P3 : Point := (1, 2);
   --  Those two declarations are equivalent.

end Test_Discriminants;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.More_About_Records.Test_Discriminants
MD5: c3ec81ccae0d4144fe952ad99482be81
```

Build output

```
test_discriminants.ads:6:08: error: unconstrained subtype not allowed (need␣
 ↪initialization)
test_discriminants.ads:6:08: error: provide initial value or explicit discriminant␣
 ↪values
test_discriminants.ads:6:08: error: or give default discriminant values for type
 ↪"Point"
gprbuild: *** compilation phase failed
```

This also means that, in the example above, you cannot declare an array of Point values, because the size of a Point is not known.

As mentioned in the example above, we could provide a default value for the discriminants, so that we could legally declare `Point` values without specifying the discriminants. For the example above, this is how it would look:

Listing 5: test_discriminants.ads

```
1  package Test_Discriminants is
2     type Point (X, Y : Natural := 0) is record
3        null;
4     end record;
5
6     P : Point;
7     --  We can now simply declare a "Point"
8     --  without further ado. In this case,
9     --  we're using the default values (0)
10    --  for X and Y.
11
12    P2 : Point (1, 2);
13    P3 : Point := (1, 2);
14    --  We can still specify discriminants.
15
16 end Test_Discriminants;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.More_About_Records.Test_Discriminants
MD5: 259f6cdf7fa857cc006dac6d1daedd73
```

Also note that, even though the `Point` type now has default discriminants, we can still specify discriminants, as we're doing in the declarations of P2 and P3.

In most other respects discriminants behave like regular fields: You have to specify their values in aggregates, as seen above, and you can access their values via the dot notation.

Listing 6: main.adb

```
1  with Ada.Text_IO;       use Ada.Text_IO;
2
3  with Var_Size_Record_2; use Var_Size_Record_2;
4
5  procedure Main is
6     procedure Print_Stack (G : Growable_Stack) is
7     begin
8        Put ("<Stack, items: [");
9        for I in G.Items'Range loop
10          exit when I > G.Len;
```

(continues on next page)

(continued from previous page)

```
         Put (" " & Integer'Image (G.Items (I)));
      end loop;
      Put_Line ("]>");
   end Print_Stack;

   S : Growable_Stack :=
     (Max_Len => 128,
      Items   => (1, 2, 3, 4, others => <>),
      Len     => 4);
begin
   Print_Stack (S);
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.More_About_Records.Var_Size_Record_2
MD5: 4e8c102cd93dc5d8aa1b402589c5239b
```

Runtime output

```
<Stack, items: [  1  2  3  4]>
```

Note: In the examples above, we used a discriminant to determine the size of an array, but it is not limited to that, and could be used, for example, to determine the size of a nested discriminated record.

10.3 Variant records

The examples of discriminants thus far have illustrated the declaration of records of varying size, by having components whose size depends on the discriminant.

However, discriminants can also be used to obtain the functionality of what are sometimes called "variant records": records that can contain different sets of fields.

Listing 7: variant_record.ads

```
package Variant_Record is
   --  Forward declaration of Expr
   type Expr;

   --  Access to a Expr
   type Expr_Access is access Expr;

   type Expr_Kind_Type is (Bin_Op_Plus,
                           Bin_Op_Minus,
                           Num);
   --  A regular enumeration type

   type Expr (Kind : Expr_Kind_Type) is record
      --       ^ The discriminant is an
      --         enumeration value
      case Kind is
         when Bin_Op_Plus | Bin_Op_Minus =>
            Left, Right : Expr_Access;
         when Num =>
            Val : Integer;
```

(continues on next page)

(continued from previous page)

```
      end case;
      --  Variant part. Only one, at the end of
      --  the record definition, but can be
      --  nested
   end record;
end Variant_Record;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.More_About_Records.Variant_Record
MD5: af9c1edca3ed6b2d938249c7258806b1
```

The fields that are in a **when** branch will be only available when the value of the discriminant is covered by the branch. In the example above, you will only be able to access the fields `Left` and `Right` when the `Kind` is `Bin_Op_Plus` or `Bin_Op_Minus`.

If you try to access a field that is not valid for your record, a `Constraint_Error` will be raised.

Listing 8: main.adb

```
with Variant_Record; use Variant_Record;

procedure Main is
   E : Expr := (Num, 12);
begin
   E.Left := new Expr'(Num, 15);
   --  Will compile but fail at runtime
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.More_About_Records.Variant_Record
MD5: d157d5f96db0825b9376ba7fca9613ed
```

Build output

```
main.adb:6:05: warning: component not present in subtype of "Expr" defined at line␣
↪4 [enabled by default]
main.adb:6:05: warning: Constraint_Error will be raised at run time [enabled by␣
↪default]
```

Runtime output

```

raised CONSTRAINT_ERROR : main.adb:6 discriminant check failed
```

Here is how you could write an evaluator for expressions:

Listing 9: main.adb

```
with Ada.Text_IO;    use Ada.Text_IO;

with Variant_Record; use Variant_Record;

procedure Main is
   function Eval_Expr (E : Expr) return Integer is
     (case E.Kind is
      when Bin_Op_Plus  =>
             Eval_Expr (E.Left.all)
             + Eval_Expr (E.Right.all),
```

(continues on next page)

(continued from previous page)

```
      when Bin_Op_Minus =>
             Eval_Expr (E.Left.all)
             - Eval_Expr (E.Right.all),
      when Num => E.Val);

   E : Expr := (Bin_Op_Plus,
                new Expr'(Bin_Op_Minus,
                          new Expr'(Num, 12),
                          new Expr'(Num, 15)),
                new Expr'(Num, 3));
begin
   Put_Line (Integer'Image (Eval_Expr (E)));
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.More_About_Records.Variant_Record
MD5: 807dbb921b44b3eaeaf1baf6ffe1afaa
```

Runtime output

```
 0
```

In other languages

Ada's variant records are very similar to Sum types in functional languages such as OCaml or Haskell. A major difference is that the discriminant is a separate field in Ada, whereas the 'tag' of a Sum type is kind of built in, and only accessible with pattern matching.

There are other differences (you can have several discriminants in a variant record in Ada). Nevertheless, they allow the same kind of type modeling as sum types in functional languages.

Compared to C/C++ unions, Ada variant records are more powerful in what they allow, and are also checked at run time, which makes them safer.

CHAPTER

ELEVEN

FIXED-POINT TYPES

11.1 Decimal fixed-point types

We have already seen how to specify floating-point types. However, in some applications floating-point is not appropriate since, for example, the roundoff error from binary arithmetic may be unacceptable or perhaps the hardware does not support floating-point instructions. Ada provides a category of types, the decimal fixed-point types, that allows the programmer to specify the required decimal precision (number of digits) as well as the scaling factor (a power of ten) and, optionally, a range. In effect the values will be represented as integers implicitly scaled by the specified power of 10. This is useful, for example, for financial applications.

The syntax for a simple decimal fixed-point type is

```
type <type-name> is delta <delta-value> digits <digits-value>;
```

In this case, the **delta** and the **digits** will be used by the compiler to derive a range.

Several attributes are useful for dealing with decimal types:

Attribute Name	Meaning
First	The first value of the type
Last	The last value of the type
Delta	The delta value of the type

In the example below, we declare two data types: T3_D3 and T6_D3. For both types, the delta value is the same: 0.001.

Listing 1: decimal_fixed_point_types.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Decimal_Fixed_Point_Types is
   type T3_D3 is delta 10.0 ** (-3) digits 3;
   type T6_D3 is delta 10.0 ** (-3) digits 6;
begin
   Put_Line ("The delta    value of T3_D3 is "
             & T3_D3'Image (T3_D3'Delta));
   Put_Line ("The minimum  value of T3_D3 is "
             & T3_D3'Image (T3_D3'First));
   Put_Line ("The maximum  value of T3_D3 is "
             & T3_D3'Image (T3_D3'Last));
   New_Line;

   Put_Line ("The delta    value of T6_D3 is "
             & T6_D3'Image (T6_D3'Delta));
```

(continues on next page)

(continued from previous page)

```
17    Put_Line ("The minimum  value of T6_D3 is "
18              & T6_D3'Image (T6_D3'First));
19    Put_Line ("The maximum  value of T6_D3 is "
20              & T6_D3'Image (T6_D3'Last));
21 end Decimal_Fixed_Point_Types;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Fixed_Point_Types.Decimal_Fixed_Point_Types
MD5: 6b1f6bfa555031b831aa872187c8bee9
```

Runtime output

```
The delta    value of T3_D3 is  0.001
The minimum  value of T3_D3 is -0.999
The maximum  value of T3_D3 is  0.999

The delta    value of T6_D3 is  0.001
The minimum  value of T6_D3 is -999.999
The maximum  value of T6_D3 is  999.999
```

When running the application, we see that the delta value of both types is indeed the same: 0.001. However, because T3_D3 is restricted to 3 digits, its range is -0.999 to 0.999. For the T6_D3, we have defined a precision of 6 digits, so the range is -999.999 to 999.999.

Similar to the type definition using the **range** syntax, because we have an implicit range, the compiled code will check that the variables contain values that are not out-of-range. Also, if the result of a multiplication or division on decimal fixed-point types is smaller than the delta value required for the context, the actual result will be zero. For example:

Listing 2: decimal_fixed_point_smaller.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Decimal_Fixed_Point_Smaller is
4     type T3_D3 is delta 10.0 ** (-3) digits 3;
5     type T6_D6 is delta 10.0 ** (-6) digits 6;
6     A : T3_D3 := T3_D3'Delta;
7     B : T3_D3 := 0.5;
8     C : T6_D6;
9  begin
10    Put_Line ("The value of A     is "
11              & T3_D3'Image (A));
12
13    A := A * B;
14    Put_Line ("The value of A * B is "
15              & T3_D3'Image (A));
16
17    A := T3_D3'Delta;
18    C := A * B;
19    Put_Line ("The value of A * B is "
20              & T6_D6'Image (C));
21 end Decimal_Fixed_Point_Smaller;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Fixed_Point_Types.Decimal_Fixed_Point_Smaller
MD5: 6b0242caa4a79f9b3447a304002e6a3b
```

Runtime output

```
The value of A     is  0.001
The value of A * B is  0.000
The value of A * B is  0.000500
```

In this example, the result of the operation 0.001 * 0.5 is 0.0005. Since this value is not representable for the T3_D3 type because the delta value is 0.001, the actual value stored in variable A is zero. However, accuracy is preserved during the arithmetic operations if the target has sufficient precision, and the value displayed for C is 0.000500.

11.2 Ordinary fixed-point types

Ordinary fixed-point types are similar to decimal fixed-point types in that the values are, in effect, scaled integers. The difference between them is in the scale factor: for a decimal fixed-point type, the scaling, given explicitly by the type's **delta**, is always a power of ten.

In contrast, for an ordinary fixed-point type, the scaling is defined by the type's `small`, which is derived from the specified **delta** and, by default, is a power of two. Therefore, ordinary fixed-point types are sometimes called binary fixed-point types.

Note: Ordinary fixed-point types can be thought of being closer to the actual representation on the machine, since hardware support for decimal fixed-point arithmetic is not widespread (rescalings by a power of ten), while ordinary fixed-point types make use of the available integer shift instructions.

The syntax for an ordinary fixed-point type is

```
type <type-name> is
  delta <delta-value>
  range <lower-bound> .. <upper-bound>;
```

By default the compiler will choose a scale factor, or `small`, that is a power of 2 no greater than <delta-value>.

For example, we may define a normalized range between -1.0 and 1.0 as following:

Listing 3: normalized_fixed_point_type.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Normalized_Fixed_Point_Type is
4     D : constant := 2.0 ** (-31);
5     type TQ31 is delta D range -1.0 .. 1.0 - D;
6  begin
7     Put_Line ("TQ31 requires "
8               & Integer'Image (TQ31'Size)
9               & " bits");
10    Put_Line ("The delta    value of TQ31 is "
11              & TQ31'Image (TQ31'Delta));
12    Put_Line ("The minimum  value of TQ31 is "
13              & TQ31'Image (TQ31'First));
14    Put_Line ("The maximum  value of TQ31 is "
15              & TQ31'Image (TQ31'Last));
16 end Normalized_Fixed_Point_Type;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Fixed_Point_Types.Normalized_Fixed_Point_Type
MD5: 778dde401c7ff3dd42938dccfe6cf9d3
```

Runtime output

```
TQ31 requires  32 bits
The delta    value of TQ31 is  0.0000000005
The minimum  value of TQ31 is -1.0000000000
The maximum  value of TQ31 is  0.9999999995
```

In this example, we are defining a 32-bit fixed-point data type for our normalized range. When running the application, we notice that the upper bound is close to one, but not exact one. This is a typical effect of fixed-point data types — you can find more details in this discussion about the Q format[18].

We may also rewrite this code with an exact type definition:

Listing 4: normalized_adapted_fixed_point_type.adb

```
procedure Normalized_Adapted_Fixed_Point_Type is
   type TQ31 is
     delta 2.0 ** (-31)
     range -1.0 .. 1.0 - 2.0 ** (-31);
begin
   null;
end Normalized_Adapted_Fixed_Point_Type;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Fixed_Point_Types.Normalized_Adapted_Fixed_Point_Type
MD5: 3421800bb47b282d601a51d276944f62
```

We may also use any other range. For example:

Listing 5: custom_fixed_point_range.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with Ada.Numerics; use Ada.Numerics;

procedure Custom_Fixed_Point_Range is
   type T_Inv_Trig is
     delta 2.0 ** (-15) * Pi
     range -Pi / 2.0 .. Pi / 2.0;
begin
   Put_Line ("T_Inv_Trig requires "
             & Integer'Image (T_Inv_Trig'Size)
             & " bits");
   Put_Line ("Delta    value of T_Inv_Trig: "
             & T_Inv_Trig'Image
                 (T_Inv_Trig'Delta));
   Put_Line ("Minimum  value of T_Inv_Trig: "
             & T_Inv_Trig'Image
                 (T_Inv_Trig'First));
   Put_Line ("Maximum  value of T_Inv_Trig: "
             & T_Inv_Trig'Image
                 (T_Inv_Trig'Last));
end Custom_Fixed_Point_Range;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Fixed_Point_Types.Custom_Fixed_Point_Range
MD5: a3e6c549cb1070aa285857ae8813de27
```

Runtime output

[18] https://en.wikipedia.org/wiki/Q_(number_format)

```
T_Inv_Trig requires  16 bits
Delta    value of T_Inv_Trig:  0.00006
Minimum  value of T_Inv_Trig: -1.57080
Maximum  value of T_Inv_Trig:  1.57080
```

In this example, we are defining a 16-bit type called `T_Inv_Trig`, which has a range from -π/2 to π/2.

All standard operations are available for fixed-point types. For example:

Listing 6: fixed_point_op.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Fixed_Point_Op is
   type TQ31 is
     delta 2.0 ** (-31)
     range -1.0 .. 1.0 - 2.0 ** (-31);

   A, B, R : TQ31;
begin
   A := 0.25;
   B := 0.50;
   R := A + B;
   Put_Line ("R is " & TQ31'Image (R));
end Fixed_Point_Op;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Fixed_Point_Types.Fixed_Point_Op
MD5: cad218b70b7fb0621468027a807431b1
```

Runtime output

```
R is  0.7500000000
```

As expected, R contains 0.75 after the addition of A and B.

In fact the language is more general than these examples imply, since in practice it is typical to need to multiply or divide values from different fixed-point types, and obtain a result that may be of a third fixed-point type. The details are outside the scope of this introductory course.

It is also worth noting, although again the details are outside the scope of this course, that you can explicitly specify a value for an ordinary fixed-point type's `small`. This allows non-binary scaling, for example:

```
type Angle is
  delta 1.0/3600.0
  range 0.0 .. 360.0 - 1.0 / 3600.0;
for Angle'Small use Angle'Delta;
```

CHAPTER

TWELVE

PRIVACY

One of the main principles of modular programming, as well as object oriented programming, is encapsulation[19].

Encapsulation, briefly, is the concept that the implementer of a piece of software will distinguish between the code's public interface and its private implementation.

This is not only applicable to software libraries but wherever abstraction is used.

In Ada, the granularity of encapsulation is a bit different from most object-oriented languages, because privacy is generally specified at the package level.

12.1 Basic encapsulation

Listing 1: encapsulate.ads

```
package Encapsulate is
   procedure Hello;

private

   procedure Hello2;
   --  Not visible from external units
end Encapsulate;
```

Listing 2: encapsulate.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Encapsulate is

   procedure Hello is
   begin
      Put_Line ("Hello");
   end Hello;

   procedure Hello2 is
   begin
      Put_Line ("Hello #2");
   end Hello2;

end Encapsulate;
```

[19] https://en.wikipedia.org/wiki/Encapsulation_(computer_programming)

Listing 3: main.adb

```
with Encapsulate;

procedure Main is
begin
   Encapsulate.Hello;
   Encapsulate.Hello2;
   --  Invalid: Hello2 is not visible
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Privacy.Encapsulate
MD5: cf56ee89481962d1e0a6d1e9ad888362
```

Build output

```
main.adb:6:15: error: "Hello2" is not a visible entity of "Encapsulate"
gprbuild: *** compilation phase failed
```

12.2 Abstract data types

With this high-level granularity, it might not seem obvious how to hide the implementation details of a type. Here is how it can be done in Ada:

Listing 4: stacks.ads

```
package Stacks is
   type Stack is private;
   --  Declare a private type: You cannot depend
   --  on its implementation. You can only assign
   --  and test for equality.

   procedure Push (S   : in out Stack;
                   Val :        Integer);
   procedure Pop (S   : in out Stack;
                  Val :    out Integer);
private

   subtype Stack_Index is
     Natural range 1 .. 10;

   type Content_Type is
     array (Stack_Index) of Natural;

   type Stack is record
      Top     : Stack_Index;
      Content : Content_Type;
   end record;
end Stacks;
```

Listing 5: stacks.adb

```
package body Stacks is

   procedure Push (S   : in out Stack;
                   Val :        Integer) is
```

(continues on next page)

(continued from previous page)

```
   begin
      --  Missing implementation!
      null;
   end Push;

   procedure Pop (S   : in out Stack;
                  Val :    out Integer) is
   begin
      --  Dummy implementation!
      Val := 0;
   end Pop;

end Stacks;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Privacy.Stacks
MD5: 364df7c6806af4a1bc957c2c2d53b2cc
```

In the above example, we define a stack type in the public part (known as the *visible part* of the package spec in Ada), but the exact representation of that type is private.

Then, in the private part, we define the representation of that type. We can also declare other types that will be used as *helpers* for our main public type. This is useful since declaring helper types is common in Ada.

A few words about terminology:

- The `Stack` type as viewed from the public part is called the partial view of the type. This is what clients have access to.
- The `Stack` type as viewed from the private part or the body of the package is called the full view of the type. This is what implementers have access to.

From the point of view of the client (the *with*'ing unit), only the public (visible) part is important, and the private part could as well not exist. It makes it very easy to read linearly the part of the package that is important for you.

```
--  No need to read the private part to use the package
package Stacks is
   type Stack is private;

   procedure Push (S   : in out Stack;
                   Val :        Integer);
   procedure Pop (S   : in out Stack;
                  Val :    out Integer);
private
   ...
end Stacks;
```

Here is how the `Stacks` package would be used:

```
--  Example of use
with Stacks; use Stacks;

procedure Test_Stack is
   S : Stack;
   Res : Integer;
begin
   Push (S, 5);
   Push (S, 7);
   Pop (S, Res);
end Test_Stack;
```

12.3 Limited types

Ada's *limited type* facility allows you to declare a type for which assignment and comparison operations are not automatically provided.

Listing 6: stacks.ads

```
package Stacks is
   type Stack is limited private;
   --  Limited type. Cannot assign nor compare.

   procedure Push (S   : in out Stack;
                   Val :        Integer);
   procedure Pop (S   : in out Stack;
                  Val :    out Integer);
private
   subtype Stack_Index is
     Natural range 1 .. 10;

   type Content_Type is
     array (Stack_Index) of Natural;

   type Stack is limited record
      Top     : Stack_Index;
      Content : Content_Type;
   end record;
end Stacks;
```

Listing 7: stacks.adb

```
package body Stacks is

   procedure Push (S   : in out Stack;
                   Val :        Integer) is
   begin
      --  Missing implementation!
      null;
   end Push;

   procedure Pop (S   : in out Stack;
                  Val :    out Integer) is
   begin
      --  Dummy implementation!
      Val := 0;
   end Pop;

end Stacks;
```

Listing 8: main.adb

```
with Stacks; use Stacks;

procedure Main is
   S, S2 : Stack;
begin
   S := S2;
   --  Illegal: S is limited.
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Privacy.Limited_Stacks
MD5: 811343b46f20ac6af5e1bf26561f8d8d
```

Build output

```
main.adb:6:04: error: left hand of assignment must not be limited type
gprbuild: *** compilation phase failed
```

This is useful because, for example, for some data types the built-in assignment operation might be incorrect (for example when a deep copy is required).

Ada does allow you to overload the comparison operators = and /= for limited types (and to override the built-in declarations for non-limited types).

Ada also allows you to implement special semantics for assignment via controlled types[20]. However, in some cases assignment is simply inappropriate; one example is the `File_Type` from the `Ada.Text_IO` package, which is declared as a limited type and thus attempts to assign one file to another would be detected as illegal.

12.4 Child packages & privacy

We've seen previously (in the *child packages section* (page 39)) that packages can have child packages. Privacy plays an important role in child packages. This section discusses some of the privacy rules that apply to child packages.

Although the private part of a package P is meant to encapsulate information, certain parts of a child package `P.C` can have access to this private part of P. In those cases, information from the private part of P can then be used as if it were declared in the public part of its specification. To be more specific, the body of `P.C` and the private part of the specification of `P.C` have access to the private part of P. However, the public part of the specification of `P.C` only has access to the public part of P's specification. The following table summarizes this:

Part of a child package	Access to the private part of its parent's specification
Specification: public part	
Specification: private part	✓
Body	✓

The rest of this section shows examples of how this access to private information actually works for child packages.

Let's first look at an example where the body of a child package `P.C` has access to the private part of the specification of its parent P. We've seen, in a previous source-code example,

[20] http://www.ada-auth.org/standards/12rm/html/RM-7-6.html

that the Hello2 procedure declared in the private part of the Encapsulate package cannot be used in the Main procedure, since it's not visible there. This limitation doesn't apply, however, for parts of the child packages of the Encapsulate package. In fact, the body of its child package Encapsulate.Child has access to the Hello2 procedure and can call it there, as you can see in the implementation of the Hello3 procedure of the Child package:

Listing 9: encapsulate.ads

```
package Encapsulate is
   procedure Hello;

private

   procedure Hello2;
   --  Not visible from external units
   --  But visible in child packages
end Encapsulate;
```

Listing 10: encapsulate.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Encapsulate is

   procedure Hello is
   begin
      Put_Line ("Hello");
   end Hello;

   procedure Hello2 is
   begin
      Put_Line ("Hello #2");
   end Hello2;

end Encapsulate;
```

Listing 11: encapsulate-child.ads

```
package Encapsulate.Child is

   procedure Hello3;

end Encapsulate.Child;
```

Listing 12: encapsulate-child.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Encapsulate.Child is

   procedure Hello3 is
   begin
      --  Using private procedure Hello2
      --  from the parent package
      Hello2;
      Put_Line ("Hello #3");
   end Hello3;

end Encapsulate.Child;
```

Listing 13: main.adb

```
with Encapsulate.Child;

procedure Main is
begin
   Encapsulate.Child.Hello3;
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Privacy.Encapsulate_Child
MD5: 1533f43eee8f8b4d14c9b2101f42f13a
```

Runtime output

```
Hello #2
Hello #3
```

The same mechanism applies to types declared in the private part of a parent package. For instance, the body of a child package can access components of a record declared in the private part of its parent package. Let's look at an example:

Listing 14: my_types.ads

```
package My_Types is

   type Priv_Rec is private;

private

   type Priv_Rec is record
      Number : Integer := 42;
   end record;

end My_Types;
```

Listing 15: my_types-ops.ads

```
package My_Types.Ops is

   procedure Display (E : Priv_Rec);

end My_Types.Ops;
```

Listing 16: my_types-ops.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body My_Types.Ops is

   procedure Display (E : Priv_Rec) is
   begin
      Put_Line ("Priv_Rec.Number: "
                & Integer'Image (E.Number));
   end Display;

end My_Types.Ops;
```

Listing 17: main.adb

```
with Ada.Text_IO;  use Ada.Text_IO;

with My_Types;     use My_Types;
with My_Types.Ops; use My_Types.Ops;

procedure Main is
   E : Priv_Rec;
begin
   Put_Line ("Presenting information:");

   --  The following code would trigger a
   --  compilation error here:
   --
   --  Put_Line ("Priv_Rec.Number: "
   --            & Integer'Image (E.Number));

   Display (E);
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Privacy.Private_Type_Child
MD5: 9960611460bc1190b30949eca08fc02b
```

Runtime output

```
Presenting information:
Priv_Rec.Number:  42
```

In this example, we don't have access to the `Number` component of the record type `Priv_Rec` in the `Main` procedure. You can see this in the call to `Put_Line` that has been commented-out in the implementation of `Main`. Trying to access the `Number` component there would trigger a compilation error. But we do have access to this component in the body of the `My_Types.Ops` package, since it's a child package of the `My_Types` package. Therefore, `Ops`'s body has access to the declaration of the `Priv_Rec` type — which is in the private part of its parent, the `My_Types` package. For this reason, the same call to `Put_Line` that would trigger a compilation error in the `Main` procedure works fine in the `Display` procedure of the `My_Types.Ops` package.

This kind of privacy rules for child packages allows for extending the functionality of a parent package and, at the same time, retain its encapsulation.

As we mentioned previously, in addition to the package body, the private part of the specification of a child package `P.C` also has access to the private part of the specification of its parent `P`. Let's look at an example where we declare an object of private type `Priv_Rec` in the private part of the child package `My_Types.Child` *and* initialize the `Number` component of the `Priv_Rec` record directly:

```
package My_Types.Child is

private

   E : Priv_Rec := (Number => 99);

end My_Types.Ops;
```

As expected, we wouldn't be able to initialize this component if we moved this declaration to the public (visible) part of the same child package:

```
package My_Types.Child is

   E : Priv_Rec := (Number => 99);

end My_Types.Ops;
```

The declaration above triggers a compilation error, since type `Priv_Rec` is private. Because the public part of `My_Types.Child` is also visible outside the child package, Ada cannot allow accessing private information in this part of the specification.

CHAPTER

THIRTEEN

GENERICS

13.1 Introduction

Generics are used for metaprogramming in Ada. They are useful for abstract algorithms that share common properties with each other.

Either a subprogram or a package can be generic. A generic is declared by using the keyword **generic**. For example:

Listing 1: operator.ads

```
generic
   type T is private;
   --  Declaration of formal types and objects
--  Below, we could use one of the following:
--  <procedure | function | package>
procedure Operator (Dummy : in out T);
```

Listing 2: operator.adb

```
procedure Operator (Dummy : in out T) is
begin
   null;
end Operator;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Generics.Show_Simple_Generic
MD5: 1321d437043dafdb725fad416e654318
```

13.2 Formal type declaration

Formal types are abstractions of a specific type. For example, we may want to create an algorithm that works on any integer type, or even on any type at all, whether a numeric type or not. The following example declares a formal type T for the Set procedure.

Listing 3: set.ads

```
generic
   type T is private;
   --  T is a formal type that indicates that
   --  any type can be used, possibly a numeric
   --  type or possibly even a record type.
procedure Set (Dummy : T);
```

Listing 4: set.adb

```
procedure Set (Dummy : T) is
begin
   null;
end Set;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Generics.Show_Formal_Type_Declaration
MD5: 668156f66b2479c4932d18b5ad35deba
```

The declaration of T as **private** indicates that you can map any definite type to it. But you can also restrict the declaration to allow only some types to be mapped to that formal type. Here are some examples:

Formal Type	Format
Any type	`type T is private;`
Any discrete type	`type T is (<>);`
Any floating-point type	`type T is digits <>;`

13.3 Formal object declaration

Formal objects are similar to subprogram parameters. They can reference formal types declared in the formal specification. For example:

Listing 5: set.ads

```
generic
   type T is private;
   X : in out T;
   --  X can be used in the Set procedure
procedure Set (E : T);
```

Listing 6: set.adb

```
procedure Set (E : T) is
   pragma Unreferenced (E, X);
begin
   null;
end Set;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Generics.Show_Formal_Object_Declaration
MD5: 1b88bc0e5b8f48a35394966e6af07ac0
```

Formal objects can be either input parameters or specified using the **in out** mode.

13.4 Generic body definition

We don't repeat the **generic** keyword for the body declaration of a generic subprogram or package. Instead, we start with the actual declaration and use the generic types and objects we declared. For example:

Listing 7: set.ads

```
generic
   type T is private;
   X : in out T;
procedure Set (E : T);
```

Listing 8: set.adb

```
procedure Set (E : T) is
--  Body definition: "generic" keyword
--  is not used
begin
   X := E;
end Set;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Generics.Show_Generic_Body_Definition
MD5: de611ef77b528543fd6bad82c53857f7
```

13.5 Generic instantiation

Generic subprograms or packages can't be used directly. Instead, they need to be instantiated, which we do using the **new** keyword, as shown in the following example:

Listing 9: set.ads

```
generic
   type T is private;
   X : in out T;
   --  X can be used in the Set procedure
procedure Set (E : T);
```

Listing 10: set.adb

```
procedure Set (E : T) is
begin
   X := E;
end Set;
```

Listing 11: show_generic_instantiation.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Set;

procedure Show_Generic_Instantiation is

   Main    : Integer := 0;
   Current : Integer;

   procedure Set_Main is new Set (T => Integer,
                                  X => Main);
   --  Here, we map the formal parameters to
   --  actual types and objects.
   --
   --  The same approach can be used to
   --  instantiate functions or packages, e.g.:
   --
   --  function Get_Main is new ...
   --  package Integer_Queue is new ...

begin
   Current := 10;

   Set_Main (Current);
   Put_Line ("Value of Main is "
             & Integer'Image (Main));
end Show_Generic_Instantiation;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Generics.Show_Generic_Instantiation
MD5: 13dc0692252496d954240952561e1c05
```

Runtime output

```
Value of Main is  10
```

In the example above, we instantiate the procedure Set by mapping the formal parameters T and X to actual existing elements, in this case the **Integer** type and the Main variable.

13.6 Generic packages

The previous examples focused on generic subprograms. In this section, we look at generic packages. The syntax is similar to that used for generic subprograms: we start with the **generic** keyword and continue with formal declarations. The only difference is that **package** is specified instead of a subprogram keyword.

Here's an example:

Listing 12: element.ads

```
generic
   type T is private;
package Element is

   procedure Set (E : T);
   procedure Reset;
   function Get return T;
   function Is_Valid return Boolean;

   Invalid_Element : exception;

private
   Value : T;
   Valid : Boolean := False;
end Element;
```

Listing 13: element.adb

```
package body Element is

   procedure Set (E : T) is
   begin
      Value := E;
      Valid := True;
   end Set;

   procedure Reset is
   begin
      Valid := False;
   end Reset;

   function Get return T is
   begin
      if not Valid then
         raise Invalid_Element;
      end if;
      return Value;
   end Get;

   function Is_Valid return Boolean is (Valid);
end Element;
```

Listing 14: show_generic_package.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Element;

procedure Show_Generic_Package is

   package I is new Element (T => Integer);

   procedure Display_Initialized is
   begin
      if I.Is_Valid then
         Put_Line ("Value is initialized");
      else
         Put_Line ("Value is not initialized");
      end if;
   end Display_Initialized;
```

(continues on next page)

(continued from previous page)

```
16
17 begin
18    Display_Initialized;
19
20    Put_Line ("Initializing...");
21    I.Set (5);
22    Display_Initialized;
23    Put_Line ("Value is now set to "
24              & Integer'Image (I.Get));
25
26    Put_Line ("Resetting...");
27    I.Reset;
28    Display_Initialized;
29
30 end Show_Generic_Package;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Generics.Show_Generic_Package
MD5: c5278a06c6d06f1f37353ee0ca6686ec
```

Runtime output

```
Value is not initialized
Initializing...
Value is initialized
Value is now set to  5
Resetting...
Value is not initialized
```

In the example above, we created a simple container named `Element`, with just one single element. This container tracks whether the element has been initialized or not.

After writing the package definition, we create the instance `I` of the `Element`. We use the instance by calling the package subprograms (`Set`, `Reset`, and `Get`).

13.7 Formal subprograms

In addition to formal types and objects, we can also declare formal subprograms or packages. This course only describes formal subprograms; formal packages are discussed in the advanced course.

We use the **`with`** keyword to declare a formal subprogram. In the example below, we declare a formal function (`Comparison`) to be used by the generic procedure `Check`.

Listing 15: check.ads

```
1 generic
2    Description : String;
3    type T is private;
4    with function Comparison (X, Y : T)
5                              return Boolean;
6 procedure Check (X, Y : T);
```

Listing 16: check.adb

```
1 with Ada.Text_IO; use Ada.Text_IO;
2
```

(continues on next page)

(continued from previous page)

```
procedure Check (X, Y : T) is
   Result : Boolean;
begin
   Result := Comparison (X, Y);
   if Result then
      Put_Line
        ("Comparison ("
         & Description
         & ") between arguments is OK!");
   else
      Put_Line
        ("Comparison ("
         & Description
         & ") between arguments is not OK!");
   end if;
end Check;
```

Listing 17: show_formal_subprogram.adb

```
with Check;

procedure Show_Formal_Subprogram is

   A, B : Integer;

   procedure Check_Is_Equal is new
     Check (Description => "equality",
            T           => Integer,
            Comparison  => Standard."=");
   --  Here, we are mapping the standard
   --  equality operator for Integer types to
   --  the Comparison formal function
begin
   A := 0;
   B := 1;
   Check_Is_Equal (A, B);
end Show_Formal_Subprogram;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Generics.Show_Formal_Subprogram
MD5: 1c463a47e9ce56b5afbca1da6acd116d
```

Runtime output

```
Comparison (equality) between arguments is not OK!
```

13.8 Example: I/O instances

Ada offers generic I/O packages that can be instantiated for standard and derived types. One example is the generic `Float_IO` package, which provides procedures such as `Put` and `Get`. In fact, `Float_Text_IO` — available from the standard library — is an instance of the `Float_IO` package, and it's defined as:

```
with Ada.Text_IO;

package Ada.Float_Text_IO is new Ada.Text_IO.Float_IO (Float);
```

You can use it directly with any object of floating-point type. For example:

Listing 18: show_float_text_io.adb

```
with Ada.Float_Text_IO;

procedure Show_Float_Text_IO is
   X : constant Float := 2.5;

   use Ada.Float_Text_IO;
begin
   Put (X);
end Show_Float_Text_IO;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Generics.Show_Float_Text_IO
MD5: 7cc9b547ef301a2071e9fb65caa4631b
```

Runtime output

```
 2.50000E+00
```

Instantiating generic I/O packages can be useful for derived types. For example, let's create a new type `Price` that must be displayed with two decimal digits after the point, and no exponent.

Listing 19: show_float_io_inst.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Float_IO_Inst is

   type Price is digits 3;

   package Price_IO is new
     Ada.Text_IO.Float_IO (Price);

   P : Price;
begin
   --  Set to zero => don't display exponent
   Price_IO.Default_Exp  := 0;

   P := 2.5;
   Price_IO.Put (P);
   New_Line;

   P := 5.75;
   Price_IO.Put (P);
   New_Line;
end Show_Float_IO_Inst;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Generics.Show_Float_IO_Inst
MD5: 583c761421d7fdb812dd2a183b676bae
```

Runtime output

```
 2.50
 5.75
```

By adjusting `Default_Exp` from the `Price_IO` instance to *remove* the exponent, we can

control how variables of Price type are displayed. Just as a side note, we could also have written:

```
-- [...]

   type Price is new Float;

   package Price_IO is new
     Ada.Text_IO.Float_IO (Price);

begin
   Price_IO.Default_Aft  := 2;
   Price_IO.Default_Exp  := 0;
```

In this case, we're ajusting Default_Aft, too, to get two decimal digits after the point when calling Put.

In addition to the generic Float_IO package, the following generic packages are available from Ada.Text_IO:

- Enumeration_IO for enumeration types;
- Integer_IO for integer types;
- Modular_IO for modular types;
- Fixed_IO for fixed-point types;
- Decimal_IO for decimal types.

In fact, we could rewrite the example above using decimal types:

Listing 20: show_decimal_io_inst.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Decimal_IO_Inst is
4
5     type Price is delta 10.0 ** (-2) digits 12;
6
7     package Price_IO is new
8       Ada.Text_IO.Decimal_IO (Price);
9
10    P : Price;
11 begin
12    Price_IO.Default_Exp  := 0;
13
14    P := 2.5;
15    Price_IO.Put (P);
16    New_Line;
17
18    P := 5.75;
19    Price_IO.Put (P);
20    New_Line;
21 end Show_Decimal_IO_Inst;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Generics.Show_Decimal_IO_Inst
MD5: f413570759dcb32cc166078b3cee1a16
```

Runtime output

```
          2.50
          5.75
```

13.9 Example: ADTs

An important application of generics is to model abstract data types (ADTs). In fact, Ada includes a library with numerous ADTs using generics: `Ada.Containers` (described in the *containers section* (page 203)).

A typical example of an ADT is a stack:

Listing 21: stacks.ads

```
generic
   Max : Positive;
   type T is private;
package Stacks is

   type Stack is limited private;

   Stack_Underflow, Stack_Overflow : exception;

   function Is_Empty (S : Stack) return Boolean;

   function Pop (S : in out Stack) return T;

   procedure Push (S : in out Stack;
                   V :        T);

private

   type Stack_Array is
     array (Natural range <>) of T;

   Min : constant := 1;

   type Stack is record
      Container : Stack_Array (Min .. Max);
      Top       : Natural := Min - 1;
   end record;

end Stacks;
```

Listing 22: stacks.adb

```
package body Stacks is

   function Is_Empty (S : Stack) return Boolean is
     (S.Top < S.Container'First);

   function Is_Full (S : Stack) return Boolean is
     (S.Top >= S.Container'Last);

   function Pop (S : in out Stack) return T is
   begin
      if Is_Empty (S) then
         raise Stack_Underflow;
      else
         return X : T do
            X     := S.Container (S.Top);
            S.Top := S.Top - 1;
         end return;
      end if;
   end Pop;
```

(continues on next page)

(continued from previous page)

```
20
21    procedure Push (S : in out Stack;
22                    V :        T) is
23    begin
24       if Is_Full (S) then
25          raise Stack_Overflow;
26       else
27          S.Top               := S.Top + 1;
28          S.Container (S.Top) := V;
29       end if;
30    end Push;
31
32 end Stacks;
```

Listing 23: show_stack.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2  with Stacks;
3
4  procedure Show_Stack is
5
6     package Integer_Stacks is new
7       Stacks (Max => 10,
8               T   => Integer);
9     use Integer_Stacks;
10
11    Values : Integer_Stacks.Stack;
12
13 begin
14    Push (Values, 10);
15    Push (Values, 20);
16
17    Put_Line ("Last value was "
18              & Integer'Image (Pop (Values)));
19 end Show_Stack;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Generics.Show_Stack
MD5: ee112d395552c1a02d211b9e5425dc71
```

Runtime output

```
Last value was  20
```

In this example, we first create a generic stack package (`Stacks`) and then instantiate it to create a stack of up to 10 integer values.

13.10 Example: Swap

Let's look at a simple procedure that swaps variables of type `Color`:

Listing 24: colors.ads

```
1  package Colors is
2     type Color is (Black, Red, Green,
3                    Blue, White);
4
```

(continues on next page)

(continued from previous page)

```
   procedure Swap_Colors (X, Y : in out Color);
end Colors;
```

Listing 25: colors.adb

```
package body Colors is

   procedure Swap_Colors (X, Y : in out Color) is
      Tmp : constant Color := X;
   begin
      X := Y;
      Y := Tmp;
   end Swap_Colors;

end Colors;
```

Listing 26: test_non_generic_swap_colors.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Colors;      use Colors;

procedure Test_Non_Generic_Swap_Colors is
   A, B, C : Color;
begin
   A := Blue;
   B := White;
   C := Red;

   Put_Line ("Value of A is "
             & Color'Image (A));
   Put_Line ("Value of B is "
             & Color'Image (B));
   Put_Line ("Value of C is "
             & Color'Image (C));

   New_Line;
   Put_Line ("Swapping A and C...");
   New_Line;
   Swap_Colors (A, C);

   Put_Line ("Value of A is "
             & Color'Image (A));
   Put_Line ("Value of B is "
             & Color'Image (B));
   Put_Line ("Value of C is "
             & Color'Image (C));
end Test_Non_Generic_Swap_Colors;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Generics.Test_Non_Generic_Swap_Colors
MD5: 4d1cf826a1676c3750a8aabd484ac71f
```

Runtime output

```
Value of A is BLUE
Value of B is WHITE
Value of C is RED

Swapping A and C...
```

(continues on next page)

(continued from previous page)

```
Value of A is RED
Value of B is WHITE
Value of C is BLUE
```

In this example, `Swap_Colors` can only be used for the `Color` type. However, this algorithm can theoretically be used for any type, whether an enumeration type or a complex record type with many elements. The algorithm itself is the same: it's only the type that differs. If, for example, we want to swap variables of **`Integer`** type, we don't want to duplicate the implementation. Therefore, such an algorithm is a perfect candidate for abstraction using generics.

In the example below, we create a generic version of `Swap_Colors` and name it **`Generic`**`_Swap`. This generic version can operate on any type due to the declaration of formal type T.

Listing 27: generic_swap.ads

```
generic
   type T is private;
procedure Generic_Swap (X, Y : in out T);
```

Listing 28: generic_swap.adb

```
procedure Generic_Swap (X, Y : in out T) is
   Tmp : constant T := X;
begin
   X := Y;
   Y := Tmp;
end Generic_Swap;
```

Listing 29: colors.ads

```

   Put_Line ("Swapping A and C...");
   New_Line;
   Swap_Colors (A, C);

   Put_Line ("Value of A is "
            & Color'Image (A));
   Put_Line ("Value of B is "
            & Color'Image (B));
   Put_Line ("Value of C is "
            & Color'Image (C));
end Test_Swap_Colors;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Generics.Test_Swap_Colors
MD5: a5d94a40bd9d1c6736cc873f8b58e867
```

Runtime output

```
Value of A is BLUE
Value of B is WHITE
Value of C is RED

Swapping A and C...

Value of A is RED
Value of B is WHITE
Value of C is BLUE
```

As we can see in the example, we can create the same `Swap_Colors` procedure as we had in the non-generic version of the algorithm by declaring it as an instance of the generic **`Generic_`**Swap procedure. We specify that the generic T type will be mapped to the `Color` type by passing it as an argument to the **`Generic_`**Swap instantiation.

13.11 Example: Reversing

The previous example, with an algorithm to swap two values, is one of the simplest examples of using generics. Next we study an algorithm for reversing elements of an array. First, let's start with a non-generic version of the algorithm, one that works specifically for the `Color` type:

Listing 31: colors.ads

```
package Colors is

   type Color is (Black, Red, Green,
                  Blue, White);

   type Color_Array is
     array (Integer range <>) of Color;

   procedure Reverse_It (X : in out Color_Array);
```

(continues on next page)

(continued from previous page)

```
10
11 end Colors;
```

Listing 32: colors.adb

```
1  package body Colors is
2
3     procedure Reverse_It (X : in out Color_Array)
4     is
5     begin
6        for I in X'First ..
7                 (X'Last + X'First) / 2 loop
8           declare
9              Tmp     : Color;
10             X_Left  : Color
11               renames X (I);
12             X_Right : Color
13               renames X (X'Last + X'First - I);
14          begin
15             Tmp     := X_Left;
16             X_Left  := X_Right;
17             X_Right := Tmp;
18          end;
19       end loop;
20    end Reverse_It;
21
22 end Colors;
```

Listing 33: test_non_generic_reverse_colors.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2  with Colors;      use Colors;
3
4  procedure Test_Non_Generic_Reverse_Colors is
5
6     My_Colors : Color_Array (1 .. 5) :=
7       (Black, Red, Green, Blue, White);
8
9  begin
10    for C of My_Colors loop
11       Put_Line ("My_Color: " & Color'Image (C));
12    end loop;
13
14    New_Line;
15    Put_Line ("Reversing My_Color...");
16    New_Line;
17    Reverse_It (My_Colors);
18
19    for C of My_Colors loop
20       Put_Line ("My_Color: " & Color'Image (C));
21    end loop;
22
23 end Test_Non_Generic_Reverse_Colors;
```

Code block metadata

```
My_Color: BLACK
My_Color: RED
My_Color: GREEN
My_Color: BLUE
My_Color: WHITE

Reversing My_Color...

My_Color: WHITE
My_Color: BLUE
My_Color: GREEN
My_Color: RED
My_Color: BLACK
```

The procedure `Reverse_It` takes an array of colors, starts by swapping the first and last elements of the array, and continues doing that with successive elements until it reaches the middle of array. At that point, the entire array has been reversed, as we see from the output of the test program.

To abstract this procedure, we declare formal types for three components of the algorithm:

- the elements of the array (`Color` type in the example)
- the range used for the array (**`Integer`** range in the example)
- the actual array type (`Color_Array` type in the example)

This is a generic version of the algorithm:

Listing 34: generic_reverse.ads

```
generic
   type T is private;
   type Index is range <>;
   type Array_T is
     array (Index range <>) of T;
procedure Generic_Reverse (X : in out Array_T);
```

Listing 35: generic_reverse.adb

```
procedure Generic_Reverse (X : in out Array_T) is
begin
   for I in X'First ..
            (X'Last + X'First) / 2 loop
      declare
         Tmp     : T;
         X_Left  : T
           renames X (I);
         X_Right : T
           renames X (X'Last + X'First - I);
      begin
         Tmp     := X_Left;
         X_Left  := X_Right;
         X_Right := Tmp;
      end;
   end loop;
end Generic_Reverse;
```

Listing 36: colors.ads

My_Color: RED
```

(continues on next page)

(continued from previous page)

```
My_Color: BLACK
```

As mentioned above, we're abstracting three components of the algorithm:

- the T type abstracts the elements of the array
- the Index type abstracts the range used for the array
- the Array_T type abstracts the array type and uses the formal declarations of the T and Index types.

13.12 Example: Test application

In the previous example we've focused only on abstracting the reversing algorithm itself. However, we could have decided to also abstract our small test application. This could be useful if we, for example, decide to test other procedures that change elements of an array.

In order to do this, we again have to choose the elements to abstract. We therefore declare the following formal parameters:

- S: the string containing the array name
- a function Image that converts an element of type T to a string
- a procedure Test that performs some operation on the array

Note that Image and Test are examples of formal subprograms and S is an example of a formal object.

Here is a version of the test application making use of the generic Perform_Test procedure:

Listing 38: generic_reverse.ads

```
generic
   type T is private;
   type Index is range <>;
   type Array_T is
     array (Index range <>) of T;
procedure Generic_Reverse (X : in out Array_T);
```

Listing 39: generic_reverse.adb

```
procedure Generic_Reverse (X : in out Array_T) is
begin
   for I in X'First ..
            (X'Last + X'First) / 2 loop
      declare
         Tmp     : T;
         X_Left  : T
           renames X (I);
         X_Right : T
           renames X (X'Last + X'First - I);
      begin
         Tmp     := X_Left;
         X_Left  := X_Right;
         X_Right := Tmp;
      end;
   end loop;
end Generic_Reverse;
```

Listing 40: perform_test.ads

```
generic
   type T is private;
   type Index is range <>;
   type Array_T is
     array (Index range <>) of T;
   S : String;
   with function Image (E : T)
                        return String is <>;
   with procedure Test (X : in out Array_T);
procedure Perform_Test (X : in out Array_T);
```

Listing 41: perform_test.adb

```
with Ada.Text_IO;  use Ada.Text_IO;

procedure Perform_Test (X : in out Array_T) is
begin
   for C of X loop
      Put_Line (S & ": " & Image (C));
   end loop;

   New_Line;
   Put_Line ("Testing " & S & "...");
   New_Line;
   Test (X);

   for C of X loop
      Put_Line (S & ": " & Image (C));
   end loop;
end Perform_Test;
```

Listing 42: colors.ads

```
with Generic_Reverse;

package Colors is

   type Color is (Black, Red, Green,
                  Blue, White);

   type Color_Array is
     array (Integer range <>) of Color;

   procedure Reverse_It is new
     Generic_Reverse (T       => Color,
                      Index   => Integer,
                      Array_T => Color_Array);

end Colors;
```

Listing 43: test_reverse_colors.adb

```
with Colors;       use Colors;
with Perform_Test;

procedure Test_Reverse_Colors is

   procedure Perform_Test_Reverse_It is new
```

(continues on next page)

(continued from previous page)

```
     Perform_Test (T       => Color,
                   Index   => Integer,
                   Array_T => Color_Array,
                   S       => "My_Color",
                   Image   => Color'Image,
                   Test    => Reverse_It);

   My_Colors : Color_Array (1 .. 5) :=
     (Black, Red, Green, Blue, White);

begin
   Perform_Test_Reverse_It (My_Colors);
end Test_Reverse_Colors;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Generics.Test_Reverse_Colors_2
MD5: 04640309f4f7e9f8bcff137d1a6f8733
```

Runtime output

```
My_Color: BLACK
My_Color: RED
My_Color: GREEN
My_Color: BLUE
My_Color: WHITE

Testing My_Color...

My_Color: WHITE
My_Color: BLUE
My_Color: GREEN
My_Color: RED
My_Color: BLACK
```

In this example, we create the procedure `Perform_Test_Reverse_It` as an instance of the generic procedure (`Perform_Test`). Note that:

- For the formal `Image` function, we use the `'Image` attribute of the `Color` type
- For the formal `Test` procedure, we reference the `Reverse_Array` procedure from the package.

CHAPTER

FOURTEEN

EXCEPTIONS

Ada uses exceptions for error handling. Unlike many other languages, Ada speaks about *raising*, not *throwing*, an exception and *handling*, not *catching*, an exception.

14.1 Exception declaration

Ada exceptions are not types, but instead objects, which may be peculiar to you if you're used to the way Java or Python support exceptions. Here's how you declare an exception:

Listing 1: exceptions.ads

```
package Exceptions is
    My_Except : exception;
    --  Like an object. *NOT* a type !
end Exceptions;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Exceptions.Show_Exception
MD5: 6201faeca9b029c790023856d2c8c419
```

Even though they're objects, you're going to use each declared exception object as a "kind" or "family" of exceptions. Ada does not require that a subprogram declare every exception it can potentially raise.

14.2 Raising an exception

To raise an exception of our newly declared exception kind, do the following:

Listing 2: main.adb

```
with Exceptions; use Exceptions;

procedure Main is
begin
   raise My_Except;
   --  Execution of current control flow
   --  abandoned; an exception of kind
   --  "My_Except" will bubble up until it
   --  is caught.
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Exceptions.Show_Exception
MD5: 24b40ae1509722adf51c3dd0d3ea4fbe
```

Runtime output

```
raised EXCEPTIONS.MY_EXCEPT : main.adb:5
```

Here, the My_Except exception is raised. We can also specify a message:

Listing 3: main.adb

```
with Exceptions; use Exceptions;

procedure Main is
begin
   raise My_Except with "My exception message";
   --  Execution of current control flow
   --  abandoned; an exception of kind
   --  "My_Except" with associated string will
   --  bubble up until it is caught.
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Exceptions.Show_Exception
MD5: 279299c9703c3ed4e51fdd7c3a5e1392
```

Runtime output

```
raised EXCEPTIONS.MY_EXCEPT : My exception message
```

In this case, we see an additional message when the exception is displayed.

14.3 Handling an exception

Next, we address how to handle exceptions that were raised by us or libraries that we call. The neat thing in Ada is that you can add an exception handler to any statement block as follows:

Listing 4: open_file.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Ada.Exceptions;  use Ada.Exceptions;

procedure Open_File is
   File : File_Type;
begin
   --  Block (sequence of statements)
   begin
      Open (File, In_File, "input.txt");
   exception
      when E : Name_Error =>
      --       ^ Exception to be handled
         Put ("Cannot open input file : ");
         Put_Line (Exception_Message (E));
         raise;
         --  Reraise current occurence
```

(continues on next page)

(continued from previous page)

```
17    end;
18 end Open_File;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Exceptions.Show_Exception_Handling
MD5: 4ea1d5da684a6d7d7ee32908810e9c8f
```

Runtime output

```
Cannot open input file : input.txt: No such file or directory

raised ADA.IO_EXCEPTIONS.NAME_ERROR : input.txt: No such file or directory
```

In the example above, we're using the Exception_Message function from the Ada.Exceptions package. This function returns the message associated with the exception as a string.

You don't need to introduce a block just to handle an exception: you can add it to the statements block of your current subprogram:

Listing 5: open_file.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2  with Ada.Exceptions;  use Ada.Exceptions;
3
4  procedure Open_File is
5     File : File_Type;
6  begin
7     Open (File, In_File, "input.txt");
8  --  Exception block can be added to any block
9  exception
10    when Name_Error =>
11       Put ("Cannot open input file");
12 end Open_File;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Exceptions.Show_Exception_Message
MD5: 838e87ae416b3a717901cdc00eb71b40
```

Runtime output

```
Cannot open input file
```

Attention

Exception handlers have an important restriction that you need to be careful about: Exceptions raised in the declarative section are not caught by the handlers of that block. So for example, in the following code, the exception will not be caught.

Listing 6: be_careful.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2  with Ada.Exceptions;  use Ada.Exceptions;
3
4  procedure Be_Careful is
5     function Dangerous return Integer is
6     begin
7        raise Constraint_Error;
```

(continues on next page)

(continued from previous page)

```
8        return 42;
9     end Dangerous;
10
11 begin
12    declare
13       A : Integer := Dangerous;
14    begin
15       Put_Line (Integer'Image (A));
16    exception
17       when Constraint_Error =>
18          Put_Line ("error!");
19    end;
20 end Be_Careful;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Exceptions.Be_Careful
MD5: 6ea8a214bbbaca09d7444136d069e782
```

Runtime output

```

raised CONSTRAINT_ERROR : be_careful.adb:7 explicit raise
```

This is also the case for the top-level exception block that is part of the current subprogram.

14.4 Predefined exceptions

Ada has a very small number of predefined exceptions:

- `Constraint_Error` is the main one you might see. It's raised:
  - When bounds don't match or, in general, any violation of constraints.
  - In case of overflow
  - In case of null dereferences
  - In case of division by 0
- `Program_Error` might appear, but probably less often. It's raised in more arcane situations, such as for order of elaboration issues and some cases of detectable erroneous execution.
- `Storage_Error` will happen because of memory issues, such as:
  - Not enough memory (allocator)
  - Not enough stack
- `Tasking_Error` will happen with task related errors, such as any error happening during task activation.

You should not reuse predefined exceptions. If you do then, it won't be obvious when one is raised that it is because something went wrong in a built-in language operation.

CHAPTER

FIFTEEN

TASKING

Tasks and protected objects allow the implementation of concurrency in Ada. The following sections explain these concepts in more detail.

15.1 Tasks

A task can be thought as an application that runs *concurrently* with the main application. In other programming languages, a task might be called a thread[21], and tasking might be called multithreading[22].

Tasks may synchronize with the main application but may also process information completely independently from the main application. Here we show how this is accomplished.

15.1.1 Simple task

Tasks are declared using the keyword **task**. The task implementation is specified in a **task body** block. For example:

Listing 1: show_simple_task.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Simple_Task is
   task T;

   task body T is
   begin
      Put_Line ("In task T");
   end T;
begin
   Put_Line ("In main");
end Show_Simple_Task;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Show_Simple_Task
MD5: b17d9b35b4b2b53bc59776749e1be219
```

Runtime output

```
In task T
In main
```

[21] https://en.wikipedia.org/wiki/Thread_(computing)
[22] https://en.wikipedia.org/wiki/Thread_(computing)#Multithreading

Here, we're declaring and implementing the task T. As soon as the main application starts, task T starts automatically — it's not necessary to manually start this task. By running the application above, we can see that both calls to `Put_Line` are performed.

Note that:

- The main application is itself a task (the main or “environment” task).
  - In this example, the subprogram `Show_Simple_Task` is the main task of the application.
- Task T is a subtask.
  - Each subtask has a master, which represents the program construct in which the subtask is declared. In this case, the main subprogram `Show_Simple_Task` is T 's master.
  - The master construct is executed by some enclosing task, which we will refer to as the "master task" of the subtask.
- The number of tasks is not limited to one: we could include a task T2 in the example above.
  - This task also starts automatically and runs *concurrently* with both task T and the main task. For example:

Listing 2: show_simple_tasks.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Simple_Tasks is
   task T;
   task T2;

   task body T is
   begin
      Put_Line ("In task T");
   end T;

   task body T2 is
   begin
      Put_Line ("In task T2");
   end T2;

begin
   Put_Line ("In main");
end Show_Simple_Tasks;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Multiple_Simple_Task
MD5: 5e24b797e742bec306ad498f4f40d2b4
```

Runtime output

```
In task T
In main
In task T2
```

15.1.2 Simple synchronization

As we've just seen, as soon as the master construct reaches its “begin”, its subtasks also start automatically. The master continues its processing until it has nothing more to do. At that point, however, it will not terminate. Instead, the master waits until its subtasks have finished before it allows itself to complete. In other words, this waiting process provides synchronization between the master task and its subtasks. After this synchronization, the master construct will complete. For example:

Listing 3: show_simple_sync.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Simple_Sync is
   task T;
   task body T is
   begin
      for I in 1 .. 10 loop
         Put_Line ("hello");
      end loop;
   end T;
begin
   null;
   --  Will wait here until all tasks
   --  have terminated
end Show_Simple_Sync;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Show_Simple_Sync
MD5: 84afce465854f99f8cbe0b57714d8a5f
```

Runtime output

```
hello
hello
hello
hello
hello
hello
hello
hello
hello
hello
```

The same mechanism is used for other subprograms that contain subtasks: the subprogram execution will wait for its subtasks to finish. So this mechanism is not limited to the main subprogram and also applies to any subprogram called by the main subprogram, directly or indirectly.

Synchronization also occurs if we move the task to a separate package. In the example below, we declare a task T in the package `Simple_Sync_Pkg`.

Listing 4: simple_sync_pkg.ads

```
package Simple_Sync_Pkg is
   task T;
end Simple_Sync_Pkg;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Simple_Sync_Pkg
MD5: 2f9be044d04994240970f150e2293d5e
```

This is the corresponding package body:

Listing 5: simple_sync_pkg.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Simple_Sync_Pkg is
   task body T is
   begin
      for I in 1 .. 10 loop
         Put_Line ("hello");
      end loop;
   end T;
end Simple_Sync_Pkg;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Simple_Sync_Pkg
MD5: b668451e4fb10e802f619889bcd743ff
```

Because the package is **with**'ed by the main procedure, the task T defined in the package will become a subtask of the main task. For example:

Listing 6: test_simple_sync_pkg.adb

```
with Simple_Sync_Pkg;

procedure Test_Simple_Sync_Pkg is
begin
   null;
   --  Will wait here until all tasks
   --  have terminated
end Test_Simple_Sync_Pkg;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Simple_Sync_Pkg
MD5: e51565b91767ce198496ef3e9c582ac8
```

Runtime output

```
hello
hello
hello
hello
hello
hello
hello
hello
hello
hello
```

As soon as the main subprogram returns, the main task synchronizes with any subtasks spawned by packages T from `Simple_Sync_Pkg` before finally terminating.

15.1.3 Delay

We can introduce a delay by using the keyword **delay**. This puts the current task to sleep for the length of time (in seconds) specified in the delay statement. For example:

Listing 7: show_delay.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Delay is

   task T;

   task body T is
   begin
      for I in 1 .. 5 loop
         Put_Line ("hello from task T");
         delay 1.0;
         --    ^ Wait 1.0 seconds
      end loop;
   end T;
begin
   delay 1.5;
   Put_Line ("hello from main");
end Show_Delay;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Show_Delay
MD5: 4a6e8039744301a128e8fb2dd27902a5
```

Runtime output

```
hello from task T
hello from task T
hello from main
hello from task T
hello from task T
hello from task T
```

In this example, we're making the task T wait one second after each time it displays the "hello" message. In addition, the main task is waiting 1.5 seconds before displaying its own "hello" message

15.1.4 Synchronization: rendezvous

The only type of synchronization we've seen so far is the one that happens automatically at the end of a master construct with a subtask. You can also define custom synchronization points using the keyword **entry**. An *entry* can be viewed as a special kind of subprogram, which is called by another task using a similar syntax, as we will see later.

In the task body definition, you define which part of the task will accept the entries by using the keyword **accept**. A task proceeds until it reaches an **accept** statement and then waits for some other task to synchronize with it. Specifically,

- The task with the entry waits at that point (in the **accept** statement), ready to accept a call to the corresponding entry from the master task.

- The other task calls the task entry, in a manner similar to a procedure call, to synchronize with the entry.

This synchronization between tasks is called a *rendezvous*. Let's see an example:

Listing 8: show_rendezvous.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Rendezvous is

   task T is
      entry Start;
   end T;

   task body T is
   begin
      accept Start;
      --     ^ Waiting for somebody
      --       to call the entry

      Put_Line ("In T");
   end T;

begin
   Put_Line ("In Main");

   --  Calling T's entry:
   T.Start;
end Show_Rendezvous;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Show_Rendezvous
MD5: 479eea7adc876ac359ad20ac6e3acf66
```

Runtime output

```
In Main
In T
```

In this example, we declare an entry `Start` for task T. In the task body, we implement this entry using **`accept`** `Start`. When task T reaches this point, it waits for some other task to call its entry. This synchronization occurs in the `T.Start` statement. After the rendezvous completes, the main task and task T again run concurrently until they synchronize one final time when the main subprogram Show_Rendezvous finishes.

An entry may be used to perform more than a simple task synchronization: it also may perform multiple statements during the time both tasks are synchronized. We do this with a **`do`** `...` **`end`** block. For the previous example, we would simply write **`accept`** `Start` **`do`** `<statements>;` **`end`**;. We use this kind of block in the next example.

15.1.5 Select loop

There's no limit to the number of times an entry can be accepted. We could even create an infinite loop in the task and accept calls to the same entry over and over again. An infinite loop, however, prevents the subtask from finishing, so it blocks its master task when it reaches the end of its processing. Therefore, a loop containing **accept** statements in a task body can be used in conjunction with a **select ... or terminate** statement. In simple terms, this statement allows its master task to automatically terminate the subtask when the master construct reaches its end. For example:

Listing 9: show_rendezvous_loop.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Rendezvous_Loop is

   task T is
      entry Reset;
      entry Increment;
   end T;

   task body T is
      Cnt : Integer := 0;
   begin
      loop
         select
            accept Reset do
               Cnt := 0;
            end Reset;
            Put_Line ("Reset");
         or
            accept Increment do
               Cnt := Cnt + 1;
            end Increment;
            Put_Line ("In T's loop ("
                      & Integer'Image (Cnt)
                      & ")");
         or
            terminate;
         end select;
      end loop;
   end T;

begin
   Put_Line ("In Main");

   for I in 1 .. 4 loop
      --  Calling T's entry multiple times
      T.Increment;
   end loop;

   T.Reset;
   for I in 1 .. 4 loop
      --  Calling T's entry multiple times
      T.Increment;
   end loop;

end Show_Rendezvous_Loop;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Show_Rendezvous_Loop
MD5: 0542dbc029cffb9f794d761bab9f3a9d
```

Runtime output

```
In Main
In T's loop ( 1)
In T's loop ( 2)
In T's loop ( 3)
In T's loop ( 4)
Reset
In T's loop ( 1)
In T's loop ( 2)
In T's loop ( 3)
In T's loop ( 4)
```

In this example, the task body implements an infinite loop that accepts calls to the `Reset` and `Increment` entry. We make the following observations:

- The **`accept`** `E` **`do`** `...` **`end`** block is used to increment a counter.
  - As long as task T is performing the **`do`** `...` **`end`** block, the main task waits for the block to complete.
- The main task is calling the `Increment` entry multiple times in the loop from `1 .. 4`. It is also calling the `Reset` entry before the second loop.
  - Because task T contains an infinite loop, it always accepts calls to the `Reset` and `Increment` entries.
  - When the master construct of the subtask (the Show_Rendezvous_Loop subprogram) completes, it checks the status of the T task. Even though task T could accept new calls to the `Reset` or `Increment` entries, the master construct is allowed to terminate task T due to the **`or terminate`** part of the **`select`** statement.

15.1.6 Cycling tasks

In a previous example, we saw how to delay a task a specified time by using the **`delay`** keyword. However, using delay statements in a loop is not enough to guarantee regular intervals between those delay statements. For example, we may have a call to a computationally intensive procedure between executions of successive delay statements:

```
while True loop
   delay 1.0;
   --    ^ Wait 1.0 seconds
   Computational_Intensive_App;
end loop;
```

In this case, we can't guarantee that exactly 10 seconds have elapsed after 10 calls to the delay statement because a time drift may be introduced by the `Computational_Intensive_App` procedure. In many cases, this time drift is not relevant, so using the **`delay`** keyword is good enough.

However, there are situations where a time drift isn't acceptable. In those cases, we need to use the **`delay until`** statement, which accepts a precise time for the end of the delay, allowing us to define a regular interval. This is useful, for example, in real-time applications.

We will soon see an example of how this time drift may be introduced and how the **`delay until`** statement circumvents the problem. But before we do that, we look at a package containing a procedure allowing us to measure the elapsed time (`Show_Elapsed_Time`) and a dummy `Computational_Intensive_App` procedure which is simulated by using a simple delay. This is the complete package:

Listing 10: delay_aux_pkg.ads

```
with Ada.Real_Time; use Ada.Real_Time;

package Delay_Aux_Pkg is

   function Get_Start_Time return Time
     with Inline;

   procedure Show_Elapsed_Time
     with Inline;

   procedure Computational_Intensive_App;
private
   Start_Time   : Time := Clock;

   function Get_Start_Time return Time is
     (Start_Time);

end Delay_Aux_Pkg;
```

Listing 11: delay_aux_pkg.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Delay_Aux_Pkg is

   procedure Show_Elapsed_Time is
      Now_Time     : Time;
      Elapsed_Time : Time_Span;
   begin
      Now_Time     := Clock;
      Elapsed_Time := Now_Time - Start_Time;
      Put_Line ("Elapsed time "
                & Duration'Image
                    (To_Duration (Elapsed_Time))
                & " seconds");
   end Show_Elapsed_Time;

   procedure Computational_Intensive_App is
   begin
      delay 0.5;
   end Computational_Intensive_App;

end Delay_Aux_Pkg;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Show_Time
MD5: 422a38c1afa0bbd659ec81de88479e0a
```

Using this auxiliary package, we're now ready to write our time-drifting application:

Listing 12: show_time_task.adb

```
with Ada.Text_IO;   use Ada.Text_IO;
with Ada.Real_Time; use Ada.Real_Time;

with Delay_Aux_Pkg;

procedure Show_Time_Task is
```

(continues on next page)

(continued from previous page)

```
   package Aux renames Delay_Aux_Pkg;

   task T;

   task body T is
      Cnt   : Integer := 1;
   begin
      for I in 1 .. 5 loop
         delay 1.0;

         Aux.Show_Elapsed_Time;
         Aux.Computational_Intensive_App;

         Put_Line ("Cycle # "
                   & Integer'Image (Cnt));
         Cnt  := Cnt + 1;
      end loop;
      Put_Line ("Finished time-drifting loop");
   end T;

begin
   null;
end Show_Time_Task;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Show_Time
MD5: fe17c902fc127c0132677ea4005ff3f1
```

Runtime output

```
Elapsed time  1.000861411 seconds
Cycle #  1
Elapsed time  2.502523200 seconds
Cycle #  2
Elapsed time  4.005045079 seconds
Cycle #  3
Elapsed time  5.507242923 seconds
Cycle #  4
Elapsed time  7.009783787 seconds
Cycle #  5
Finished time-drifting loop
```

We can see by running the application that we already have a time difference of about four seconds after three iterations of the loop due to the drift introduced by `Computational_Intensive_App`. Using the **`delay until`** statement, however, we're able to avoid this time drift and have a regular interval of exactly one second:

Listing 13: show_time_task.adb

```
with Ada.Text_IO;   use Ada.Text_IO;
with Ada.Real_Time; use Ada.Real_Time;

with Delay_Aux_Pkg;

procedure Show_Time_Task is
   package Aux renames Delay_Aux_Pkg;

   task T;

   task body T is
```

(continues on next page)

(continued from previous page)

```
      Cycle : constant Time_Span :=
        Milliseconds (1000);
      Next  : Time := Aux.Get_Start_Time
                    + Cycle;

      Cnt   : Integer := 1;
   begin
      for I in 1 .. 5 loop
         delay until Next;

         Aux.Show_Elapsed_Time;
         Aux.Computational_Intensive_App;

         --  Calculate next execution time
         --  using a cycle of one second
         Next := Next + Cycle;

         Put_Line ("Cycle # "
                   & Integer'Image (Cnt));
         Cnt  := Cnt + 1;
      end loop;
      Put_Line ("Finished cycling");
   end T;

begin
   null;
end Show_Time_Task;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Show_Time
MD5: 1456c0feee6def8b370d994c0ab75a15
```

Runtime output

```
Elapsed time  1.002023906 seconds
Cycle #  1
Elapsed time  2.001625482 seconds
Cycle #  2
Elapsed time  3.001321807 seconds
Cycle #  3
Elapsed time  4.000818117 seconds
Cycle #  4
Elapsed time  5.000505447 seconds
Cycle #  5
Finished cycling
```

Now, as we can see by running the application, the **`delay until`** statement ensures that the `Computational_Intensive_App` doesn't disturb the regular interval of one second between iterations.

15.2 Protected objects

When multiple tasks are accessing shared data, corruption of that data may occur. For example, data may be inconsistent if one task overwrites parts of the information that's being read by another task at the same time. In order to avoid these kinds of problems and ensure information is accessed in a coordinated way, we use *protected objects*.

Protected objects encapsulate data and provide access to that data by means of *protected operations*, which may be subprograms or protected entries. Using protected objects ensures that data is not corrupted by race conditions or other concurrent access.

Important

Objects can be protected from concurrent access using Ada tasks. In fact, this was the *only* way of protecting objects from concurrent access in Ada 83 (the first version of the Ada language). However, the use of protected objects is much simpler than using similar mechanisms implemented using only tasks. Therefore, you should use protected objects when your main goal is only to protect data.

15.2.1 Simple object

You declare a protected object with the **protected** keyword. The syntax is similar to that used for packages: you can declare operations (e.g., procedures and functions) in the public part and data in the private part. The corresponding implementation of the operations is included in the **protected body** of the object. For example:

Listing 14: show_protected_objects.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Protected_Objects is

   protected Obj is
      --  Operations go here (only subprograms)
      procedure Set (V : Integer);
      function Get return Integer;
   private
      --  Data goes here
      Local : Integer := 0;
   end Obj;

   protected body Obj is
      --  procedures can modify the data
      procedure Set (V : Integer) is
      begin
         Local := V;
      end Set;

      --  functions cannot modify the data
      function Get return Integer is
      begin
         return Local;
      end Get;
   end Obj;

begin
   Obj.Set (5);
```

(continues on next page)

(continued from previous page)

```
30    Put_Line ("Number is: "
31              & Integer'Image (Obj.Get));
32 end Show_Protected_Objects;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Show_Protected_Objects
MD5: dd97dd584ba2f13def3c04725d4e48a7
```

Runtime output

```
Number is:  5
```

In this example, we define two operations for `Obj`: `Set` and `Get`. The implementation of these operations is in the `Obj` body. The syntax used for writing these operations is the same as that for normal procedures and functions. The implementation of protected objects is straightforward — we simply access and update `Local` in these subprograms. To call these operations in the main application, we use prefixed notation, e.g., `Obj.Get`.

15.2.2 Entries

In addition to protected procedures and functions, you can also define protected entry points. Do this using the **entry** keyword. Protected entry points allow you to define barriers using the **when** keyword. Barriers are conditions that must be fulfilled before the entry can start performing its actual processing — we speak of *releasing* the barrier when the condition is fulfilled.

The previous example used procedures and functions to define operations on the protected objects. However, doing so permits reading protected information (via `Obj.Get`) before it's set (via `Obj.Set`). To allow that to be a defined operation, we specified a default value (0). Instead, by rewriting `Obj.Get` using an *entry* instead of a function, we implement a barrier, ensuring no task can read the information before it's been set.

The following example implements the barrier for the `Obj.Get` operation. It also contains two concurrent subprograms (main task and task T) that try to access the protected object.

Listing 15: show_protected_objects_entries.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Protected_Objects_Entries is
4
5     protected Obj is
6        procedure Set (V : Integer);
7        entry Get (V : out Integer);
8     private
9        Local  : Integer;
10       Is_Set : Boolean := False;
11    end Obj;
12
13    protected body Obj is
14       procedure Set (V : Integer) is
15       begin
16          Local := V;
17          Is_Set := True;
18       end Set;
19
20       entry Get (V : out Integer)
21         when Is_Set is
```

(continues on next page)

(continued from previous page)

```
22          --  Entry is blocked until the
23          --  condition is true. The barrier
24          --  is evaluated at call of entries
25          --  and at exits of procedures and
26          --  entries. The calling task sleeps
27          --  until the barrier is released.
28       begin
29          V := Local;
30          Is_Set := False;
31       end Get;
32    end Obj;
33
34    N : Integer := 0;
35
36    task T;
37
38    task body T is
39    begin
40       Put_Line
41         ("Task T will delay for 4 seconds...");
42       delay 4.0;
43
44       Put_Line
45         ("Task T will set Obj...");
46       Obj.Set (5);
47
48       Put_Line
49         ("Task T has just set Obj...");
50    end T;
51 begin
52    Put_Line
53      ("Main application will get Obj...");
54    Obj.Get (N);
55
56    Put_Line
57      ("Main application has retrieved Obj...");
58    Put_Line
59      ("Number is: " & Integer'Image (N));
60
61 end Show_Protected_Objects_Entries;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Show_Protected_Objects_Entries
MD5: c1134445a96700b871fb76c4d6342359
```

Runtime output

```
Task T will delay for 4 seconds...
Main application will get Obj...
Task T will set Obj...
Task T has just set Obj...
Main application has retrieved Obj...
Number is:  5
```

As we see by running it, the main application waits until the protected object is set (by the call to `Obj.Set` in task T) before it reads the information (via `Obj.Get`). Because a 4-second delay has been added in task T, the main application is also delayed by 4 seconds. Only after this delay does task T set the object and release the barrier in `Obj.Get` so that the main application can then resume processing (after the information is retrieved from the protected object).

15.3 Task and protected types

In the previous examples, we defined single tasks and protected objects. We can, however, generalize tasks and protected objects using type definitions. This allows us, for example, to create multiple tasks based on just a single task type.

15.3.1 Task types

A task type is a generalization of a task. The declaration is similar to simple tasks: you replace **task** with **task type**. The difference between simple tasks and task types is that task types don't create actual tasks that automatically start. Instead, a task object declaration is needed. This is exactly the way normal variables and types work: objects are only created by variable definitions, not type definitions.

To illustrate this, we repeat our first example:

Listing 16: show_simple_task.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Simple_Task is
   task T;

   task body T is
   begin
      Put_Line ("In task T");
   end T;
begin
   Put_Line ("In main");
end Show_Simple_Task;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Show_Simple_Task
MD5: b17d9b35b4b2b53bc59776749e1be219
```

Runtime output

```
In task T
In main
```

We now rewrite it by replacing **task** T with **task type TT**. We declare a task (A_Task) based on the task type TT after its definition:

Listing 17: show_simple_task_type.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Simple_Task_Type is
   task type TT;

   task body TT is
   begin
      Put_Line ("In task type TT");
   end TT;

   A_Task : TT;
begin
   Put_Line ("In main");
end Show_Simple_Task_Type;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Show_Simple_Task_Type
MD5: 24c26dcbba6f5c54f0a7d47c3c0da728
```

Runtime output

```
In task type TT
In main
```

We can extend this example and create an array of tasks. Since we're using the same syntax as for variable declarations, we use a similar syntax for task types: **array** (<>) **of** **Task_**Type. Also, we can pass information to the individual tasks by defining a `Start` entry. Here's the updated example:

Listing 18: show_task_type_array.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Task_Type_Array is
   task type TT is
      entry Start (N : Integer);
   end TT;

   task body TT is
      Task_N : Integer;
   begin
      accept Start (N : Integer) do
         Task_N := N;
      end Start;
      Put_Line ("In task T: "
                & Integer'Image (Task_N));
   end TT;

   My_Tasks : array (1 .. 5) of TT;
begin
   Put_Line ("In main");

   for I in My_Tasks'Range loop
      My_Tasks (I).Start (I);
   end loop;
end Show_Task_Type_Array;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Show_Task_Type_Array
MD5: bba072dfc52fb2bfbef6e7b9f8191464
```

Runtime output

```
In main
In task T:  1
In task T:  2
In task T:  3
In task T:  4
In task T:  5
```

In this example, we're declaring five tasks in the array `My_Tasks`. We pass the array index to the individual tasks in the entry point (`Start`). After the synchronization between the individual subtasks and the main task, each subtask calls `Put_Line` concurrently.

15.3.2 Protected types

A protected type is a generalization of a protected object. The declaration is similar to that for protected objects: you replace **protected** with **protected type**. Like task types, protected types require an object declaration to create actual objects. Again, this is similar to variable declarations and allows for creating arrays (or other composite objects) of protected objects.

We can reuse a previous example and rewrite it to use a protected type:

Listing 19: show_protected_object_type.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Protected_Object_Type is

   protected type P_Obj_Type is
      procedure Set (V : Integer);
      function Get return Integer;
   private
      Local : Integer := 0;
   end P_Obj_Type;

   protected body P_Obj_Type is
      procedure Set (V : Integer) is
      begin
         Local := V;
      end Set;

      function Get return Integer is
      begin
         return Local;
      end Get;
   end P_Obj_Type;

   Obj : P_Obj_Type;
begin
   Obj.Set (5);
   Put_Line ("Number is: "
             & Integer'Image (Obj.Get));
end Show_Protected_Object_Type;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Tasking.Show_Protected_Object_Type
MD5: c50321e55afef0d72f263fee0669e55f
```

Runtime output

```
Number is:  5
```

In this example, instead of directly defining the protected object `Obj`, we first define a protected type `P_Obj_Type` and then declare `Obj` as an object of that protected type. Note that the main application hasn't changed: we still use `Obj.Set` and `Obj.Get` to access the protected object, just like in the original example.

CHAPTER

SIXTEEN

DESIGN BY CONTRACTS

Contracts are used in programming to codify expectations. Parameter modes of a subprogram can be viewed as a simple form of contracts. When the specification of subprogram 0p declares a parameter using **in** mode, the caller of 0p knows that the **in** argument won't be changed by 0p. In other words, the caller expects that 0p doesn't modify the argument it's providing, but just reads the information stored in the argument. Constraints and subtypes are other examples of contracts. In general, these specifications improve the consistency of the application.

Design-by-contract programming refers to techniques that include pre- and postconditions, subtype predicates, and type invariants. We study those topics in this chapter.

16.1 Pre- and postconditions

Pre- and postconditions provide expectations regarding input and output parameters of subprograms and return value of functions. If we say that certain requirements must be met before calling a subprogram 0p, those are preconditions. Similarly, if certain requirements must be met after a call to the subprogram 0p, those are postconditions. We can think of preconditions and postconditions as promises between the subprogram caller and the callee: a precondition is a promise from the caller to the callee, and a postcondition is a promise in the other direction.

Pre- and postconditions are specified using an aspect clause in the subprogram declaration. A **with** `Pre => <condition>` clause specifies a precondition and a **with** `Post => <condition>` clause specifies a postcondition.

The following code shows an example of preconditions:

Listing 1: show_simple_precondition.adb

```
procedure Show_Simple_Precondition is

   procedure DB_Entry (Name : String;
                       Age  : Natural)
     with Pre => Name'Length > 0
   is
   begin
      --  Missing implementation
      null;
   end DB_Entry;
begin
   DB_Entry ("John", 30);

   --  Precondition will fail!
   DB_Entry ("",     21);
end Show_Simple_Precondition;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Contracts.Show_Simple_Precondition
MD5: 87b6e080555603111801a0fcd2469acd
```

Runtime output

```
raised ADA.ASSERTIONS.ASSERTION_ERROR : failed precondition from show_simple_
↪precondition.adb:5
```

In this example, we want to prevent the name field in our database from containing an empty string. We implement this requirement by using a precondition requiring that the length of the string used for the `Name` parameter of the `DB_Entry` procedure is greater than zero. If the `DB_Entry` procedure is called with an empty string for the `Name` parameter, the call will fail because the precondition is not met.

In the GNAT toolchain

GNAT handles pre- and postconditions by generating runtime assertions for them. By default, however, assertions aren't enabled. Therefore, in order to check pre- and postconditions at runtime, you need to enable assertions by using the *-gnata* switch.

Before we get to our next example, let's briefly discuss quantified expressions, which are quite useful in concisely writing pre- and postconditions. Quantified expressions return a Boolean value indicating whether elements of an array or container match the expected condition. They have the form: `(for all I in A'Range => <condition on A(I)>`, where `A` is an array and `I` is an index. Quantified expressions using `for all` check whether the condition is true for every element. For example:

```
(for all I in A'Range => A (I) = 0)
```

This quantified expression is only true when all elements of the array `A` have a value of zero.

Another kind of quantified expressions uses `for some`. The form looks similar: `(for some I in A'Range => <condition on A(I)>`. However, in this case the qualified expression tests whether the condition is true only on *some* elements (hence the name) instead of all elements.

We illustrate postconditions using the following example:

Listing 2: show_simple_postcondition.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Simple_Postcondition is
4
5     type Int_8 is range -2 ** 7 .. 2 ** 7 - 1;
6
7     type Int_8_Array is
8       array (Integer range <>) of Int_8;
9
10    function Square (A : Int_8) return Int_8 is
11      (A * A)
12        with Post => (if abs A in 0 | 1
13                      then Square'Result = abs A
14                      else Square'Result > A);
15
16    procedure Square (A : in out Int_8_Array)
17      with Post => (for all I in A'Range =>
18                      A (I) = A'Old (I) *
```

(continues on next page)

(continued from previous page)

```
                              A'Old (I))
   is
   begin
      for V of A loop
         V := Square (V);
      end loop;
   end Square;

   V : Int_8_Array := (-2, -1, 0, 1, 10, 11);
begin
   for E of V loop
      Put_Line ("Original: "
                & Int_8'Image (E));
   end loop;
   New_Line;

   Square (V);
   for E of V loop
      Put_Line ("Square:   "
                & Int_8'Image (E));
   end loop;
end Show_Simple_Postcondition;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Contracts.Show_Simple_Postcondition
MD5: b9bae9fe09cefcbe6769ad9cd6739e2a
```

Runtime output

Square:    4
Square:    1
Square:    0
Square:    1
Square:    100
Square:    121
```

We declare a signed 8-bit type `Int_8` and an array of that type (`Int_8_Array`). We want to ensure each element of the array is squared after calling the procedure `Square` for an object of the `Int_8_Array` type. We do this with a postcondition using a **`for all`** expression. This postcondition also uses the `'Old` attribute to refer to the original value of the parameter (before the call).

We also want to ensure that the result of calls to the `Square` function for the `Int_8` type are greater than the input to that call. To do that, we write a postcondition using the `'Result` attribute of the function and comparing it to the input value.

We can use both pre- and postconditions in the declaration of a single subprogram. For example:

Listing 3: show_simple_contract.adb

```
with Ada.Text_IO; use Ada.Text_IO;

```

(continues on next page)

(continued from previous page)

```
procedure Show_Simple_Contract is

   type Int_8 is range -2 ** 7 .. 2 ** 7 - 1;

   function Square (A : Int_8) return Int_8 is
     (A * A)
       with
         Pre  => (Integer'Size >= Int_8'Size * 2
                  and Integer (A) *
                        Integer (A) <=
                      Integer (Int_8'Last)),
         Post => (if abs A in 0 | 1
                  then Square'Result = abs A
                  else Square'Result > A);

   V : Int_8;
begin
   V := Square (11);
   Put_Line ("Square of 11 is "
             & Int_8'Image (V));

   --  Precondition will fail...
   V := Square (12);
   Put_Line ("Square of 12 is "
             & Int_8'Image (V));
end Show_Simple_Contract;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Contracts.Show_Simple_Contract
MD5: 1d928dd100704907c858562155f90ee2
```

Runtime output

```
Square of 11 is  121

raised ADA.ASSERTIONS.ASSERTION_ERROR : failed precondition from show_simple_
↪contract.adb:10
```

In this example, we want to ensure that the input value of calls to the `Square` function for the `Int_8` type won't cause overflow in that function. We do this by converting the input value to the **`Integer`** type, which is used for the temporary calculation, and check if the result is in the appropriate range for the `Int_8` type. We have the same postcondition in this example as in the previous one.

16.2 Predicates

Predicates specify expectations regarding types. They're similar to pre- and postconditions, but apply to types instead of subprograms. Their conditions are checked for each object of a given type, which allows verifying that an object of type T is conformant to the requirements of its type.

There are two kinds of predicates: static and dynamic. In simple terms, static predicates are used to check objects at compile-time, while dynamic predicates are used for checks at run time. Normally, static predicates are used for scalar types and dynamic predicates for the more complex types.

Static and dynamic predicates are specified using the following clauses, respectively:

- `with Static_Predicate => <property>`
- `with Dynamic_Predicate => <property>`

Let's use the following example to illustrate dynamic predicates:

Listing 4: show_dynamic_predicate_courses.adb

```
with Ada.Calendar; use Ada.Calendar;

with Ada.Containers.Vectors;

with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

procedure Show_Dynamic_Predicate_Courses is

   package Courses is
      type Course_Container is private;

      type Course is record
         Name       : Unbounded_String;
         Start_Date : Time;
         End_Date   : Time;
      end record
        with Dynamic_Predicate =>
          Course.Start_Date <= Course.End_Date;

      procedure Add (CC : in out Course_Container;
                     C  :        Course);
   private
      package Course_Vectors is new
        Ada.Containers.Vectors
          (Index_Type   => Natural,
           Element_Type => Course);

      type Course_Container is record
         V : Course_Vectors.Vector;
      end record;
   end Courses;

   package body Courses is
      procedure Add (CC : in out Course_Container;
                     C  :        Course) is
      begin
         CC.V.Append (C);
      end Add;
   end Courses;

   use Courses;

   CC : Course_Container;
begin
   Add (CC,
        Course'(
          Name       =>
            To_Unbounded_String
              ("Intro to Photography"),
          Start_Date =>
            Time_Of (2018, 5, 1),
          End_Date   =>
            Time_Of (2018, 5, 10)));

```

(continues on next page)

(continued from previous page)

```
56    --  This should trigger an error in the
57    --  dynamic predicate check
58    Add (CC,
59         Course'(
60           Name       =>
61             To_Unbounded_String
62               ("Intro to Video Recording"),
63           Start_Date =>
64             Time_Of (2019, 5, 1),
65           End_Date   =>
66             Time_Of (2018, 5, 10)));
67
68 end Show_Dynamic_Predicate_Courses;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Contracts.Show_Dynamic_Predicate_Courses

```

Runtime output

```
raised ADA.ASSERTIONS.ASSERTION_ERROR : Dynamic_Predicate failed at show_dynamic_
↪predicate_courses.adb:59
```

In this example, the package `Courses` defines a type `Course` and a type `Course_Container`, an object of which contains all courses. We want to ensure that the dates of each course are consistent, specifically that the start date is no later than the end date. To enforce this rule, we declare a dynamic predicate for the `Course` type that performs the check for each object. The predicate uses the type name where a variable of that type would normally be used: this is a reference to the instance of the object being tested.

Note that the example above makes use of unbounded strings and dates. Both types are available in Ada's standard library. Please refer to the following sections for more information about:

- the unbounded string type (`Unbounded_String`): *Unbounded Strings* (page 246) section;
- dates and times: *Dates & Times* (page 231) section.

Static predicates, as mentioned above, are mostly used for scalar types and checked during compilation. They're particularly useful for representing non-contiguous elements of an enumeration. A classic example is a list of week days:

```
type Week is (Mon, Tue, Wed, Thu, Fri, Sat, Sun);
```

We can easily create a sub-list of work days in the week by specifying a **subtype** with a range based on `Week`. For example:

```
subtype Work_Week is Week range Mon .. Fri;
```

Ranges in Ada can only be specified as contiguous lists: they don't allow us to pick specific days. However, we may want to create a list containing just the first, middle and last day of the work week. To do that, we use a static predicate:

```
subtype Check_Days is Work_Week
  with Static_Predicate =>
         Check_Days in Mon | Wed | Fri;
```

Let's look at a complete example:

Listing 5: show_predicates.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Predicates is

   type Week is (Mon, Tue, Wed, Thu,
                 Fri, Sat, Sun);

   subtype Work_Week is Week range Mon .. Fri;

   subtype Test_Days is Work_Week
     with Static_Predicate =>
       Test_Days in Mon | Wed | Fri;

   type Tests_Week is array (Week) of Natural
     with Dynamic_Predicate =>
       (for all I in Tests_Week'Range =>
          (case I is
               when Test_Days =>
                  Tests_Week (I) > 0,
               when others    =>
                  Tests_Week (I) = 0));

   Num_Tests : Tests_Week :=
                 (Mon => 3, Tue => 0,
                  Wed => 4, Thu => 0,
                  Fri => 2, Sat => 0,
                  Sun => 0);

   procedure Display_Tests (N : Tests_Week) is
   begin
      for I in Test_Days loop
         Put_Line ("# tests on "
                   & Test_Days'Image (I)
                   & " => "
                   & Integer'Image (N (I)));
      end loop;
   end Display_Tests;

begin
   Display_Tests (Num_Tests);

   --  Assigning non-conformant values to
   --  individual elements of the Tests_Week
   --  type does not trigger a predicate
   --  check:
   Num_Tests (Tue) := 2;

   --  However, assignments with the "complete"
   --  Tests_Week type trigger a predicate
   --  check. For example:
   --
   --  Num_Tests := (others => 0);

   --  Also, calling any subprogram with
   --  parameters of Tests_Week type
   --  triggers a predicate check. Therefore,
   --  the following line will fail:
   Display_Tests (Num_Tests);
end Show_Predicates;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Contracts.Show_Predicates
MD5: 126c47033fc67fc8b6d7f6479205e752
```

Runtime output

```
# tests on MON =>  3
# tests on WED =>  4
# tests on FRI =>  2

raised ADA.ASSERTIONS.ASSERTION_ERROR : Dynamic_Predicate failed at show_
 ↪predicates.adb:58
```

Here we have an application that wants to perform tests only on three days of the work week. These days are specified in the `Test_Days` subtype. We want to track the number of tests that occur each day. We declare the type `Tests_Week` as an array, an object of which will contain the number of tests done each day. According to our requirements, these tests should happen only in the aforementioned three days; on other days, no tests should be performed. This requirement is implemented with a dynamic predicate of the type `Tests_Week`. Finally, the actual information about these tests is stored in the array `Num_Tests`, which is an instance of the `Tests_Week` type.

The dynamic predicate of the `Tests_Week` type is verified during the initialization of `Num_Tests`. If we have a non-conformant value there, the check will fail. However, as we can see in our example, individual assignments to elements of the array do not trigger a check. We can't check for consistency at this point because the initialization of the a complex data structure (such as arrays or records) may not be performed with a single assignment. However, as soon as the object is passed as an argument to a subprogram, the dynamic predicate is checked because the subprogram requires the object to be consistent. This happens in the last call to `Display_Tests` in our example. Here, the predicate check fails because the previous assignment has a non-conformant value.

16.3 Type invariants

Type invariants are another way of specifying expectations regarding types. While predicates are used for *non-private* types, type invariants are used exclusively to define expectations about private types. If a type T from a package P has a type invariant, the results of operations on objects of type T are always consistent with that invariant.

Type invariants are specified with a **`with`** `Type_Invariant => <property>` clause. Like predicates, the *property* defines a condition that allows us to check if an object of type T is conformant to its requirements. In this sense, type invariants can be viewed as a sort of predicate for private types. However, there are some differences in terms of checks. The following table summarizes the differences:

Element	Subprogram parameter checks	Assignment checks
Predicates	On all **`in`** and **`out`** parameters	On assignments and explicit initializations
Type invariants	On **`out`** parameters returned from subprograms declared in the same public scope	On all initializations

We could rewrite our previous example and replace dynamic predicates by type invariants. It would look like this:

Listing 6: show_type_invariant.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with Ada.Calendar; use Ada.Calendar;

with Ada.Containers.Vectors;

with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

procedure Show_Type_Invariant is

   package Courses is
      type Course is private
        with Type_Invariant => Check (Course);

      type Course_Container is private;

      procedure Add (CC : in out Course_Container;
                     C  :        Course);

      function Init
        (Name                 : String;
         Start_Date, End_Date : Time)
         return Course;

      function Check (C : Course)
                      return Boolean;

   private
      type Course is record
         Name       : Unbounded_String;
         Start_Date : Time;
         End_Date   : Time;
      end record;

      function Check (C : Course)
                      return Boolean is
        (C.Start_Date <= C.End_Date);

      package Course_Vectors is new
        Ada.Containers.Vectors
          (Index_Type   => Natural,
           Element_Type => Course);

      type Course_Container is record
         V : Course_Vectors.Vector;
      end record;
   end Courses;

   package body Courses is
      procedure Add (CC : in out Course_Container;
                     C  :        Course) is
      begin
         CC.V.Append (C);
      end Add;

      function Init
        (Name                 : String;
         Start_Date, End_Date : Time)
         return Course is
```

(continues on next page)

(continued from previous page)

62            Course'(Name       =>
63                      To_Unbounded_String (Name),
64                    Start_Date => Start_Date,
65                    End_Date   => End_Date);
66       end Init;
67    end Courses;
68
69    use Courses;
70
71    CC : Course_Container;
72 begin
73    Add (CC,
74         Init (Name       =>
75                 "Intro to Photography",
76               Start_Date =>
77                 Time_Of (2018, 5, 1),
78               End_Date   =>
79                 Time_Of (2018, 5, 10)));
80
81    --  This should trigger an error in the
82    --  type-invariant check
83    Add (CC,
84         Init (Name       =>
85                 "Intro to Video Recording",
86               Start_Date =>
87                 Time_Of (2019, 5, 1),
88               End_Date   =>
89                 Time_Of (2018, 5, 10)));
90 end Show_Type_Invariant;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Contracts.Show_Type_Invariant
MD5: c6ef863da94285f927dd106645af8650
```

Runtime output

```

raised ADA.ASSERTIONS.ASSERTION_ERROR : failed invariant from show_type_invariant.
 ↪adb:13
```

The major difference is that the `Course` type was a visible (public) type of the `Courses` package in the previous example, but in this example is a private type.

CHAPTER

SEVENTEEN

INTERFACING WITH C

Ada allows us to interface with code in many languages, including C and C++. This section discusses how to interface with C.

17.1 Multi-language project

By default, when using **gprbuild** we only compile Ada source files. To compile C files as well, we need to modify the project file used by **gprbuild**. We use the Languages entry, as in the following example:

```
project Multilang is

   for Languages use ("ada", "c");

   for Source_Dirs use ("src");
   for Main use ("main.adb");
   for Object_Dir use "obj";

end Multilang;
```

17.2 Type convention

To interface with data types declared in a C application, you specify the `Convention` aspect on the corresponding Ada type declaration. In the following example, we interface with the `C_Enum` enumeration declared in a C source file:

Listing 1: show_c_enum.adb

```
1  procedure Show_C_Enum is
2
3     type C_Enum is (A, B, C)
4       with Convention => C;
5     --  Use C convention for C_Enum
6  begin
7     null;
8  end Show_C_Enum;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.Ada_C_Enum
MD5: a14d7d981fd7d6d806cf3c55f35e19c8
```

To interface with C's built-in types, we use the `Interfaces.C` package, which contains most of the type definitions we need. For example:

Listing 2: show_c_struct.adb

```
with Interfaces.C; use Interfaces.C;

procedure Show_C_Struct is

   type c_struct is record
      a : int;
      b : long;
      c : unsigned;
      d : double;
   end record
     with Convention => C;

begin
   null;
end Show_C_Struct;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.Ada_C_Struct
MD5: dda4d3f8e4ddf5c5138a990a9a8ac427
```

Here, we're interfacing with a C struct (`C_Struct`) and using the corresponding data types in C (**`int`**, **`long`**, **`unsigned`** and **`double`**). This is the declaration in C:

Listing 3: c_struct.h

```
struct c_struct
{
    int         a;
    long        b;
    unsigned    c;
    double      d;
};
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.Ada_C_Struct
MD5: 58709b6a9eea2606d7ec0aaca0a749ff
```

17.3 Foreign subprograms

17.3.1 Calling C subprograms in Ada

We use a similar approach when interfacing with subprograms written in C. Consider the following declaration in the C header file:

Listing 4: my_func.h

```
int my_func (int a);
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.Ada_C_Func
MD5: 37b9d7ba668f7ec83c2b27ee33637937
```

Here's the corresponding C definition:

Listing 5: my_func.c

```c
#include "my_func.h"

int my_func (int a)
{
    return a * 2;
}
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.Ada_C_Func
MD5: 284b1639cb393fc14ed196d78429f3ba
```

We can interface this code in Ada using the `Import` aspect. For example:

Listing 6: show_c_func.adb

```
with Interfaces.C; use Interfaces.C;
with Ada.Text_IO;  use Ada.Text_IO;

procedure Show_C_Func is

   function my_func (a : int) return int
     with
       Import        => True,
       Convention    => C;

   --  Imports function 'my_func' from C.
   --  You can now call it from Ada.

   V : int;
begin
   V := my_func (2);
   Put_Line ("Result is " & int'Image (V));
end Show_C_Func;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.Ada_C_Func
MD5: 6c5d85c1debdeaa642946eacf413dfd2
```

If you want, you can use a different subprogram name in the Ada code. For example, we could call the C function `Get_Value`:

Listing 7: show_c_func.adb

```
with Interfaces.C; use Interfaces.C;
with Ada.Text_IO;  use Ada.Text_IO;

procedure Show_C_Func is

   function Get_Value (a : int) return int
     with
       Import        => True,
       Convention    => C,
       External_Name => "my_func";

   --  Imports function 'my_func' from C and
   --  renames it to 'Get_Value'
```

(continues on next page)

(continued from previous page)

```
14
15    V : int;
16 begin
17    V := Get_Value (2);
18    Put_Line ("Result is " & int'Image (V));
19 end Show_C_Func;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.Ada_C_Func
MD5: 856b4d99dfaa6946fb4597f254fd2f97
```

17.3.2 Calling Ada subprograms in C

You can also call Ada subprograms from C applications. You do this with the `Export` aspect. For example:

Listing 8: c_api.ads

```
1  with Interfaces.C; use Interfaces.C;
2
3  package C_API is
4
5     function My_Func (a : int) return int
6       with
7         Export        => True,
8         Convention    => C,
9         External_Name => "my_func";
10
11 end C_API;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.C_Ada_Func
MD5: 00aa4ec29fc551e710900e2ee7d96bc9
```

This is the corresponding body that implements that function:

Listing 9: c_api.adb

```
1  package body C_API is
2
3     function My_Func (a : int) return int is
4     begin
5        return a * 2;
6     end My_Func;
7
8  end C_API;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.C_Ada_Func
MD5: 2b999ab431bbc1ee223a654ad84b8248
```

On the C side, we do the same as we would if the function were written in C: simply declare it using the **`extern`** keyword. For example:

Listing 10: main.c

```c
#include <stdio.h>

extern int my_func (int a);

int main (int argc, char **argv) {

  int v = my_func(2);

  printf("Result is %d\n", v);

  return 0;
}
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.C_Ada_Func
MD5: 69301036be9be16ed45895c2a86bc352
```

17.4 Foreign variables

17.4.1 Using C global variables in Ada

To use global variables from C code, we use the same method as subprograms: we specify the `Import` and `Convention` aspects for each variable we want to import.

Let's reuse an example from the previous section. We'll add a global variable (`func_cnt`) to count the number of times the function (`my_func`) is called:

Listing 11: test.h

```c
extern int func_cnt;

int my_func (int a);
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.Ada_C_Vars
MD5: 11ba8f7a72ce7058571994870a02b052
```

The variable is declared in the C file and incremented in `my_func`:

Listing 12: test.c

```c
#include "test.h"

int func_cnt = 0;

int my_func (int a)
{
  func_cnt++;

  return a * 2;
}
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.Ada_C_Vars
MD5: 23631537cb877a03d1243c94cb7b48e8
```

In the Ada application, we just reference the foreign variable:

Listing 13: show_c_func.adb

```
with Interfaces.C; use Interfaces.C;
with Ada.Text_IO;  use Ada.Text_IO;

procedure Show_C_Func is

   function my_func (a : int) return int
     with
       Import     => True,
       Convention => C;

   V : int;

   func_cnt : int
     with
       Import        => True,
       Convention    => C;
   --  We can access the func_cnt variable
   --  from test.c

begin
   V := my_func (1);
   V := my_func (2);
   V := my_func (3);

   Put_Line ("Result is "
             & int'Image (V));

   Put_Line ("Function was called "
             & int'Image (func_cnt)
             & " times");
end Show_C_Func;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.Ada_C_Vars
MD5: cf64a9dfbc6be853ba19729fe55f0ba4
```

As we see by running the application, the value of the counter is the number of times my_func was called.

We can use the External_Name aspect to give a different name for the variable in the Ada application in the same way we do for subprograms.

17.4.2 Using Ada variables in C

You can also use variables declared in Ada files in C applications. In the same way as we did for subprograms, you do this with the `Export` aspect.

Let's reuse a past example and add a counter, as in the previous example, but this time have the counter incremented in Ada code:

Listing 14: c_api.ads

```
with Interfaces.C; use Interfaces.C;

package C_API is

   func_cnt : int := 0
     with
       Export     => True,
       Convention => C;

   function My_Func (a : int) return int
     with
       Export        => True,
       Convention    => C,
       External_Name => "my_func";

end C_API;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.C_Ada_Vars
MD5: fc118cddd797b669d2c68e57f90f69b2
```

The variable is then incremented in `My_Func`:

Listing 15: c_api.adb

```
package body C_API is

   function My_Func (a : int) return int is
   begin
      func_cnt := func_cnt + 1;
      return a * 2;
   end My_Func;

end C_API;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.C_Ada_Vars
MD5: adff5f3088da8b0dd853f1fb8b1e204f
```

In the C application, we just need to declare the variable and use it:

Listing 16: main.c

```
#include <stdio.h>

extern int my_func (int a);

extern int func_cnt;

int main (int argc, char **argv) {
```

(continues on next page)

(continued from previous page)

```
8
9   int v;
10
11  v = my_func(1);
12  v = my_func(2);
13  v = my_func(3);
14
15  printf("Result is %d\n", v);
16
17  printf("Function was called %d times\n",
18         func_cnt);
19
20  return 0;
21 }
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.C_Ada_Vars
MD5: 07fb3fbadb8ed4c0543fbfd7b5ef5c57
```

Again, by running the application, we see that the value from the counter is the number of times that `my_func` was called.

17.5 Generating bindings

In the examples above, we manually added aspects to our Ada code to correspond to the C source-code we're interfacing with. This is called creating a *binding*. We can automate this process by using the *Ada spec dump* compiler option: `-fdump-ada-spec`. We illustrate this by revisiting our previous example.

This was our C header file:

Listing 17: test.h

```
1 extern int func_cnt;
2
3 int my_func (int a);
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.C_Binds
MD5: 11ba8f7a72ce7058571994870a02b052
```

To create Ada bindings, we'll call the compiler like this:

```
gcc -c -fdump-ada-spec -C ./test.h
```

The result is an Ada spec file called `test_h.ads`:

Listing 18: test_h.ads

```
1 pragma Ada_2005;
2 pragma Style_Checks (Off);
3
4 with Interfaces.C; use Interfaces.C;
5
6 package test_h is
7
```

(continues on next page)

(continued from previous page)

```
   func_cnt : aliased int;  -- ./test.h:3
   pragma Import (C, func_cnt, "func_cnt");

   function my_func (arg1 : int) return int;  -- ./test.h:5
   pragma Import (C, my_func, "my_func");

end test_h;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.C_Binds
MD5: 8d18aeae72dba3a9ab4f9f3943fab839
```

Now we simply refer to this `test_h` package in our Ada application:

Listing 19: show_c_func.adb

```
with Interfaces.C; use Interfaces.C;
with Ada.Text_IO;  use Ada.Text_IO;
with test_h;       use test_h;

procedure Show_C_Func is
   V : int;
begin
   V := my_func (1);
   V := my_func (2);
   V := my_func (3);

   Put_Line ("Result is "
             & int'Image (V));

   Put_Line ("Function was called "
             & int'Image (func_cnt)
             & " times");
end Show_C_Func;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.C_Binds
MD5: 8a07aae87b9f36c3fce84b75e8388933
```

You can specify the name of the parent unit for the bindings you're creating as the operand to `fdump-ada-spec`:

```
gcc -c -fdump-ada-spec -fada-spec-parent=Ext_C_Code -C ./test.h
```

This creates the file `ext_c_code-test_h.ads`:

Listing 20: ext_c_code-test_h.ads

```
package Ext_C_Code.test_h is

   --  automatic generated bindings...

end Ext_C_Code.test_h;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.C_Binds_2
MD5: 3bd4087edff145a70d2a6db8543859ad
```

17.5.1 Adapting bindings

The compiler does the best it can when creating bindings for a C header file. However, sometimes it has to guess about the translation and the generated bindings don't always match our expectations. For example, this can happen when creating bindings for functions that have pointers as arguments. In this case, the compiler may use `System.Address` as the type of one or more pointers. Although this approach works fine (as we'll see later), this is usually not how a human would interpret the C header file. The following example illustrates this issue.

Let's start with this C header file:

Listing 21: test.h

```
struct test;

struct test * test_create(void);

void test_destroy(struct test *t);

void test_reset(struct test *t);

void test_set_name(struct test *t,
                   char        *name);

void test_set_address(struct test *t,
                      char        *address);

void test_display(const struct test *t);
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.C_Binds_3
MD5: af642d9ea995bf01f13f8ff41bb0f4f6
```

And the corresponding C implementation:

Listing 22: test.c

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

#include "test.h"

struct test {
  char name[80];
  char address[120];
};

static size_t
strlcpy_stat(char       *dst,
             const char *src,
             size_t      dstsize)
{
  size_t len = strlen(src);
  if (dstsize) {
    size_t bl = (len < dstsize-1 ?
                 len : dstsize-1);
    ((char*)memcpy(dst, src, bl))[bl] = 0;
  }
  return len;
```

(continues on next page)

(continued from previous page)

```
}

struct test * test_create(void)
{
  return malloc (sizeof (struct test));
}

void test_destroy(struct test *t)
{
  if (t != NULL) {
    free(t);
  }
}

void test_reset(struct test *t)
{
  t->name[0]    = '\0';
  t->address[0] = '\0';
}

void test_set_name(struct test *t,
                   char        *name)
{
  strlcpy_stat(t->name,
               name,
               sizeof(t->name));
}

void test_set_address(struct test *t,
                      char        *address)
{
  strlcpy_stat(t->address,
               address,
               sizeof(t->address));
}

void test_display(const struct test *t)
{
  printf("Name:    %s\n", t->name);
  printf("Address: %s\n", t->address);
}
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.C_Binds_3
MD5: 32652eb76ad92212609680d64e5687d3
```

Next, we'll create our bindings:

```
gcc -c -fdump-ada-spec -C ./test.h
```

This creates the following specification in `test_h.ads`:

Listing 23: test_h.ads

```
pragma Ada_2005;
pragma Style_Checks (Off);

with Interfaces.C; use Interfaces.C;
with System;
with Interfaces.C.Strings;
```

(continues on next page)

(continued from previous page)

```
7
8  package test_h is
9
10    --  skipped empty struct test
11
12    function test_create return System.Address;  -- ./test.h:5
13    pragma Import (C, test_create, "test_create");
14
15    procedure test_destroy (arg1 : System.Address);  -- ./test.h:7
16    pragma Import (C, test_destroy, "test_destroy");
17
18    procedure test_reset (arg1 : System.Address);  -- ./test.h:9
19    pragma Import (C, test_reset, "test_reset");
20
21    procedure test_set_name (arg1 : System.Address; arg2 : Interfaces.C.Strings.
   ↪chars_ptr);  -- ./test.h:11
22    pragma Import (C, test_set_name, "test_set_name");
23
24    procedure test_set_address (arg1 : System.Address; arg2 : Interfaces.C.Strings.
   ↪chars_ptr);  -- ./test.h:13
25    pragma Import (C, test_set_address, "test_set_address");
26
27    procedure test_display (arg1 : System.Address);  -- ./test.h:15
28    pragma Import (C, test_display, "test_display");
29
30 end test_h;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.C_Binds_3
MD5: 3bf8f01b94fd28594e4121a6a36afdf7
```

As we can see, the binding generator completely ignores the declaration **`struct test`** and all references to the `test` struct are replaced by addresses (`System.`**`Address`**). Nevertheless, these bindings are good enough to allow us to create a test application in Ada:

Listing 24: show_automatic_c_struct_bindings.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  with Interfaces.C;
4  use  Interfaces.C;
5
6  with Interfaces.C.Strings;
7  use  Interfaces.C.Strings;
8
9  with test_h; use test_h;
10
11 with System;
12
13 procedure Show_Automatic_C_Struct_Bindings is
14
15    Name    : constant chars_ptr :=
16      New_String ("John Doe");
17    Address : constant chars_ptr :=
18      New_String ("Small Town");
19
20    T : System.Address := test_create;
21
22 begin
23    test_reset (T);
```

(continues on next page)

(continued from previous page)

```
   test_set_name (T, Name);
   test_set_address (T, Address);

   test_display (T);
   test_destroy (T);
end Show_Automatic_C_Struct_Bindings;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.C_Binds_3
MD5: 99d64fb14d9c869d140dd2fb7d3888d7
```

We can successfully bind our C code with Ada using the automatically-generated bindings, but they aren't ideal. Instead, we would prefer Ada bindings that match our (human) interpretation of the C header file. This requires manual analysis of the header file. The good news is that we can use the automatic generated bindings as a starting point and adapt them to our needs. For example, we can:

1. Define a `Test` type based on `System.Address` and use it in all relevant functions.
2. Remove the `test_` prefix in all operations on the `Test` type.

This is the resulting specification:

Listing 25: adapted_test_h.ads

```
with System;

with Interfaces.C; use Interfaces.C;
with Interfaces.C.Strings;

package adapted_test_h is

   type Test is new System.Address;

   function Create return Test;
   pragma Import (C, Create, "test_create");

   procedure Destroy (T : Test);
   pragma Import (C, Destroy, "test_destroy");

   procedure Reset (T : Test);
   pragma Import (C, Reset, "test_reset");

   procedure Set_Name (T    : Test;
                       Name : Interfaces.C.Strings.chars_ptr);  -- ./test.h:11
   pragma Import (C, Set_Name, "test_set_name");

   procedure Set_Address (T       : Test;
                          Address : Interfaces.C.Strings.chars_ptr);
   pragma Import (C, Set_Address, "test_set_address");

   procedure Display (T : Test);  -- ./test.h:15
   pragma Import (C, Display, "test_display");

end adapted_test_h;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.C_Binds_3
MD5: 5cc875e1b01af839141e5e623f6c5b7a
```

And this is the corresponding Ada body:

Listing 26: show_adapted_c_struct_bindings.adb

```
with Interfaces.C;
use  Interfaces.C;

with Interfaces.C.Strings;
use  Interfaces.C.Strings;

with adapted_test_h; use  adapted_test_h;

with System;

procedure Show_Adapted_C_Struct_Bindings is

   Name    : constant chars_ptr :=
     New_String ("John Doe");
   Address : constant chars_ptr :=
     New_String ("Small Town");

   T : Test := Create;

begin
   Reset (T);
   Set_Name (T, Name);
   Set_Address (T, Address);

   Display (T);
   Destroy (T);
end Show_Adapted_C_Struct_Bindings;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Interfacing_With_C.C_Binds_3
MD5: 626d07b080fbbd2bf1d5f9140b64955c
```

Now we can use the Test type and its operations in a clean, readable way.

CHAPTER

EIGHTEEN

OBJECT-ORIENTED PROGRAMMING

Object-oriented programming (OOP) is a large and ill-defined concept in programming languages and one that tends to encompass many different meanings because different languages often implement their own vision of it, with similarities and differences from the implementations in other languages.

However, one model mostly "won" the battle of what object-oriented means, if only by sheer popularity. It's the model used in the Java programming language, which is very similar to the one used by C++. Here are some defining characteristics:

- Type derivation and extension: Most object oriented languages allow the user to add fields to derived types.
- Subtyping: Objects of a type derived from a base type can, in some instances, be substituted for objects of the base type.
- Runtime polymorphism: Calling a subprogram, usually called a *method*, attached to an object type can dispatch at runtime depending on the exact type of the object.
- Encapsulation: Objects can hide some of their data.
- Extensibility: People from the "outside" of your package, or even your whole library, can derive from your object types and define their own behaviors.

Ada dates from before object-oriented programming was as popular as it is today. Some of the mechanisms and concepts from the above list were in the earliest version of Ada even before what we would call OOP was added:

- As we saw, encapsulation is not implemented at the type level in Ada, but instead at the package level.
- Subtyping can be implemented using, well, subtypes, which have a full and permissive static substitutability model. The substitution will fail at runtime if the dynamic constraints of the subtype are not fulfilled.
- Runtime polymorphism can be implemented using variant records.

However, this lists leaves out type extensions, if you don't consider variant records, and extensibility.

The 1995 revision of Ada added a feature filling the gaps, which allowed people to program following the object-oriented paradigm in an easier fashion. This feature is called *tagged types*.

Note: It's possible to program in Ada without ever creating tagged types. If that's your prefered style of programming or you have no specific use for tagged types, feel free to not use them, as is the case for many features of Ada.

However, they can be the best way to express solutions to certain problems and they may be the best way to solve your problem. If that's the case, read on!

18.1 Derived types

Before presenting tagged types, we should discuss a topic we have brushed on, but not really covered, up to now:

You can create one or more new types from every type in Ada. Type derivation is built into the language.

Listing 1: newtypes.ads

```
package Newtypes is
   type Point is record
      X, Y : Integer;
   end record;

   type New_Point is new Point;
end Newtypes;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Object_Oriented_Programming.Newtypes
MD5: 0d45096755b4bfb08ba8db19ecba3f57
```

Type derivation is useful to enforce strong typing because the type system treats the two types as incompatible.

But the benefits are not limited to that: you can inherit things from the type you derive from. You not only inherit the representation of the data, but you can also inherit behavior.

When you inherit a type you also inherit what are called *primitive operations*. A primitive operation (or just a *primitive*) is a subprogram attached to a type. Ada defines primitives as subprograms defined in the same scope as the type.

> **Attention:** A subprogram will only become a primitive of the type if:
>
> 1. The subprogram is declared in the same scope as the type and
> 2. The type and the subprogram are declared in a package

Listing 2: primitives.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Primitives is
   package Week is
      type Days is (Monday, Tuesday, Wednesday,
                    Thursday, Friday,
                    Saturday, Sunday);

      --  Print_Day is a primitive
      --  of the type Days
     procedure Print_Day (D : Days);
   end Week;

   package body Week is
      procedure Print_Day (D : Days) is
      begin
         Put_Line (Days'Image (D));
      end Print_Day;
   end Week;
```

(continues on next page)

(continued from previous page)

```
20
21    use Week;
22    type Weekend_Days is new
23      Days range Saturday .. Sunday;
24
25    --  A procedure Print_Day is automatically
26    --  inherited here. It is as if the procedure
27    --
28    --  procedure Print_Day (D : Weekend_Days);
29    --
30    --  has been declared with the same body
31
32    Sat : Weekend_Days := Saturday;
33 begin
34    Print_Day (Sat);
35 end Primitives;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Object_Oriented_Programming.Primitives
MD5: eb1b0eb66f03a4a17bd9686ec4e12e2e
```

Runtime output

```
SATURDAY
```

This kind of inheritance can be very useful, and is not limited to record types (you can use it on discrete types, as in the example above), but it's only superficially similar to object-oriented inheritance:

- Records can't be extended using this mechanism alone. You also can't specify a new representation for the new type: it will **always** have the same representation as the base type.
- There's no facility for dynamic dispatch or polymorphism. Objects are of a fixed, static type.

There are other differences, but it's not useful to list them all here. Just remember that this is a kind of inheritance you can use if you only want to statically inherit behavior without duplicating code or using composition, but a kind you can't use if you want any dynamic features that are usually associated with OOP.

18.2 Tagged types

The 1995 revision of the Ada language introduced tagged types to fullfil the need for an unified solution that allows programming in an object-oriented style similar to the one described at the beginning of this chapter.

Tagged types are very similar to normal records except that some functionality is added:

- Types have a *tag*, stored inside each object, that identifies the runtime type[23] of that object.
- Primitives can dispatch. A primitive on a tagged type is what you would call a *method* in Java or C++. If you derive a base type and override a primitive of it, you can often call it on an object with the result that which primitive is called depends on the exact runtime type of the object.

[23] https://en.wikipedia.org/wiki/Run-time_type_information

- Subtyping rules are introduced allowing a tagged type derived from a base type to be statically compatible with the base type.

Let's see our first tagged type declarations:

Listing 3: p.ads

```
package P is
   type My_Class is tagged null record;
   --  Just like a regular record, but
   --  with tagged qualifier

   --  Methods are outside of the type
   --  definition:

   procedure Foo (Self : in out My_Class);
   --  If you define a procedure taking a
   --  My_Class argument in the same package,
   --  it will be a method.

   --  Here's how you derive a tagged type:

   type Derived is new My_Class with record
      A : Integer;
      --  You can add fields in derived types.
   end record;

   overriding
   procedure Foo (Self : in out Derived);
   --  The "overriding" qualifier is optional,
   --  but if it is present, it must be valid.
end P;
```

Listing 4: p.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body P is
   procedure Foo (Self : in out My_Class) is
   begin
      Put_Line ("In My_Class.Foo");
   end Foo;

   procedure Foo (Self : in out Derived) is
   begin
      Put_Line ("In Derived.Foo, A = "
                & Integer'Image (Self.A));
   end Foo;
end P;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Object_Oriented_Programming.Tagged_Types
MD5: 45baaad66a1047358addb574d0fa00bc
```

18.3 Classwide types

To remain consistent with the rest of the language, a new notation needed to be introduced to say "This object is of this type or any descendant derives tagged type".

In Ada, we call this the *classwide type*. It's used in OOP as soon as you need polymorphism. For example, you can't do the following:

Listing 5: main.adb

```
with P; use P;

procedure Main is

   O1 : My_Class;
   --  Declaring an object of type My_Class

   O2 : Derived := (A => 12);
   --  Declaring an object of type Derived

   O3 : My_Class := O2;
   --  INVALID: Trying to assign a value
   --  of type derived to a variable of
   --  type My_Class.
begin
   null;
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Object_Oriented_Programming.Tagged_Types
MD5: c87ad8bb686cb1763740750846258357
```

Build output

```
main.adb:11:21: error: expected type "My_Class" defined at p.ads:2
main.adb:11:21: error: found type "Derived" defined at p.ads:16
gprbuild: *** compilation phase failed
```

This is because an object of a type T is exactly of the type T, whether T is tagged or not. What you want to say as a programmer is "I want O3 to be able to hold an object of type `My_Class` or any type descending from `My_Class`". Here's how you do that:

Listing 6: main.adb

```
with P; use P;

procedure Main is
   O1 : My_Class;
   --  Declare an object of type My_Class

   O2 : Derived := (A => 12);
   --  Declare an object of type Derived

   O3 : My_Class'Class := O2;
   --  Now valid: My_Class'Class designates
   --  the classwide type for My_Class,
   --  which is the set of all types
   --  descending from My_Class (including
   --  My_Class).
begin
```

(continues on next page)

(continued from previous page)

```
   null;
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Object_Oriented_Programming.Tagged_Types
MD5: 35412176a248015a26e507164ce526af
```

Attention: Because an object of a classwide type can be the size of any descendant of its base type, it has an unknown size. It's therefore an indefinite type, with the expected restrictions:

- It can't be stored as a field/component of a record
- An object of a classwide type needs to be initialized immediately (you can't specify the constraints of such a type in any way other than by initializing it).

18.4 Dispatching operations

We saw that you can override operations in types derived from another tagged type. The eventual goal of OOP is to make a dispatching call: a call to a primitive (method) that depends on the exact type of the object.

But, if you think carefully about it, a variable of type `My_Class` always contains an object of exactly that type. If you want to have a variable that can contain a `My_Class` or any derived type, it has to be of type `My_Class'Class`.

In other words, to make a dispatching call, you must first have an object that can be either of a type or any type derived from this type, namely an object of a classwide type.

Listing 7: main.adb

```
with P; use P;

procedure Main is
   O1 : My_Class;
   --  Declare an object of type My_Class

   O2 : Derived := (A => 12);
   --  Declare an object of type Derived

   O3 : My_Class'Class := O2;

   O4 : My_Class'Class := O1;
begin
   Foo (O1);
   --  Non dispatching: Calls My_Class.Foo
   Foo (O2);
   --  Non dispatching: Calls Derived.Foo
   Foo (O3);
   --  Dispatching: Calls Derived.Foo
   Foo (O4);
   --  Dispatching: Calls My_Class.Foo
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Object_Oriented_Programming.Tagged_Types
MD5: 7631f823b0dd9e5474f6bb2dc35af2a2
```

Runtime output

```
In My_Class.Foo
In Derived.Foo, A =  12
In Derived.Foo, A =  12
In My_Class.Foo
```

Attention

You can convert an object of type `Derived` to an object of type `My_Class`. This is called a *view conversion* in Ada parlance and is useful, for example, if you want to call a parent method.

In that case, the object really is converted to a `My_Class` object, which means its tag is changed. Since tagged objects are always passed by reference, you can use this kind of conversion to modify the state of an object: changes to converted object will affect the original one.

Listing 8: main.adb

```
1  with P; use P;
2
3  procedure Main is
4     O1 : Derived := (A => 12);
5     --  Declare an object of type Derived
6
7     O2 : My_Class := My_Class (O1);
8
9     O3 : My_Class'Class := O2;
10 begin
11    Foo (O1);
12    --  Non dispatching: Calls Derived.Foo
13    Foo (O2);
14    --  Non dispatching: Calls My_Class.Foo
15
16    Foo (O3);
17    --  Dispatching: Calls My_Class.Foo
18 end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Object_Oriented_Programming.Tagged_Types
MD5: b92112b05201ff14789baca258fa0cbc
```

Runtime output

```
In Derived.Foo, A =  12
In My_Class.Foo
In My_Class.Foo
```

18.5 Dot notation

You can also call primitives of tagged types with a notation that's more familiar to object oriented programmers. Given the Foo primitive above, you can also write the above program this way:

Listing 9: main.adb

```
with P; use P;

procedure Main is
   O1 : My_Class;
   --  Declare an object of type My_Class

   O2 : Derived := (A => 12);
   --  Declare an object of type Derived

   O3 : My_Class'Class := O2;

   O4 : My_Class'Class := O1;
begin
   O1.Foo;
   --  Non dispatching: Calls My_Class.Foo
   O2.Foo;
   --  Non dispatching: Calls Derived.Foo
   O3.Foo;
   --  Dispatching: Calls Derived.Foo
   O4.Foo;
   --  Dispatching: Calls My_Class.Foo
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Object_Oriented_Programming.Tagged_Types
MD5: 9c6ebdfec9ceeb986d92eb90ec9ff59b
```

Runtime output

```
In My_Class.Foo
In Derived.Foo, A =  12
In Derived.Foo, A =  12
In My_Class.Foo
```

If the dispatching parameter of a primitive is the first parameter, which is the case in our examples, you can call the primitive using the dot notation. Any remaining parameter are passed normally:

Listing 10: main.adb

```
with P; use P;

procedure Main is
   package Extend is
      type D2 is new Derived with null record;

      procedure Bar (Self : in out D2;
                     Val  :        Integer);
   end Extend;

   package body Extend is
      procedure Bar (Self : in out D2;
```

(continues on next page)

(continued from previous page)

```
                     Val  :        Integer) is
      begin
         Self.A := Self.A + Val;
      end Bar;
   end Extend;

   use Extend;

   Obj : D2 := (A => 15);
begin
   Obj.Bar (2);
   Obj.Foo;
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Object_Oriented_Programming.Tagged_Types
MD5: fec4f5cc4213cc111708dcc276e870c2
```

Runtime output

```
In Derived.Foo, A =  17
```

18.6 Private & Limited

We've seen previously (in the *Privacy* (page 113) chapter) that types can be declared limited or private. These encapsulation techniques can also be applied to tagged types, as we'll see in this section.

This is an example of a tagged private type:

Listing 11: p.ads

```
package P is
   type T is tagged private;
private
   type T is tagged record
      E : Integer;
   end record;
end P;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Object_Oriented_Programming.Tagged_Private_Types
MD5: 4cd4bcd1a54d5f6407a500558b5da417
```

This is an example of a tagged limited type:

Listing 12: p.ads

```
package P is
   type T is tagged limited record
      E : Integer;
   end record;
end P;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Object_Oriented_Programming.Tagged_Limited_Types
MD5: 13228777133aa6db97da1c29f732459c
```

Naturally, you can combine both *limited* and *private* types and declare a tagged limited private type:

Listing 13: p.ads

```
package P is
   type T is tagged limited private;

   procedure Init (A : in out T);
private
   type T is tagged limited record
      E : Integer;
   end record;
end P;
```

Listing 14: p.adb

```
package body P is

   procedure Init (A : in out T) is
   begin
      A.E := 0;
   end Init;

end P;
```

Listing 15: main.adb

```
with P; use P;

procedure Main is
   T1, T2 : T;
begin
   T1.Init;
   T2.Init;

   --  The following line doesn't work
   --  because type T is private:
   --
   --  T1.E := 0;

   --  The following line doesn't work
   --  because type T is limited:
   --
   --  T2 := T1;
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Object_Oriented_Programming.Tagged_Limited_Private_
↪Types
MD5: 68240374505bcaf7aad4ebaed3b9127b
```

Note that the code in the `Main` procedure above presents two assignments that trigger compilation errors because type T is limited private. In fact, you cannot:

- assign to `T1.E` directly because type T is private;
- assign T1 to T2 because type T is limited.

In this case, there's no distinction between tagged and non-tagged types: these compilation errors would also occur for non-tagged types.

18.7 Classwide access types

In this section, we'll discuss an useful pattern for object-oriented programming in Ada: class-wide access type. Let's start with an example where we declare a tagged type T and a derived type T_New:

Listing 16: p.ads

```
package P is
   type T is tagged null record;

   procedure Show (Dummy : T);

   type T_New is new T with null record;

   procedure Show (Dummy : T_New);
end P;
```

Listing 17: p.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body P is

   procedure Show (Dummy : T) is
   begin
      Put_Line ("Using type "
                & T'External_Tag);
   end Show;

   procedure Show (Dummy : T_New) is
   begin
      Put_Line ("Using type "
                & T_New'External_Tag);
   end Show;

end P;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Object_Oriented_Programming.Classwide_Error
MD5: fd5cb99925d3c88536546aa0be8104b7
```

Note that we're using null records for both types T and T_New. Although these types don't actually have any component, we can still use them to demonstrate dispatching. Also note that the example above makes use of the `'External_Tag` attribute in the implementation of the Show procedure to get a string for the corresponding tagged type.

As we've seen before, we must use a classwide type to create objects that can make dispatching calls. In other words, objects of type `T'Class` will dispatch. For example:

Listing 18: dispatching_example.adb

```
with P; use P;

procedure Dispatching_Example is
```

(continues on next page)

(continued from previous page)

```
   T2         :          T_New;
   T_Dispatch : constant T'Class := T2;
begin
   T_Dispatch.Show;
end Dispatching_Example;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Object_Oriented_Programming.Classwide_Error
MD5: f8957b31c9c62db23759baad7b867a57
```

Runtime output

```
Using type P.T_NEW
```

A more useful application is to declare an array of objects that can dispatch. For example, we'd like to declare an array T_Arr, loop over this array and dispatch according to the actual type of each individual element:

```
for I in T_Arr'Range loop
   T_Arr (I).Show;
   --  Call Show procedure according
   --  to actual type of T_Arr (I)
end loop;
```

However, it's not possible to declare an array of type T'Class directly:

Listing 19: classwide_compilation_error.adb

```
with P; use P;

procedure Classwide_Compilation_Error is
   T_Arr  : array (1 .. 2) of T'Class;
   --                         ^
   --               Compilation Error!
begin
   for I in T_Arr'Range loop
      T_Arr (I).Show;
   end loop;
end Classwide_Compilation_Error;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Object_Oriented_Programming.Classwide_Error
MD5: e86f6c6ee35dced8f330bf6177d178fd
```

Build output

```
classwide_compilation_error.adb:4:32: error: unconstrained element type in array␣
 ↪declaration
gprbuild: *** compilation phase failed
```

In fact, it's impossible for the compiler to know which type would actually be used for each element of the array. However, if we use dynamic allocation via access types, we can allocate objects of different types for the individual elements of an array T_Arr. We do this by using classwide access types, which have the following format:

```
type T_Class is access T'Class;
```

We can rewrite the previous example using the T_Class type. In this case, dynamically allocated objects of this type will dispatch according to the actual type used during the

allocation. Also, let's introduce an `Init` procedure that won't be overridden for the derived T_New type. This is the adapted code:

Listing 20: p.ads

```
package P is
   type T is tagged record
      E : Integer;
   end record;

   type T_Class is access T'Class;

   procedure Init (A : in out T);

   procedure Show (Dummy : T);

   type T_New is new T with null record;

   procedure Show (Dummy : T_New);

end P;
```

Listing 21: p.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body P is

   procedure Init (A : in out T) is
   begin
      Put_Line ("Initializing type T...");
      A.E := 0;
   end Init;

   procedure Show (Dummy : T) is
   begin
      Put_Line ("Using type "
                & T'External_Tag);
   end Show;

   procedure Show (Dummy : T_New) is
   begin
      Put_Line ("Using type "
                & T_New'External_Tag);
   end Show;

end P;
```

Listing 22: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with P;           use P;

procedure Main is
   T_Arr  : array (1 .. 2) of T_Class;
begin
   T_Arr (1) := new T;
   T_Arr (2) := new T_New;

   for I in T_Arr'Range loop
      Put_Line ("Element # "
                & Integer'Image (I));
```

(continues on next page)

(continued from previous page)

```
13
14       T_Arr (I).Init;
15       T_Arr (I).Show;
16
17       Put_Line ("-----------");
18    end loop;
19 end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Object_Oriented_Programming.Classwide_Access
MD5: 97c05a8f911d0a0e39c0cc90fae184a7
```

Runtime output

```
Element #  1
Initializing type T...
Using type P.T
-----------
Element #  2
Initializing type T...
Using type P.T_NEW
-----------
```

In this example, the first element (`T_Arr (1)`) is of type `T`, while the second element is of type `T_New`. When running the example, the `Init` procedure of type `T` is called for both elements of the `T_Arr` array, while the call to the `Show` procedure selects the corresponding procedure according to the type of each element of `T_Arr`.

CHAPTER

NINETEEN

STANDARD LIBRARY: CONTAINERS

In previous chapters, we've used arrays as the standard way to group multiple objects of a specific data type. In many cases, arrays are good enough for manipulating those objects. However, there are situations that require more flexibility and more advanced operations. For those cases, Ada provides support for containers — such as vectors and sets — in its standard library.

We present an introduction to containers here. For a list of all containers available in Ada, see *Appendix B* (page 271).

19.1 Vectors

In the following sections, we present a general overview of vectors, including instantiation, initialization, and operations on vector elements and vectors.

19.1.1 Instantiation

Here's an example showing the instantiation and declaration of a vector V:

Listing 1: show_vector_inst.adb

```
with Ada.Containers.Vectors;

procedure Show_Vector_Inst is

   package Integer_Vectors is new
     Ada.Containers.Vectors
       (Index_Type   => Natural,
        Element_Type => Integer);

   V : Integer_Vectors.Vector;
begin
   null;
end Show_Vector_Inst;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Vector_Inst
MD5: 8b737842d2784f25502990f21e1cf6de
```

Containers are based on generic packages, so we can't simply declare a vector as we would declare an array of a specific type:

```
A : array (1 .. 10) of Integer;
```

Instead, we first need to instantiate one of those packages. We **with** the container package (`Ada.Containers.Vectors` in this case) and instantiate it to create an instance of the generic package for the desired type. Only then can we declare the vector using the type from the instantiated package. This instantiation needs to be done for any container type from the standard library.

In the instantiation of `Integer_Vectors`, we indicate that the vector contains elements of **`Integer`** type by specifying it as the `Element_Type`. By setting `Index_Type` to **`Natural`**, we specify that the allowed range includes all natural numbers. We could have used a more restrictive range if desired.

19.1.2 Initialization

One way to initialize a vector is from a concatenation of elements. We use the `&` operator, as shown in the following example:

Listing 2: show_vector_init.adb

```
with Ada.Containers; use Ada.Containers;
with Ada.Containers.Vectors;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Vector_Init is

   package Integer_Vectors is new
     Ada.Containers.Vectors
       (Index_Type   => Natural,
        Element_Type => Integer);

   use Integer_Vectors;

   V : Vector := 20 & 10 & 0 & 13;
begin
   Put_Line ("Vector has "
             & Count_Type'Image (V.Length)
             & " elements");
end Show_Vector_Init;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Vector_Init
MD5: 0087b0a15e0c88b27ac36c3b27159a17
```

Runtime output

```
Vector has  4 elements
```

We specify **`use`** `Integer_Vectors`, so we have direct access to the types and operations from the instantiated package. Also, the example introduces another operation on the vector: `Length`, which retrieves the number of elements in the vector. We can use the dot notation because `Vector` is a tagged type, allowing us to write either `V.Length` or `Length (V)`.

19.1.3 Appending and prepending elements

You add elements to a vector using the Prepend and Append operations. As the names suggest, these operations add elements to the beginning or end of a vector, respectively. For example:

Listing 3: show_vector_append.adb

```
with Ada.Containers; use Ada.Containers;
with Ada.Containers.Vectors;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Vector_Append is

   package Integer_Vectors is new
     Ada.Containers.Vectors
       (Index_Type   => Natural,
        Element_Type => Integer);

   use Integer_Vectors;

   V : Vector;
begin
   Put_Line ("Appending some elements "
             & "to the vector...");
   V.Append (20);
   V.Append (10);
   V.Append (0);
   V.Append (13);
   Put_Line ("Finished appending.");

   Put_Line ("Prepending some elements"
             & "to the vector...");
   V.Prepend (30);
   V.Prepend (40);
   V.Prepend (100);
   Put_Line ("Finished prepending.");

   Put_Line ("Vector has "
             & Count_Type'Image (V.Length)
             & " elements");
end Show_Vector_Append;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Vector_Append
MD5: f88d393ba96a7950f58d9f1c0c74a021
```

Runtime output

```
Appending some elements to the vector...
Finished appending.
Prepending some elementsto the vector...
Finished prepending.
Vector has  7 elements
```

This example puts elements into the vector in the following sequence: (100, 40, 30, 20, 10, 0, 13).

The Reference Manual specifies that the worst-case complexity must be:

- O(log N) for the Append operation, and

- O(N log N) for the Prepend operation.

19.1.4 Accessing first and last elements

We access the first and last elements of a vector using the `First_Element` and `Last_Element` functions. For example:

Listing 4: show_vector_first_last_element.adb

```
with Ada.Containers; use Ada.Containers;
with Ada.Containers.Vectors;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Vector_First_Last_Element is

   package Integer_Vectors is new
     Ada.Containers.Vectors
       (Index_Type   => Natural,
        Element_Type => Integer);

   use Integer_Vectors;

   function Img (I : Integer)    return String
     renames Integer'Image;
   function Img (I : Count_Type) return String
     renames Count_Type'Image;

   V : Vector := 20 & 10 & 0 & 13;
begin
   Put_Line ("Vector has "
             & Img (V.Length)
             & " elements");

   --  Using V.First_Element to
   --  retrieve first element
   Put_Line ("First element is "
             & Img (V.First_Element));

   --  Using V.Last_Element to
   --  retrieve last element
   Put_Line ("Last element is "
             & Img (V.Last_Element));
end Show_Vector_First_Last_Element;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Vector_First_Last_Element
MD5: 602255760d0017ced6b4115c845cd48d
```

Runtime output

```
Vector has  4 elements
First element is  20
Last element is  13
```

You can swap elements by calling the procedure Swap and retrieving a reference (a *cursor*) to the first and last elements of the vector by calling `First` and `Last`. A cursor allows us to iterate over a container and process individual elements from it.

With these operations, we're able to write code to swap the first and last elements of a vector:

Listing 5: show_vector_first_last_element.adb

```
with Ada.Containers; use Ada.Containers;
with Ada.Containers.Vectors;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Vector_First_Last_Element is

   package Integer_Vectors is new
     Ada.Containers.Vectors
       (Index_Type   => Natural,
        Element_Type => Integer);

   use Integer_Vectors;

   function Img (I : Integer) return String
     renames Integer'Image;

   V : Vector := 20 & 10 & 0 & 13;
begin
   --  We use V.First and V.Last to retrieve
   --  cursor for first and last elements.
   --  We use V.Swap to swap elements.
   V.Swap (V.First, V.Last);

   Put_Line ("First element is now "
             & Img (V.First_Element));
   Put_Line ("Last element is now "
             & Img (V.Last_Element));
end Show_Vector_First_Last_Element;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Vector_First_Last_Element
MD5: 1a0c0bf28bb661b3f328473ac3c2eb54
```

Runtime output

```
First element is now  13
Last element is now  20
```

19.1.5 Iterating

The easiest way to iterate over a container is to use a `for E of Our_Container` loop. This gives us a reference (E) to the element at the current position. We can then use E directly. For example:

Listing 6: show_vector_iteration.adb

```
with Ada.Containers.Vectors;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Vector_Iteration is

   package Integer_Vectors is new
     Ada.Containers.Vectors
       (Index_Type   => Natural,
```

(continues on next page)

(continued from previous page)

```
        Element_Type => Integer);

   use Integer_Vectors;

   function Img (I : Integer) return String
     renames Integer'Image;

   V : Vector := 20 & 10 & 0 & 13;
begin
   Put_Line ("Vector elements are: ");

   --
   --  Using for ... of loop to iterate:
   --
   for E of V loop
      Put_Line ("- " & Img (E));
   end loop;

end Show_Vector_Iteration;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Vector_Iteration
MD5: 4fc9a939aa822097d3a937646d3e2910
```

Runtime output

```
Vector elements are:
-  20
-  10
-  0
-  13
```

This code displays each element from the vector `V`.

Because we're given a reference, we can display not only the value of an element but also modify it. For example, we could easily write a loop to add one to each element of vector `V`:

```
for E of V loop
   E := E + 1;
end loop;
```

We can also use indices to access vector elements. The format is similar to a loop over array elements: we use a **`for`** `I` **`in`** <**`range`**> loop. The range is provided by `V.First_Index` and `V.Last_Index`. We can access the current element by using it as an array index: `V (I)`. For example:

Listing 7: show_vector_index_iteration.adb

```
with Ada.Containers.Vectors;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Vector_Index_Iteration is

   package Integer_Vectors is new
     Ada.Containers.Vectors
       (Index_Type   => Natural,
        Element_Type => Integer);

```

(continues on next page)

(continued from previous page)

```
   use Integer_Vectors;

   V : Vector := 20 & 10 & 0 & 13;
begin
   Put_Line ("Vector elements are: ");

   --
   --  Using indices in a "for I in ..." loop
   --  to iterate:
   --
   for I in V.First_Index .. V.Last_Index loop
      --  Displaying current index I
      Put ("- ["
           & Extended_Index'Image (I)
           & "] ");

      Put (Integer'Image (V (I)));

      --  We could also use the V.Element (I)
      --  function to retrieve the element at
      --  the current index I

      New_Line;
   end loop;

end Show_Vector_Index_Iteration;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Vector_Index_Iteration
MD5: f5600bbcc53d6d6887a771b1505676e9
```

Runtime output

```
Vector elements are:
- [ 0]  20
- [ 1]  10
- [ 2]  0
- [ 3]  13
```

Here, in addition to displaying the vector elements, we're also displaying each index, `I`, just like what we can do for array indices. Also, we can access the element by using either the short form `V (I)` or the longer form `V.Element (I)` but not `V.I`.

As mentioned in the previous section, you can use cursors to iterate over containers. For this, use the function `Iterate`, which retrieves a cursor for each position in the vector. The corresponding loop has the format **`for`** `C` **`in`** `V.Iterate` **`loop`**. Like the previous example using indices, you can again access the current element by using the cursor as an array index: `V (C)`. For example:

Listing 8: show_vector_cursor_iteration.adb

```
with Ada.Containers.Vectors;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Vector_Cursor_Iteration is

   package Integer_Vectors is new
     Ada.Containers.Vectors
       (Index_Type   => Natural,
```

(continues on next page)

(continued from previous page)

```
10          Element_Type => Integer);
11
12    use Integer_Vectors;
13
14    V : Vector := 20 & 10 & 0 & 13;
15 begin
16    Put_Line ("Vector elements are: ");
17
18    --
19    --  Use a cursor to iterate in a loop:
20    --
21    for C in V.Iterate loop
22       --  Using To_Index function to retrieve
23       --  the index for the cursor position
24       Put ("- ["
25            & Extended_Index'Image (To_Index (C))
26            & "] ");
27
28       Put (Integer'Image (V (C)));
29
30       --  We could use Element (C) to retrieve
31       --  the vector element for the cursor
32       --  position
33
34       New_Line;
35    end loop;
36
37    --  Alternatively, we could iterate with a
38    --  while-loop:
39    --
40    --  declare
41    --     C : Cursor := V.First;
42    --  begin
43    --     while C /= No_Element loop
44    --        some processing here...
45    --
46    --        C := Next (C);
47    --     end loop;
48    --  end;
49
50 end Show_Vector_Cursor_Iteration;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Vector_Cursor_Iteration
MD5: de789bbd2e1814aae3fb5213c99ac25c
```

Runtime output

```
Vector elements are:
- [ 0]  20
- [ 1]  10
- [ 2]  0
- [ 3]  13
```

Instead of accessing an element in the loop using `V (C)`, we could also have used the longer form `Element (C)`. In this example, we're using the function `To_Index` to retrieve the index corresponding to the current cursor.

As shown in the comments after the loop, we could also use a **`while ... loop`** to iterate over the vector. In this case, we would start with a cursor for the first element (retrieved by calling `V.First`) and then call `Next (C)` to retrieve a cursor for subsequent elements.

`Next (C)` returns `No_Element` when the cursor reaches the end of the vector.

You can directly modify the elements using a reference. This is what it looks like when using both indices and cursors:

```
--  Modify vector elements using index
for I in V.First_Index .. V.Last_Index loop
   V (I) := V (I) + 1;
end loop;

--  Modify vector elements using cursor
for C in V.Iterate loop
   V (C) := V (C) + 1;
end loop;
```

The Reference Manual requires that the worst-case complexity for accessing an element be O(log N).

Another way of modifying elements of a vector is using a *process procedure*, which takes an individual element and does some processing on it. You can call `Update_Element` and pass both a cursor and an access to the process procedure. For example:

Listing 9: show_vector_update.adb

```
with Ada.Containers.Vectors;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Vector_Update is

   package Integer_Vectors is new
     Ada.Containers.Vectors
       (Index_Type   => Natural,
        Element_Type => Integer);

   use Integer_Vectors;

   procedure Add_One (I : in out Integer) is
   begin
      I := I + 1;
   end Add_One;

   V : Vector := 20 & 10 & 12;
begin
   --
   --  Use V.Update_Element to process elements
   --
   for C in V.Iterate loop
      V.Update_Element (C, Add_One'Access);
   end loop;

end Show_Vector_Update;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Vector_Update
MD5: 5dcc3dd8020632a8ea2ce975ecd8f4da
```

19.1.6 Finding and changing elements

You can locate a specific element in a vector by retrieving its index. `Find_Index` retrieves the index of the first element matching the value you're looking for. Alternatively, you can use `Find` to retrieve a cursor referencing that element. For example:

Listing 10: show_find_vector_element.adb

```
with Ada.Containers.Vectors;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Find_Vector_Element is

   package Integer_Vectors is new
     Ada.Containers.Vectors
       (Index_Type   => Natural,
        Element_Type => Integer);

   use Integer_Vectors;

   V : Vector := 20 & 10 & 0 & 13;
   Idx : Extended_Index;
   C   : Cursor;
begin
   --  Using Find_Index to retrieve the index
   --  of element with value 10
   Idx := V.Find_Index (10);
   Put_Line ("Index of element with value 10 is "
             & Extended_Index'Image (Idx));

   --  Using Find to retrieve the cursor for
   --  the element with value 13
   C   := V.Find (13);
   Idx := To_Index (C);
   Put_Line ("Index of element with value 13 is "
             & Extended_Index'Image (Idx));
end Show_Find_Vector_Element;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Find_Vector_Element
MD5: c3da01cd66c8705a7cbccae8390d5f81
```

Runtime output

```
Index of element with value 10 is  1
Index of element with value 13 is  3
```

As we saw in the previous section, we can directly access vector elements by using either an index or cursor. However, an exception is raised if we try to access an element with an invalid index or cursor, so we must check whether the index or cursor is valid before using it to access an element. In our example, `Find_Index` or `Find` might not have found the element in the vector. We check for this possibility by comparing the index to `No_Index` or the cursor to `No_Element`. For example:

```
--  Modify vector element using index
if Idx /= No_Index then
   V (Idx) := 11;
end if;
```

(continues on next page)

(continued from previous page)

```
--  Modify vector element using cursor
if C /= No_Element then
   V (C) := 14;
end if;
```

Instead of writing `V (C) := 14`, we could use the longer form `V.Replace_Element (C, 14)`.

19.1.7 Inserting elements

In the previous sections, we've seen examples of how to add elements to a vector:

- using the concatenation operator (&) at the vector declaration, or
- calling the Prepend and Append procedures.

You may want to insert an element at a specific position, e.g. before a certain element in the vector. You do this by calling `Insert`. For example:

Listing 11: show_vector_insert.adb

```
with Ada.Containers; use Ada.Containers;
with Ada.Containers.Vectors;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Vector_Insert is

   package Integer_Vectors is new
     Ada.Containers.Vectors
       (Index_Type   => Natural,
        Element_Type => Integer);

   use Integer_Vectors;

   procedure Show_Elements (V : Vector) is
   begin
      New_Line;
      Put_Line ("Vector has "
                & Count_Type'Image (V.Length)
                & " elements");

      if not V.Is_Empty then
         Put_Line ("Vector elements are: ");
         for E of V loop
            Put_Line ("- " & Integer'Image (E));
         end loop;
      end if;
   end Show_Elements;

   V : Vector := 20 & 10 & 12;
   C : Cursor;
begin
   Show_Elements (V);

   New_Line;
   Put_Line ("Adding element with value 9");
   Put_Line ("  (before 10)...");

   --
```

(continues on next page)

(continued from previous page)

```
   --  Using V.Insert to insert the element
   --  into the vector
   --
   C := V.Find (10);
   if C /= No_Element then
      V.Insert (C, 9);
   end if;

   Show_Elements (V);

end Show_Vector_Insert;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Vector_Insert
MD5: af49f390388896c51ab97541036fbcaf
```

Runtime output

```

Vector has  3 elements
Vector elements are:
-  20
-  10
-  12

Adding element with value 9
  (before 10)...

Vector has  4 elements
Vector elements are:
-  20
-  9
-  10
-  12
```

In this example, we're looking for an element with the value of 10. If we find it, we insert an element with the value of 9 before it.

19.1.8 Removing elements

You can remove elements from a vector by passing either a valid index or cursor to the `Delete` procedure. If we combine this with the functions `Find_Index` and `Find` from the previous section, we can write a program that searches for a specific element and deletes it, if found:

Listing 12: show_remove_vector_element.adb

```
with Ada.Containers.Vectors;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Remove_Vector_Element is
   package Integer_Vectors is new
     Ada.Containers.Vectors
       (Index_Type   => Natural,
        Element_Type => Integer);

   use Integer_Vectors;
```

(continues on next page)

(continued from previous page)

```
12
13    V : Vector := 20 & 10 & 0 & 13 & 10 & 13;
14    Idx : Extended_Index;
15    C   : Cursor;
16 begin
17    --  Use Find_Index to retrieve index of
18    --  the element with value 10
19    Idx := V.Find_Index (10);
20
21    --  Checking whether index is valid
22    if Idx /= No_Index then
23       --  Removing element using V.Delete
24       V.Delete (Idx);
25    end if;
26
27    --  Use Find to retrieve cursor for
28    --  the element with value 13
29    C := V.Find (13);
30
31    --  Check whether index is valid
32    if C /= No_Element then
33       --  Remove element using V.Delete
34       V.Delete (C);
35    end if;
36
37 end Show_Remove_Vector_Element;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Remove_Vector_Element
MD5: 540d0dc5715e58926e9dc4600bd6ad5d
```

We can extend this approach to delete all elements matching a certain value. We just need to keep searching for the element in a loop until we get an invalid index or cursor. For example:

Listing 13: show_remove_vector_elements.adb

```
1  with Ada.Containers; use Ada.Containers;
2  with Ada.Containers.Vectors;
3
4  with Ada.Text_IO; use Ada.Text_IO;
5
6  procedure Show_Remove_Vector_Elements is
7
8     package Integer_Vectors is new
9       Ada.Containers.Vectors
10       (Index_Type   => Natural,
11        Element_Type => Integer);
12
13    use Integer_Vectors;
14
15    procedure Show_Elements (V : Vector) is
16    begin
17       New_Line;
18       Put_Line ("Vector has "
19                 & Count_Type'Image (V.Length)
20                 & " elements");
21
22       if not V.Is_Empty then
23          Put_Line ("Vector elements are: ");
```

(continues on next page)

(continued from previous page)

```
         for E of V loop
            Put_Line ("- " & Integer'Image (E));
         end loop;
      end if;
   end Show_Elements;

   V : Vector := 20 & 10 & 0 & 13 & 10 & 14 & 13;
begin
   Show_Elements (V);

   --
   --  Remove elements using an index
   --
   declare
      E : constant Integer := 10;
      I : Extended_Index;
   begin
      New_Line;
      Put_Line
        ("Removing all elements with value of "
         & Integer'Image (E) & "...");
      loop
         I := V.Find_Index (E);
         exit when I = No_Index;
         V.Delete (I);
      end loop;
   end;

   --
   --  Remove elements using a cursor
   --
   declare
      E : constant Integer := 13;
      C : Cursor;
   begin
      New_Line;
      Put_Line
        ("Removing all elements with value of "
         & Integer'Image (E) & "...");
      loop
         C := V.Find (E);
         exit when C = No_Element;
         V.Delete (C);
      end loop;
   end;

   Show_Elements (V);
end Show_Remove_Vector_Elements;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Remove_Vector_Elements
MD5: 6e364843b9638224bd9a36eb9d45e446
```

Runtime output

```

Vector has  7 elements
Vector elements are:
-  20
-  10
```

(continues on next page)

(continued from previous page)

```
-  0
-  13
-  10
-  14
-  13

Removing all elements with value of  10...

Removing all elements with value of  13...

Vector has  3 elements
Vector elements are:
-  20
-  0
-  14
```

In this example, we remove all elements with the value 10 from the vector by retrieving their index. Likewise, we remove all elements with the value 13 by retrieving their cursor.

19.1.9 Other Operations

We've seen some operations on vector elements. Here, we'll see operations on the vector as a whole. The most prominent is the concatenation of multiple vectors, but we'll also see operations on vectors, such as sorting and sorted merging operations, that view the vector as a sequence of elements and operate on the vector considering the element's relations to each other.

We do vector concatenation using the `&` operator on vectors. Let's consider two vectors `V1` and `V2`. We can concatenate them by doing `V := V1 & V2`. `V` contains the resulting vector.

The generic package **`Generic_`**`Sorting` is a child package of `Ada.Containers.Vectors`. It contains sorting and merging operations. Because it's a generic package, you can't use it directly, but have to instantiate it. In order to use these operations on a vector of integer values (`Integer_Vectors`, in our example), you need to instantiate it directly as a child of `Integer_Vectors`. The next example makes it clear how to do this.

After instantiating **`Generic_`**`Sorting`, we make all the operations available to us with the **`use`** statement. We can then call `Sort` to sort the vector and `Merge` to merge one vector into another.

The following example presents code that manipulates three vectors (`V1`, `V2`, `V3`) using the concatenation, sorting and merging operations:

Listing 14: show_vector_ops.adb

```
1  with Ada.Containers; use Ada.Containers;
2  with Ada.Containers.Vectors;
3
4  with Ada.Text_IO; use Ada.Text_IO;
5
6  procedure Show_Vector_Ops is
7
8     package Integer_Vectors is new
9       Ada.Containers.Vectors
10        (Index_Type   => Natural,
11         Element_Type => Integer);
12
13    package Integer_Vectors_Sorting is
14      new Integer_Vectors.Generic_Sorting;
15
```

(continues on next page)

(continued from previous page)

```
   use Integer_Vectors;
   use Integer_Vectors_Sorting;

   procedure Show_Elements (V : Vector) is
   begin
      New_Line;
      Put_Line ("Vector has "
                & Count_Type'Image (V.Length)
                & " elements");

      if not V.Is_Empty then
         Put_Line ("Vector elements are: ");
         for E of V loop
            Put_Line ("- " & Integer'Image (E));
         end loop;
      end if;
   end Show_Elements;

   V, V1, V2, V3 : Vector;
begin
   V1 := 10 & 12 & 18;
   V2 := 11 & 13 & 19;
   V3 := 15 & 19;

   New_Line;
   Put_Line ("---- V1 ----");
   Show_Elements (V1);

   New_Line;
   Put_Line ("---- V2 ----");
   Show_Elements (V2);

   New_Line;
   Put_Line ("---- V3 ----");
   Show_Elements (V3);

   New_Line;
   Put_Line
     ("Concatenating V1, V2 and V3 into V:");

   V := V1 & V2 & V3;

   Show_Elements (V);

   New_Line;
   Put_Line ("Sorting V:");

   Sort (V);

   Show_Elements (V);

   New_Line;
   Put_Line ("Merging V2 into V1:");

   Merge (V1, V2);

   Show_Elements (V1);

end Show_Vector_Ops;
```

Code block metadata

-  11
-  12
```

(continues on next page)

(continued from previous page)

```
-   13
-   18
-   19
```

The Reference Manual requires that the worst-case complexity of a call to `Sort` be $O(N^2)$ and the average complexity be better than $O(N^2)$.

19.2 Sets

Sets are another class of containers. While vectors allow duplicated elements to be inserted, sets ensure that no duplicated elements exist.

In the following sections, we'll see operations you can perform on sets. However, since many of the operations on vectors are similar to the ones used for sets, we'll cover them more quickly here. Please refer back to the section on vectors for a more detailed discussion.

19.2.1 Initialization and iteration

To initialize a set, you can call the `Insert` procedure. However, if you do, you need to ensure no duplicate elements are being inserted: if you try to insert a duplicate, you'll get an exception. If you have less control over the elements to be inserted so that there may be duplicates, you can use another option instead:

- a version of `Insert` that returns a Boolean value indicating whether the insertion was successful;
- the `Include` procedure, which silently ignores any attempt to insert a duplicated element.

To iterate over a set, you can use a `for E of S` loop, as you saw for vectors. This gives you a reference to each element in the set.

Let's see an example:

Listing 15: show_set_init.adb

```
with Ada.Containers; use Ada.Containers;
with Ada.Containers.Ordered_Sets;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Set_Init is

   package Integer_Sets is new
     Ada.Containers.Ordered_Sets
       (Element_Type => Integer);

   use Integer_Sets;

   S : Set;
   --  Same as:  S : Integer_Sets.Set;
   C : Cursor;
   Ins : Boolean;
begin
   S.Insert (20);
   S.Insert (10);
```

(continues on next page)

(continued from previous page)

```
   S.Insert (0);
   S.Insert (13);

   --  Calling S.Insert(0) now would raise
   --  Constraint_Error because this element
   --  is already in the set. We instead call a
   --  version of Insert that doesn't raise an
   --  exception but instead returns a Boolean
   --  indicating the status

   S.Insert (0, C, Ins);
   if not Ins then
      Put_Line
        ("Error while inserting 0 into set");
   end if;

   --  We can also call S.Include instead
   --  If the element is already present,
   --  the set remains unchanged
   S.Include (0);
   S.Include (13);
   S.Include (14);

   Put_Line ("Set has "
             & Count_Type'Image (S.Length)
             & " elements");

   --
   --  Iterate over set using for .. of loop
   --
   Put_Line ("Elements:");
   for E of S loop
       Put_Line ("- " & Integer'Image (E));
   end loop;
end Show_Set_Init;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Set_Init
MD5: b87f6729fea278396347248b95a30cb6
```

Runtime output

```
Error while inserting 0 into set
Set has  5 elements
Elements:
-  0
-  10
-  13
-  14
-  20
```

19.2.2 Operations on elements

In this section, we briefly explore the following operations on sets:

- `Delete` and `Exclude` to remove elements;
- `Contains` and `Find` to verify the existence of elements.

To delete elements, you call the procedure `Delete`. However, analogously to the `Insert` procedure above, `Delete` raises an exception if the element to be deleted isn't present in the set. If you want to permit the case where an element might not exist, you can call `Exclude`, which silently ignores any attempt to delete a non-existent element.

`Contains` returns a Boolean value indicating whether a value is contained in the set. `Find` also looks for an element in a set, but returns a cursor to the element or `No_Element` if the element doesn't exist. You can use either function to search for elements in a set.

Let's look at an example that makes use of these operations:

Listing 16: show_set_element_ops.adb

```
with Ada.Containers; use Ada.Containers;
with Ada.Containers.Ordered_Sets;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Set_Element_Ops is

   package Integer_Sets is new
     Ada.Containers.Ordered_Sets
       (Element_Type => Integer);

   use Integer_Sets;

   procedure Show_Elements (S : Set) is
   begin
      New_Line;
      Put_Line ("Set has "
                & Count_Type'Image (S.Length)
                & " elements");
      Put_Line ("Elements:");
      for E of S loop
         Put_Line ("- " & Integer'Image (E));
      end loop;
   end Show_Elements;

   S : Set;
begin
   S.Insert (20);
   S.Insert (10);
   S.Insert (0);
   S.Insert (13);

   S.Delete (13);

   --  Calling S.Delete (13) again raises
   --  Constraint_Error because the element
   --  is no longer present in the set, so
   --  it can't be deleted. We can call
   --  V.Exclude instead:
   S.Exclude (13);

   if S.Contains (20) then
      Put_Line ("Found element 20 in set");
```

(continues on next page)

(continued from previous page)

```
44    end if;
45
46    --  Alternatively, we could use S.Find
47    --  instead of S.Contains
48    if S.Find (0) /= No_Element then
49       Put_Line ("Found element 0 in set");
50    end if;
51
52    Show_Elements (S);
53 end Show_Set_Element_Ops;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Set_Element_Ops
MD5: 77fb2aaba4221e337b0f90dd1a49c556
```

Runtime output

```
Found element 20 in set
Found element 0 in set

Set has  3 elements
Elements:
-  0
-  10
-  20
```

In addition to ordered sets used in the examples above, the standard library also offers hashed sets. The Reference Manual requires the following average complexity of each operation:

Operations	`Ordered_Sets`	`Hashed_Sets`
• Insert • Include • Replace • Delete • Exclude • Find	$O((\log N)^2)$ or better	O(log N)
Subprogram using cursor	O(1)	O(1)

19.2.3 Other Operations

The previous sections mostly dealt with operations on individual elements of a set. But Ada also provides typical set operations: union, intersection, difference and symmetric difference. In contrast to some vector operations we've seen before (e.g. `Merge`), here you can use built-in operators, such as `-`. The following table lists the operations and its associated operator:

Set Operation	Operator
Union	`or`
Intersection	`and`
Difference	`-`
Symmetric difference	`xor`

The following example makes use of these operators:

Listing 17: show_set_ops.adb

```
with Ada.Containers; use Ada.Containers;
with Ada.Containers.Ordered_Sets;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Set_Ops is

   package Integer_Sets is new
     Ada.Containers.Ordered_Sets
       (Element_Type => Integer);

   use Integer_Sets;

   procedure Show_Elements (S : Set) is
   begin
      Put_Line ("Elements:");
      for E of S loop
         Put_Line ("- " & Integer'Image (E));
      end loop;
   end Show_Elements;

   procedure Show_Op (S       : Set;
                      Op_Name : String) is
   begin
      New_Line;
      Put_Line (Op_Name
                & "(set #1, set #2) has "
                & Count_Type'Image (S.Length)
                & " elements");
   end Show_Op;

   S1, S2, S3 : Set;
begin
   S1.Insert (0);
   S1.Insert (10);
   S1.Insert (13);

   S2.Insert (0);
   S2.Insert (10);
   S2.Insert (14);

   S3.Insert (0);
   S3.Insert (10);

   New_Line;
   Put_Line ("---- Set #1 ----");
   Show_Elements (S1);

   New_Line;
   Put_Line ("---- Set #2 ----");
   Show_Elements (S2);

   New_Line;
   Put_Line ("---- Set #3 ----");
   Show_Elements (S3);

   New_Line;
   if S3.Is_Subset (S1) then
      Put_Line ("S3 is a subset of S1");
```

(continues on next page)

(continued from previous page)

```
60    else
61       Put_Line ("S3 is not a subset of S1");
62    end if;
63
64    S3 := S1 and S2;
65    Show_Op (S3, "Intersection");
66    Show_Elements (S3);
67
68    S3 := S1 or S2;
69    Show_Op (S3, "Union");
70    Show_Elements (S3);
71
72    S3 := S1 - S2;
73    Show_Op (S3, "Difference");
74    Show_Elements (S3);
75
76    S3 := S1 xor S2;
77    Show_Op (S3, "Symmetric difference");
78    Show_Elements (S3);
79
80 end Show_Set_Ops;
```

Code block metadata

```

```

19.3 Indefinite maps

The previous sections presented containers for elements of definite types. Although most examples in those sections presented `Integer` types as element type of the containers, containers can also be used with indefinite types, an example of which is the `String` type. However, indefinite types require a different kind of containers designed specially for them.

We'll also be exploring a different class of containers: maps. They associate a key with a specific value. An example of a map is the one-to-one association between a person and their age. If we consider a person's name to be the key, the value is the person's age.

19.3.1 Hashed maps

Hashed maps are maps that make use of a hash as a key. The hash itself is calculated by a function you provide.

In other languages

Hashed maps are similar to dictionaries in Python and hashes in Perl. One of the main differences is that these scripting languages allow using different types for the values contained in a single map, while in Ada, both the type of key and value are specified in the package instantiation and remains constant for that specific map. You can't have a map where two elements are of different types or two keys are of different types. If you want to use multiple types, you must create a different map for each and use only one type in each map.

When instantiating a hashed map from `Ada.Containers.Indefinite_Hashed_Maps`, we specify following elements:

- `Key_Type`: type of the key
- `Element_Type`: type of the element
- `Hash`: hash function for the `Key_Type`
- `Equivalent_Keys`: an equality operator (e.g. `=`) that indicates whether two keys are to be considered equal.
  - If the type specified in `Key_Type` has a standard operator, you can use it, which you do by specifying that operator as the value of `Equivalent_Keys`.

In the next example, we'll use a string as a key type. We'll use the `Hash` function provided by the standard library for strings (in the `Ada.Strings` package) and the standard equality operator.

You add elements to a hashed map by calling `Insert`. If an element is already contained in a map `M`, you can access it directly by using its key. For example, you can change the value of an element by calling `M ("My_Key") := 10`. If the key is not found, an exception

is raised. To verify if a key is available, use the function `Contains` (as we've seen above in the section on sets).

Let's see an example:

Listing 18: show_hashed_map.adb

```
with Ada.Containers.Indefinite_Hashed_Maps;
with Ada.Strings.Hash;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Hashed_Map is

   package Integer_Hashed_Maps is new
     Ada.Containers.Indefinite_Hashed_Maps
       (Key_Type        => String,
        Element_Type    => Integer,
        Hash            => Ada.Strings.Hash,
        Equivalent_Keys => "=");

   use Integer_Hashed_Maps;

   M : Map;
   --  Same as:
   --
   --  M : Integer_Hashed_Maps.Map;
begin
   M.Include ("Alice", 24);
   M.Include ("John",  40);
   M.Include ("Bob",   28);

   if M.Contains ("Alice") then
      Put_Line ("Alice's age is "
                & Integer'Image (M ("Alice")));
   end if;

   --  Update Alice's age
   --  Key must already exist in M.
   --  Otherwise an exception is raised.
   M ("Alice") := 25;

   New_Line; Put_Line ("Name & Age:");
   for C in M.Iterate loop
      Put_Line (Key (C) & ": "
                & Integer'Image (M (C)));
   end loop;

end Show_Hashed_Map;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Hashed_Map
MD5: 6117775bd9ce2b1466f448b100117ded
```

Runtime output

```
Alice's age is  24

Name & Age:
John:  40
Bob:  28
Alice:  25
```

19.3.2 Ordered maps

Ordered maps share many features with hashed maps. The main differences are:

- A hash function isn't needed. Instead, you must provide an ordering function (< operator), which the ordered map will use to order elements and allow fast access, O(log N), using a binary search.
  - If the type specified in Key_Type has a standard < operator, you can use it in a similar way as we did for Equivalent_Keys above for hashed maps.

Let's see an example:

Listing 19: show_ordered_map.adb

```
with Ada.Containers.Indefinite_Ordered_Maps;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Ordered_Map is

   package Integer_Ordered_Maps is new
     Ada.Containers.Indefinite_Ordered_Maps
       (Key_Type        => String,
        Element_Type    => Integer);

   use Integer_Ordered_Maps;

   M : Map;
begin
   M.Include ("Alice", 24);
   M.Include ("John",  40);
   M.Include ("Bob",   28);

   if M.Contains ("Alice") then
      Put_Line ("Alice's age is "
                & Integer'Image (M ("Alice")));
   end if;

   --  Update Alice's age
   --  Key must already exist in M
   M ("Alice") := 25;

   New_Line; Put_Line ("Name & Age:");
   for C in M.Iterate loop
      Put_Line (Key (C) & ": "
                & Integer'Image (M (C)));
   end loop;

end Show_Ordered_Map;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Ordered_Map
MD5: 3deb3c685e767cee271b06e87727b086
```

Runtime output

```
Alice's age is  24

Name & Age:
Alice:  25
```

(continues on next page)

(continued from previous page)

```
Bob:  28
John:  40
```

You can see a great similarity between the examples above and from the previous section. In fact, since both kinds of maps share many operations, we didn't need to make extensive modifications when we changed our example to use ordered maps instead of hashed maps. The main difference is seen when we run the examples: the output of a hashed map is usually unordered, but the output of a ordered map is always ordered, as implied by its name.

19.3.3 Complexity

Hashed maps are generally the fastest data structure available to you in Ada if you need to associate heterogeneous keys to values and search for them quickly. In most cases, they are slightly faster than ordered maps. So if you don't need ordering, use hashed maps.

The Reference Manual requires the following average complexity of operations:

Operations	`Ordered_Maps`	`Hashed_Maps`
• Insert • Include • Replace • Delete • Exclude • Find	O((log N)^2) or better	O(log N)
Subprogram using cursor	O(1)	O(1)

CHAPTER

TWENTY

STANDARD LIBRARY: DATES & TIMES

The standard library supports processing of dates and times using two approaches:

- *Calendar* approach, which is suitable for handling dates and times in general;
- *Real-time* approach, which is better suited for real-time applications that require enhanced precision — for example, by having access to an absolute clock and handling time spans. Note that this approach only supports times, not dates.

The following sections present these two approaches.

20.1 Date and time handling

The `Ada.Calendar` package supports handling of dates and times. Let's look at a simple example:

Listing 1: display_current_time.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with Ada.Calendar; use Ada.Calendar;

with Ada.Calendar.Formatting;
use  Ada.Calendar.Formatting;

procedure Display_Current_Time is
   Now : Time := Clock;
begin
   Put_Line ("Current time: " & Image (Now));
end Display_Current_Time;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Display_Current_Time
MD5: 4a88069b33ecf80314b0164a472ff606
```

Runtime output

```
Current time: 2024-07-20 19:17:04
```

This example displays the current date and time, which is retrieved by a call to the `Clock` function. We call the function `Image` from the `Ada.Calendar.Formatting` package to get a `String` for the current date and time. We could instead retrieve each component using the `Split` function. For example:

Listing 2: display_current_year.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with Ada.Calendar; use Ada.Calendar;

procedure Display_Current_Year is
   Now         : Time := Clock;

   Now_Year    : Year_Number;
   Now_Month   : Month_Number;
   Now_Day     : Day_Number;
   Now_Seconds : Day_Duration;
begin
   Split (Now,
          Now_Year,
          Now_Month,
          Now_Day,
          Now_Seconds);

   Put_Line ("Current year  is: "
             & Year_Number'Image (Now_Year));
   Put_Line ("Current month is: "
             & Month_Number'Image (Now_Month));
   Put_Line ("Current day   is: "
             & Day_Number'Image (Now_Day));
end Display_Current_Year;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Display_Current_Year
MD5: fdf298ee97f225261ce3839ebd833bbe
```

Runtime output

```
Current year  is:  2024
Current month is:  7
Current day   is:  20
```

Here, we're retrieving each element and displaying it separately.

20.1.1 Delaying using date

You can delay an application so that it restarts at a specific date and time. We saw something similar in the chapter on tasking. You do this using a **delay until** statement. For example:

Listing 3: display_delay_next_specific_time.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with Ada.Calendar; use Ada.Calendar;

with Ada.Calendar.Formatting;
use  Ada.Calendar.Formatting;

with Ada.Calendar.Time_Zones;
use  Ada.Calendar.Time_Zones;

procedure Display_Delay_Next_Specific_Time is
   TZ   : Time_Offset := UTC_Time_Offset;
   Next : Time        :=
```

(continues on next page)

(continued from previous page)

```
     Ada.Calendar.Formatting.Time_Of
       (Year        => 2018,
        Month       => 5,
        Day         => 1,
        Hour        => 15,
        Minute      => 0,
        Second      => 0,
        Sub_Second  => 0.0,
        Leap_Second => False,
        Time_Zone   => TZ);

   --  Next = 2018-05-01 15:00:00.00
   --         (local time-zone)
begin
   Put_Line ("Let's wait until...");
   Put_Line (Image (Next, True, TZ));

   delay until Next;

   Put_Line ("Enough waiting!");
end Display_Delay_Next_Specific_Time;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Display_Delay_Next_Specific_Time
MD5: 36ec2bdce7c1e8d107fae54ef9852d3f
```

Runtime output

```
Let's wait until...
2018-05-01 15:00:00.00
Enough waiting!
```

In this example, we specify the date and time by initializing `Next` using a call to `Time_Of`, a function taking the various components of a date (year, month, etc) and returning an element of the `Time` type. Because the date specified is in the past, the **`delay until`** statement won't produce any noticeable effect. However, if we passed a date in the future, the program would wait until that specific date and time arrived.

Here we're converting the time to the local timezone. If we don't specify a timezone, *Coordinated Universal Time* (abbreviated to UTC) is used by default. By retrieving the time offset to UTC with a call to `UTC_Time_Offset` from the `Ada.Calendar.Time_Zones` package, we can initialize `TZ` and use it in the call to `Time_Of`. This is all we need do to make the information provided to `Time_Of` relative to the local time zone.

We could achieve a similar result by initializing `Next` with a **`String`**. We can do this with a call to `Value` from the `Ada.Calendar.Formatting` package. This is the modified code:

Listing 4: display_delay_next_specific_time.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with Ada.Calendar; use Ada.Calendar;

with Ada.Calendar.Formatting;
use  Ada.Calendar.Formatting;

with Ada.Calendar.Time_Zones;
use  Ada.Calendar.Time_Zones;

procedure Display_Delay_Next_Specific_Time is
   TZ   : Time_Offset := UTC_Time_Offset;
```

(continues on next page)

(continued from previous page)

```
   Next : Time        :=
     Ada.Calendar.Formatting.Value
       ("2018-05-01 15:00:00.00", TZ);

   --  Next = 2018-05-01 15:00:00.00
   --         (local time-zone)
begin
   Put_Line ("Let's wait until...");
   Put_Line (Image (Next, True, TZ));

   delay until Next;

   Put_Line ("Enough waiting!");
end Display_Delay_Next_Specific_Time;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Display_Delay_Next_Specific_Time
MD5: fdf6ad7fca303d4d7bd444c23e11c7bd
```

Runtime output

```
Let's wait until...
2018-05-01 15:00:00.00
Enough waiting!
```

In this example, we're again using TZ in the call to Value to adjust the input time to the current time zone.

In the examples above, we were delaying to a specific date and time. Just like we saw in the tasking chapter, we could instead specify the delay relative to the current time. For example, we could delay by 5 seconds, using the current time:

Listing 5: display_delay_next.adb

```
with Ada.Calendar; use Ada.Calendar;
with Ada.Text_IO;  use Ada.Text_IO;

procedure Display_Delay_Next is
   D    : Duration := 5.0;
   --                 ^ seconds
   Now  : Time     := Clock;
   Next : Time     := Now + D;
   --                       ^ use duration to
   --                         specify next
   --                         point in time
begin
   Put_Line ("Let's wait "
             & Duration'Image (D)
             & " seconds...");
   delay until Next;
   Put_Line ("Enough waiting!");
end Display_Delay_Next;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Display_Delay_Next
MD5: 58360d93388c3fe027c3d9d67389efc7
```

Runtime output

```
Let's wait  5.000000000 seconds...
Enough waiting!
```

Here, we're specifying a duration of 5 seconds in D, adding it to the current time from Now, and storing the sum in Next. We then use it in the **delay until** statement.

20.2 Real-time

In addition to Ada.Calendar, the standard library also supports time operations for real-time applications. These are included in the Ada.Real_Time package. This package also include a Time type. However, in the Ada.Real_Time package, the Time type is used to represent an absolute clock and handle a time span. This contrasts with the Ada.Calendar, which uses the Time type to represent dates and times.

In the previous section, we used the Time type from the Ada.Calendar and the **delay until** statement to delay an application by 5 seconds. We could have used the Ada.Real_Time package instead. Let's modify that example:

Listing 6: display_delay_next_real_time.adb

```
with Ada.Text_IO;   use Ada.Text_IO;
with Ada.Real_Time; use Ada.Real_Time;

procedure Display_Delay_Next_Real_Time is
   D     : Time_Span := Seconds (5);
   Next  : Time      := Clock + D;
begin
   Put_Line ("Let's wait "
             & Duration'Image (To_Duration (D))
             & " seconds...");
   delay until Next;
   Put_Line ("Enough waiting!");
end Display_Delay_Next_Real_Time;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Display_Delay_Next_Real_Time
MD5: a80e96c4ac7bd3ba7813f983b10cb038
```

Runtime output

```
Let's wait  5.000000000 seconds...
Enough waiting!
```

The main difference is that D is now a variable of type Time_Span, defined in the Ada.Real_Time package. We call the function Seconds to initialize D, but could have gotten a finer granularity by calling Nanoseconds instead. Also, we need to first convert D to the **Duration** type using To_Duration before we can display it.

20.2.1 Benchmarking

One interesting application using the Ada.Real_Time package is benchmarking. We've used that package before in a previous section when discussing tasking. Let's look at an example of benchmarking:

Listing 7: display_benchmarking.adb

```
with Ada.Text_IO;   use Ada.Text_IO;
with Ada.Real_Time; use Ada.Real_Time;

procedure Display_Benchmarking is

   procedure Computational_Intensive_App is
   begin
      delay 5.0;
   end Computational_Intensive_App;

   Start_Time, Stop_Time : Time;
   Elapsed_Time          : Time_Span;

begin
   Start_Time := Clock;

   Computational_Intensive_App;

   Stop_Time    := Clock;
   Elapsed_Time := Stop_Time - Start_Time;

   Put_Line ("Elapsed time: "
             & Duration'Image
                 (To_Duration (Elapsed_Time))
             & " seconds");
end Display_Benchmarking;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Display_Benchmarking
MD5: 4b20940cb613d3f634be5224f409efeb
```

Runtime output

```
Elapsed time:  5.001428484 seconds
```

This example defines a dummy Computational_Intensive_App implemented using a simple **delay** statement. We initialize Start_Time and Stop_Time from the then-current clock and calculate the elapsed time. By running this program, we see that the time is roughly 5 seconds, which is expected due to the **delay** statement.

A similar application is benchmarking of CPU time. We can implement this using the Execution_Time package. Let's modify the previous example to measure CPU time:

Listing 8: display_benchmarking_cpu_time.adb

```
with Ada.Text_IO;         use Ada.Text_IO;
with Ada.Real_Time;       use Ada.Real_Time;
with Ada.Execution_Time; use Ada.Execution_Time;

procedure Display_Benchmarking_CPU_Time is

   procedure Computational_Intensive_App is
   begin
```

(continues on next page)

(continued from previous page)

```
      delay 5.0;
   end Computational_Intensive_App;

   Start_Time, Stop_Time : CPU_Time;
   Elapsed_Time          : Time_Span;

begin
   Start_Time := Clock;

   Computational_Intensive_App;

   Stop_Time    := Clock;
   Elapsed_Time := Stop_Time - Start_Time;

   Put_Line ("CPU time: "
             & Duration'Image
                 (To_Duration (Elapsed_Time))
             & " seconds");
end Display_Benchmarking_CPU_Time;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Display_Benchmarking_CPU_Time
MD5: ba83ddbd05db523479be5692c4134901
```

Runtime output

```
CPU time:  0.000099326 seconds
```

In this example, `Start_Time` and `Stop_Time` are of type `CPU_Time` instead of `Time`. However, we still call the `Clock` function to initialize both variables and calculate the elapsed time in the same way as before. By running this program, we see that the CPU time is significantly lower than the 5 seconds we've seen before. This is because the **`delay`** statement doesn't require much CPU time. The results will be different if we change the implementation of `Computational_Intensive_App` to use a mathematical function in a long loop. For example:

Listing 9: display_benchmarking_math.adb

```
with Ada.Text_IO;        use Ada.Text_IO;
with Ada.Real_Time;      use Ada.Real_Time;
with Ada.Execution_Time; use Ada.Execution_Time;

with Ada.Numerics.Generic_Elementary_Functions;

procedure Display_Benchmarking_Math is

   procedure Computational_Intensive_App is
      package Funcs is new
        Ada.Numerics.Generic_Elementary_Functions
          (Float_Type => Long_Long_Float);
      use Funcs;

      X : Long_Long_Float;
   begin
      for I in 0 .. 1_000_000 loop
         X := Tan (Arctan
                (Tan (Arctan
                  (Tan (Arctan
                    (Tan (Arctan
                      (Tan (Arctan
```

(continues on next page)

(continued from previous page)

```
                        (Tan (Arctan
                          (0.577))))))))))));
      end loop;
   end Computational_Intensive_App;

   procedure Benchm_Elapsed_Time is
      Start_Time, Stop_Time : Time;
      Elapsed_Time          : Time_Span;

   begin
      Start_Time := Clock;

      Computational_Intensive_App;

      Stop_Time    := Clock;
      Elapsed_Time := Stop_Time - Start_Time;

      Put_Line ("Elapsed time: "
                & Duration'Image
                    (To_Duration (Elapsed_Time))
                & " seconds");
   end Benchm_Elapsed_Time;

   procedure Benchm_CPU_Time is
      Start_Time, Stop_Time : CPU_Time;
      Elapsed_Time          : Time_Span;

   begin
      Start_Time := Clock;

      Computational_Intensive_App;

      Stop_Time    := Clock;
      Elapsed_Time := Stop_Time - Start_Time;

      Put_Line ("CPU time: "
                & Duration'Image
                    (To_Duration (Elapsed_Time))
                & " seconds");
   end Benchm_CPU_Time;
begin
   Benchm_Elapsed_Time;
   Benchm_CPU_Time;
end Display_Benchmarking_Math;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Display_Benchmarking_Math
MD5: 06fe96bf03321c248dd1ed843648cf0b
```

Runtime output

```
Elapsed time:  1.368787582 seconds
CPU time:  1.379256710 seconds
```

Now that our dummy `Computational_Intensive_App` involves mathematical operations requiring significant CPU time, the measured elapsed and CPU time are much closer to each other than before.

CHAPTER

TWENTYONE

STANDARD LIBRARY: STRINGS

In previous chapters, we've seen source-code examples using the **String** type, which is a fixed-length string type — essentialy, it's an array of characters. In many cases, this data type is good enough to deal with textual information. However, there are situations that require more advanced text processing. Ada offers alternative approaches for these cases:

- *Bounded strings*: similar to fixed-length strings, bounded strings have a maximum length, which is set at its instantiation. However, bounded strings are not arrays of characters. At any time, they can contain a string of varied length — provided this length is below or equal to the maximum length.
- *Unbounded strings*: similar to bounded strings, unbounded strings can contain strings of varied length. However, in addition to that, they don't have a maximum length. In this sense, they are very flexible.

The following sections present an overview of the different string types and common operations for string types.

21.1 String operations

Operations on standard (fixed-length) strings are available in the `Ada.Strings.Fixed` package. As mentioned previously, standard strings are arrays of elements of **Character** type with *a fixed-length*. That's why this child package is called `Fixed`.

One of the simplest operations provided is counting the number of substrings available in a string (**Count**) and finding their corresponding indices (`Index`). Let's look at an example:

Listing 1: show_find_substring.adb

```
with Ada.Strings.Fixed; use Ada.Strings.Fixed;
with Ada.Text_IO;       use Ada.Text_IO;

procedure Show_Find_Substring is

   S   : String := "Hello" & 3 * " World";
   P   : constant String := "World";
   Idx : Natural;
   Cnt : Natural;
begin
   Cnt := Ada.Strings.Fixed.Count
     (Source  => S,
      Pattern => P);

   Put_Line ("String: " & S);
   Put_Line ("Count for '" & P & "': "
             & Natural'Image (Cnt));

```

(continues on next page)

(continued from previous page)

```
   Idx := 0;
   for I in 1 .. Cnt loop
      Idx := Index
        (Source  => S,
         Pattern => P,
         From    => Idx + 1);

      Put_Line ("Found instance of '"
                & P & "' at position: "
                & Natural'Image (Idx));
   end loop;

end Show_Find_Substring;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Find_Substring
MD5: faa8373bf9aec9f9f5507cf55590b0c0
```

Runtime output

```
String: Hello World World World
Count for 'World':  3
Found instance of 'World' at position:  7
Found instance of 'World' at position:  13
Found instance of 'World' at position:  19
```

We initialize the string S using a multiplication. Writing `"Hello" & 3 * " World"` creates the string `Hello World World World`. We then call the function `Count` to get the number of instances of the word `World` in S. Next we call the function `Index` in a loop to find the index of each instance of `World` in S.

That example looked for instances of a specific substring. In the next example, we retrieve all the words in the string. We do this using `Find_Token` and specifying whitespaces as separators. For example:

Listing 2: show_find_words.adb

```
with Ada.Strings;       use Ada.Strings;
with Ada.Strings.Fixed; use Ada.Strings.Fixed;
with Ada.Strings.Maps;  use Ada.Strings.Maps;
with Ada.Text_IO;       use Ada.Text_IO;

procedure Show_Find_Words is

   S   : String := "Hello" & 3 * " World";
   F   : Positive;
   L   : Natural;
   I   : Natural := 1;

   Whitespace : constant Character_Set :=
     To_Set (' ');
begin
   Put_Line ("String: " & S);
   Put_Line ("String length: "
             & Integer'Image (S'Length));

   while I in S'Range loop
      Find_Token
        (Source  => S,
         Set     => Whitespace,
```

(continues on next page)

(continued from previous page)

```
24          From    => I,
25          Test    => Outside,
26          First   => F,
27          Last    => L);
28
29       exit when L = 0;
30
31       Put_Line ("Found word instance at position "
32                 & Natural'Image (F)
33                 & ": '" & S (F .. L) & "'");
34       --   & "-" & F'Img & "-" & L'Img
35
36       I := L + 1;
37    end loop;
38 end Show_Find_Words;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Find_Words
MD5: e622f489af5901e5d31f314efc3324d2
```

Runtime output

```
String: Hello World World World
String length:  23
Found word instance at position  1: 'Hello'
Found word instance at position  7: 'World'
Found word instance at position  13: 'World'
Found word instance at position  19: 'World'
```

We pass a set of characters to be used as delimitators to the procedure `Find_Token`. This set is a member of the `Character_Set` type from the `Ada.Strings.Maps` package. We call the `To_Set` function (from the same package) to initialize the set to `Whitespace` and then call `Find_Token` to loop over each valid index and find the starting index of each word. We pass `Outside` to the `Test` parameter of the `Find_Token` procedure to indicate that we're looking for indices that are outside the `Whitespace` set, i.e. actual words. The `First` and `Last` parameters of `Find_Token` are output parameters that indicate the valid range of the substring. We use this information to display the string (`S (F .. L)`).

The operations we've looked at so far read strings, but don't modify them. We next discuss operations that change the content of strings:

Operation	Description
Insert	Insert substring in a string
Overwrite	Overwrite a string with a substring
Delete	Delete a substring
Trim	Remove whitespaces from a string

All these operations are available both as functions or procedures. Functions create a new string but procedures perform the operations in place. The procedure will raise an exception if the constraints of the string are not satisfied. For example, if we have a string S containing 10 characters, inserting a string with two characters (e.g. `"!!"`) into it produces a string containing 12 characters. Since it has a fixed length, we can't increase its size. One possible solution in this case is to specify that truncation should be applied while inserting the substring. This keeps the length of S fixed. Let's see an example that makes use of both function and procedure versions of `Insert`, `Overwrite`, and `Delete`:

Listing 3: show_adapted_strings.adb

```
with Ada.Strings;       use Ada.Strings;
with Ada.Strings.Fixed; use Ada.Strings.Fixed;
with Ada.Text_IO;       use Ada.Text_IO;

procedure Show_Adapted_Strings is

   S   : String := "Hello World";
   P   : constant String := "World";
   N   : constant String := "Beautiful";

   procedure Display_Adapted_String
     (Source   : String;
      Before   : Positive;
      New_Item : String;
      Pattern  : String)
   is
      S_Ins_In : String := Source;
      S_Ovr_In : String := Source;
      S_Del_In : String := Source;

      S_Ins : String :=
        Insert (Source,
                Before,
                New_Item & " ");
      S_Ovr : String :=
        Overwrite (Source,
                   Before,
                   New_Item);
      S_Del : String :=
        Trim (Delete (Source,
                      Before,
                      Before +
                        Pattern'Length - 1),
              Ada.Strings.Right);
   begin
      Insert (S_Ins_In,
              Before,
              New_Item,
              Right);

      Overwrite (S_Ovr_In,
                 Before,
                 New_Item,
                 Right);

      Delete (S_Del_In,
              Before,
              Before + Pattern'Length - 1);

      Put_Line ("Original:  '"
                & Source & "'");

      Put_Line ("Insert:    '"
                & S_Ins  & "'");
      Put_Line ("Overwrite: '"
                & S_Ovr  & "'");
      Put_Line ("Delete:    '"
                & S_Del  & "'");

      Put_Line ("Insert    (in-place): '"
```

(continues on next page)

(continued from previous page)

```
                & S_Ins_In & "'");
      Put_Line ("Overwrite (in-place): '"
                & S_Ovr_In & "'");
      Put_Line ("Delete    (in-place): '"
                & S_Del_In & "'");
   end Display_Adapted_String;

   Idx : Natural;
begin
   Idx := Index
     (Source  => S,
      Pattern => P);

   if Idx > 0 then
      Display_Adapted_String (S, Idx, N, P);
   end if;
end Show_Adapted_Strings;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Adapted_Strings
MD5: b31b6bc94d8bdbec717c6b6b2534beb6
```

Runtime output

```
Original:  'Hello World'
Insert:    'Hello Beautiful World'
Overwrite: 'Hello Beautiful'
Delete:    'Hello'
Insert    (in-place): 'Hello Beaut'
Overwrite (in-place): 'Hello Beaut'
Delete    (in-place): 'Hello      '
```

In this example, we look for the index of the substring `World` and perform operations on this substring within the outer string. The procedure `Display_Adapted_String` uses both versions of the operations. For the procedural version of `Insert` and `Overwrite`, we apply truncation to the right side of the string (`Right`). For the `Delete` procedure, we specify the range of the substring, which is replaced by whitespaces. For the function version of `Delete`, we also call `Trim` which trims the trailing whitespace.

21.2 Limitation of fixed-length strings

Using fixed-length strings is usually good enough for strings that are initialized when they are declared. However, as seen in the previous section, procedural operations on strings cause difficulties when done on fixed-length strings because fixed-length strings are arrays of characters. The following example shows how cumbersome the initialization of fixed-length strings can be when it's not performed in the declaration:

Listing 4: show_char_array.adb

```
with Ada.Text_IO;         use Ada.Text_IO;

procedure Show_Char_Array is
   S : String (1 .. 15);
   --  Strings are arrays of Character
begin
   S := "Hello          ";
```

(continues on next page)

(continued from previous page)

```
   --  Alternatively:
   --
   --  #1:
   --      S (1 .. 5)      := "Hello";
   --      S (6 .. S'Last) := (others => ' ');
   --
   --  #2:
   --      S := ('H', 'e', 'l', 'l', 'o',
   --            others => ' ');

   Put_Line ("String: " & S);
   Put_Line ("String Length: "
             & Integer'Image (S'Length));
end Show_Char_Array;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Char_Array
MD5: 9f3df03c9c5336184139cf2a22f2cb7e
```

Runtime output

```
String: Hello
String Length:  15
```

In this case, we can't simply write `S := "Hello"` because the resulting array of characters for the `Hello` constant has a different length than the `S` string. Therefore, we need to include trailing whitespaces to match the length of `S`. As shown in the example, we could use an exact range for the initialization (`S (1 .. 5)`) or use an explicit array of individual characters.

When strings are initialized or manipulated at run-time, it's usually better to use bounded or unbounded strings. An important feature of these types is that they aren't arrays, so the difficulties presented above don't apply. Let's start with bounded strings.

21.3 Bounded strings

Bounded strings are defined in the `Ada.Strings.Bounded.Generic_Bounded_Length` package. Because this is a generic package, you need to instantiate it and set the maximum length of the bounded string. You can then declare bounded strings of the `Bounded_String` type.

Both bounded and fixed-length strings have a maximum length that they can hold. However, bounded strings are not arrays, so initializing them at run-time is much easier. For example:

Listing 5: show_bounded_string.adb

```
with Ada.Strings;          use Ada.Strings;
with Ada.Strings.Bounded;
with Ada.Text_IO;          use Ada.Text_IO;

procedure Show_Bounded_String is
   package B_Str is new
     Ada.Strings.Bounded.Generic_Bounded_Length
       (Max => 15);
   use B_Str;

```

(continues on next page)

(continued from previous page)

```
   S1, S2 : Bounded_String;

   procedure Display_String_Info
     (S : Bounded_String)
   is
   begin
      Put_Line ("String: " & To_String (S));
      Put_Line ("String Length: "
                & Integer'Image (Length (S)));
      --  String:
      --           S'Length => ok
      --  Bounded_String:
      --           S'Length => compilation error:
      --                       bounded strings are
      --                       not arrays!

      Put_Line ("Max.   Length: "
                & Integer'Image (Max_Length));
   end Display_String_Info;

begin
   S1 := To_Bounded_String ("Hello");
   Display_String_Info (S1);

   S2 := To_Bounded_String ("Hello World");
   Display_String_Info (S2);

   S1 := To_Bounded_String
     ("Something longer to say here...",
      Right);
   Display_String_Info (S1);
end Show_Bounded_String;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Bounded_String
MD5: a51fdeacfd43923145ee92bf5c72ecd6
```

Runtime output

```
String: Hello
String Length:  5
Max.   Length:  15
String: Hello World
String Length:  11
Max.   Length:  15
String: Something longe
String Length:  15
Max.   Length:  15
```

By using bounded strings, we can easily assign to S1 and S2 multiple times during execution. We use the `To_Bounded_String` and `To_String` functions to convert, in the respective direction, between fixed-length and bounded strings. A call to `To_Bounded_String` raises an exception if the length of the input string is greater than the maximum capacity of the bounded string. To avoid this, we can use the truncation parameter (`Right` in our example).

Bounded strings are not arrays, so we can't use the `'Length` attribute as we did for fixed-length strings. Instead, we call the `Length` function, which returns the length of the bounded string. The `Max_Length` constant represents the maximum length of the bounded string that we set when we instantiated the package.

After initializing a bounded string, we can manipulate it. For example, we can append

a string to a bounded string using Append or concatenate bounded strings using the & operator. Like so:

Listing 6: show_bounded_string_op.adb

```
with Ada.Strings;         use Ada.Strings;
with Ada.Strings.Bounded;
with Ada.Text_IO;         use Ada.Text_IO;

procedure Show_Bounded_String_Op is
   package B_Str is new
     Ada.Strings.Bounded.Generic_Bounded_Length
       (Max => 30);
   use B_Str;

   S1, S2 : Bounded_String;
begin
   S1 := To_Bounded_String ("Hello");
   --  Alternatively:
   --
   --  A := Null_Bounded_String & "Hello";

   Append (S1, " World");
   --  Alternatively:
   --    Append (A, " World", Right);

   Put_Line ("String: " & To_String (S1));

   S2 := To_Bounded_String ("Hello!");
   S1 := S1 & " " & S2;
   Put_Line ("String: " & To_String (S1));
end Show_Bounded_String_Op;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Bounded_String_Op
MD5: c7c6a840c314a9cd9f75aac082a63159
```

Runtime output

```
String: Hello World
String: Hello World Hello!
```

We can initialize a bounded string with an empty string using the `Null_Bounded_String` constant. Also, we can use the Append procedure and specify the truncation mode like we do with the `To_Bounded_String` function.

21.4 Unbounded strings

Unbounded strings are defined in the `Ada.Strings.Unbounded` package. This is *not* a generic package, so we don't need to instantiate it before using the `Unbounded_String` type. As you may recall from the previous section, bounded strings require a package instantiation.

Unbounded strings are similar to bounded strings. The main difference is that they can hold strings of any size and adjust according to the input string: if we assign, e.g., a 10-character string to an unbounded string and later assign a 50-character string, internal operations in the container ensure that memory is allocated to store the new string. In most cases, developers don't need to worry about these operations. Also, no truncation is necessary.

Initialization of unbounded strings is very similar to bounded strings. Let's look at an example:

Listing 7: show_unbounded_string.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Ada.Strings; use Ada.Strings;

with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

procedure Show_Unbounded_String is
   S1, S2 : Unbounded_String;

   procedure Display_String_Info
     (S : Unbounded_String)
   is
   begin
      Put_Line ("String: " & To_String (S));
      Put_Line ("String Length: "
                & Integer'Image (Length (S)));
   end Display_String_Info;
begin
   S1 := To_Unbounded_String ("Hello");
   --  Alternatively:
   --
   --  A := Null_Unbounded_String & "Hello";

   Display_String_Info (S1);

   S2 := To_Unbounded_String ("Hello World");
   Display_String_Info (S2);

   S1 := To_Unbounded_String
           ("Something longer to say here...");
   Display_String_Info (S1);
end Show_Unbounded_String;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Unbounded_String
MD5: 904402992c96eb393b875d1b7cf49c1b
```

Runtime output

```
String: Hello
String Length:  5
String: Hello World
String Length:  11
String: Something longer to say here...
String Length:  31
```

Like bounded strings, we can assign to S1 and S2 multiple times during execution and use the `To_Unbounded_String` and `To_String` functions to convert back-and-forth between fixed-length strings and unbounded strings. However, in this case, truncation is not needed.

And, just like for bounded strings, you can use the Append procedure and the `&` operator for unbounded strings. For example:

Listing 8: show_unbounded_string_op.adb

```
with Ada.Text_IO; use Ada.Text_IO;

```

(continues on next page)

(continued from previous page)

```
with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

procedure Show_Unbounded_String_Op is
   S1, S2 : Unbounded_String :=
               Null_Unbounded_String;
begin
   S1 := S1 & "Hello";
   S2 := S2 & "Hello!";

   Append (S1, " World");
   Put_Line ("String: " & To_String (S1));

   S1 := S1 & " " & S2;
   Put_Line ("String: " & To_String (S1));
end Show_Unbounded_String_Op;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Unbounded_String_Op
MD5: 806e24a6dd0bc87e76f73a22e42ba390
```

Runtime output

```
String: Hello World
String: Hello World Hello!
```

In this example, we're concatenating the unbounded S1 and S2 strings with the `"Hello"` and `"Hello!"` strings, respectively. Also, we're using the Append procedure, just like we did with bounded strings.

CHAPTER

TWENTYTWO

STANDARD LIBRARY: FILES AND STREAMS

Ada provides different approaches for file input/output (I/O):

- *Text I/O*, which supports file I/O in text format, including the display of information on the console.
- *Sequential I/O*, which supports file I/O in binary format written in a sequential fashion for a specific data type.
- *Direct I/O*, which supports file I/O in binary format for a specific data type, but also supporting access to any position of a file.
- *Stream I/O*, which supports I/O of information for multiple data types, including objects of unbounded types, using files in binary format.

This table presents a summary of the features we've just seen:

File I/O option	Format	Random access	Data types
Text I/O	text		string type
Sequential I/O	binary		single type
Direct I/O	binary	✓	single type
Stream I/O	binary	✓	multiple types

In the following sections, we discuss details about these I/O approaches.

22.1 Text I/O

In most parts of this course, we used the `Put_Line` procedure to display information on the console. However, this procedure also accepts a `File_Type` parameter. For example, you can select between standard output and standard error by setting this parameter explicitly:

Listing 1: show_std_text_out.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Std_Text_Out is
begin
   Put_Line (Standard_Output, "Hello World #1");
   Put_Line (Standard_Error,  "Hello World #2");
end Show_Std_Text_Out;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Std_Text_Out
MD5: 4d75bd2906226897244e3d2a611c9725
```

Runtime output

```
Hello World #1
Hello World #2
```

You can also use this parameter to write information to any text file. To create a new file for writing, use the `Create` procedure, which initializes a **`File_Type`** element that you can later pass to `Put_Line` (instead of, e.g., `Standard_Output`). After you finish writing information, you can close the file by calling the `Close` procedure.

You use a similar method to read information from a text file. However, when opening the file, you must specify that it's an input file (`In_File`) instead of an output file. Also, instead of calling the `Put_Line` procedure, you call the `Get_Line` function to read information from the file.

Let's see an example that writes information into a new text file and then reads it back from the same file:

Listing 2: show_simple_text_file_io.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Simple_Text_File_IO is
4     F         : File_Type;
5     File_Name : constant String := "simple.txt";
6  begin
7     Create (F, Out_File, File_Name);
8     Put_Line (F, "Hello World #1");
9     Put_Line (F, "Hello World #2");
10    Put_Line (F, "Hello World #3");
11    Close (F);
12
13    Open (F, In_File, File_Name);
14    while not End_Of_File (F) loop
15       Put_Line (Get_Line (F));
16    end loop;
17    Close (F);
18 end Show_Simple_Text_File_IO;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Simple_Text_File_IO
MD5: 7461e946eef18c93219fa4ce3afbb1ea
```

Runtime output

```
Hello World #1
Hello World #2
Hello World #3
```

In addition to the `Create` and `Close` procedures, the standard library also includes a `Reset` procedure, which, as the name implies, resets (erases) all the information from the file. For example:

Listing 3: show_text_file_reset.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Text_File_Reset is
4     F         : File_Type;
5     File_Name : constant String := "simple.txt";
6  begin
```

(continues on next page)

(continued from previous page)

```
   Create (F, Out_File, File_Name);
   Put_Line (F, "Hello World #1");
   Reset (F);
   Put_Line (F, "Hello World #2");
   Close (F);

   Open (F, In_File, File_Name);
   while not End_Of_File (F) loop
      Put_Line (Get_Line (F));
   end loop;
   Close (F);
end Show_Text_File_Reset;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Text_File_Reset
MD5: 5e5498f03b2c829513af062c5959fc93
```

Runtime output

```
Hello World #2
```

By running this program, we notice that, although we've written the first string (`"Hello World #1"`) to the file, it has been erased because of the call to `Reset`.

In addition to opening a file for reading or writing, you can also open an existing file and append to it. Do this by calling the `Open` procedure with the `Append_File` option.

When calling the `Open` procedure, an exception is raised if the specified file isn't found. Therefore, you should handle exceptions in that context. The following example deletes a file and then tries to open the same file for reading:

Listing 4: show_text_file_input_except.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Text_File_Input_Except is
   F         : File_Type;
   File_Name : constant String := "simple.txt";
begin
   --  Open output file and delete it
   Create (F, Out_File, File_Name);
   Delete (F);

   --  Try to open deleted file
   Open (F, In_File, File_Name);
   Close (F);
exception
   when Name_Error =>
      Put_Line ("File does not exist");
   when others =>
      Put_Line
        ("Error while processing input file");
end Show_Text_File_Input_Except;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Text_File_Input_Except
MD5: c8d257091831c48d10b6e70e34b4261b
```

Runtime output

```
File does not exist
```

In this example, we create the file by calling `Create` and then delete it by calling `Delete`. After the call to `Delete`, we can no longer use the **`File_Type`** element. After deleting the file, we try to open the non-existent file, which raises a `Name_Error` exception.

22.2 Sequential I/O

The previous section presented details about text file I/O. Here, we discuss doing file I/O in binary format. The first package we'll explore is the `Ada.Sequential_IO` package. Because this package is a generic package, you need to instantiate it for the data type you want to use for file I/O. Once you've done that, you can use the same procedures we've seen in the previous section: `Create`, `Open`, `Close`, `Reset` and `Delete`. However, instead of calling the `Get_Line` and `Put_Line` procedures, you'd call the `Read` and `Write` procedures.

In the following example, we instantiate the `Ada.Sequential_IO` package for floating-point types:

Listing 5: show_seq_float_io.adb

```
with Ada.Text_IO;
with Ada.Sequential_IO;

procedure Show_Seq_Float_IO is
   package Float_IO is
     new Ada.Sequential_IO (Float);
   use Float_IO;

   F         : Float_IO.File_Type;
   File_Name : constant String :=
                 "float_file.bin";
begin
   Create (F, Out_File, File_Name);
   Write (F,  1.5);
   Write (F,  2.4);
   Write (F,  6.7);
   Close (F);

   declare
      Value : Float;
   begin
      Open (F, In_File, File_Name);
      while not End_Of_File (F) loop
         Read (F, Value);
         Ada.Text_IO.Put_Line
           (Float'Image (Value));
      end loop;
      Close (F);
   end;
end Show_Seq_Float_IO;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Seq_Float_IO
MD5: 27aa5daf92cba5df23fdc55c3578aa34
```

Runtime output

```
 1.50000E+00
 2.40000E+00
 6.70000E+00
```

We use the same approach to read and write complex information. The following example uses a record that includes a Boolean and a floating-point value:

Listing 6: show_seq_rec_io.adb

```
with Ada.Text_IO;
with Ada.Sequential_IO;

procedure Show_Seq_Rec_IO is
   type Num_Info is record
      Valid : Boolean := False;
      Value : Float;
   end record;

   procedure Put_Line (N : Num_Info) is
   begin
      if N.Valid then
         Ada.Text_IO.Put_Line
           ("(ok,     "
            & Float'Image (N.Value) & ")");
      else
         Ada.Text_IO.Put_Line
           ("(not ok,  -----------)");
      end if;
   end Put_Line;

   package Num_Info_IO is new
     Ada.Sequential_IO (Num_Info);
   use Num_Info_IO;

   F         : Num_Info_IO.File_Type;
   File_Name : constant String :=
                 "float_file.bin";
begin
   Create (F, Out_File, File_Name);
   Write (F,  (True,  1.5));
   Write (F,  (False, 2.4));
   Write (F,  (True,  6.7));
   Close (F);

   declare
      Value : Num_Info;
   begin
      Open (F, In_File, File_Name);
      while not End_Of_File (F) loop
         Read (F, Value);
         Put_Line (Value);
      end loop;
      Close (F);
   end;
end Show_Seq_Rec_IO;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Seq_Rec_IO
MD5: a88b1428cc50745dce0509087e74adb7
```

Runtime output

```
(ok,      1.50000E+00)
(not ok,  -----------)
(ok,      6.70000E+00)
```

As the example shows, we can use the same approach we used for floating-point types to perform file I/O for this record. Once we instantiate the `Ada.Sequential_IO` package for the record type, file I/O operations are performed the same way.

22.3 Direct I/O

Direct I/O is available in the `Ada.Direct_IO` package. This mechanism is similar to the sequential I/O approach just presented, but allows us to access any position in the file. The package instantiation and most operations are very similar to sequential I/O. To rewrite the `Show_Seq_Float_IO` application presented in the previous section to use the `Ada.Direct_IO` package, we just need to replace the instances of the `Ada.Sequential_IO` package by the `Ada.Direct_IO` package. This is the new source code:

Listing 7: show_dir_float_io.adb

```
with Ada.Text_IO;
with Ada.Direct_IO;

procedure Show_Dir_Float_IO is
   package Float_IO is new Ada.Direct_IO (Float);
   use Float_IO;

   F         : Float_IO.File_Type;
   File_Name : constant String :=
                 "float_file.bin";
begin
   Create (F, Out_File, File_Name);
   Write (F,  1.5);
   Write (F,  2.4);
   Write (F,  6.7);
   Close (F);

   declare
      Value : Float;
   begin
      Open (F, In_File, File_Name);
      while not End_Of_File (F) loop
         Read (F, Value);
         Ada.Text_IO.Put_Line
           (Float'Image (Value));
      end loop;
      Close (F);
   end;
end Show_Dir_Float_IO;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Dir_Float_IO
MD5: e4e5855976de44f53a821eb90dcbb206
```

Runtime output

```
 1.50000E+00
 2.40000E+00
 6.70000E+00
```

Unlike sequential I/O, direct I/O allows you to access any position in the file. However, it doesn't offer an option to append information to a file. Instead, it provides an `Inout_File` mode allowing reading and writing to a file via the same **`File_Type`** element.

To access any position in the file, call the `Set_Index` procedure to set the new position / index. You can use the `Index` function to retrieve the current index. Let's see an example:

Listing 8: show_dir_float_in_out_file.adb

```
with Ada.Text_IO;
with Ada.Direct_IO;

procedure Show_Dir_Float_In_Out_File is
   package Float_IO is new Ada.Direct_IO (Float);
   use Float_IO;

   F         : Float_IO.File_Type;
   File_Name : constant String :=
                  "float_file.bin";
begin
   --  Open file for input / output
   Create (F, Inout_File, File_Name);
   Write (F,  1.5);
   Write (F,  2.4);
   Write (F,  6.7);

   --  Set index to previous position
   --  and overwrite value
   Set_Index (F, Index (F) - 1);
   Write (F,  7.7);

   declare
      Value : Float;
   begin
      --  Set index to start of file
      Set_Index (F, 1);

      while not End_Of_File (F) loop
         Read (F, Value);
         Ada.Text_IO.Put_Line
           (Float'Image (Value));
      end loop;
      Close (F);
   end;
end Show_Dir_Float_In_Out_File;
```

Code block metadata

```

Runtime output

```
 1.50000E+00
 2.40000E+00
 7.70000E+00
```

By running this example, we see that the file contains `7.7`, rather than the previous `6.7` that we wrote. We overwrote the value by changing the index to the previous position before doing another write.

In this example we used the `Inout_File` mode. Using that mode, we just changed the index back to the initial position before reading from the file (`Set_Index (F, 1)`) instead

of closing the file and reopening it for reading.

22.4 Stream I/O

All the previous approaches for file I/O in binary format (sequential and direct I/O) are specific for a single data type (the one we instantiate them with). You can use these approaches to write objects of a single data type that may be an array or record (potentially with many fields), but if you need to create and process files that include different data types, or any objects of an unbounded type, these approaches are not sufficient. Instead, you should use stream I/O.

Stream I/O shares some similarities with the previous approaches. We still use the `Create`, `Open` and `Close` procedures. However, instead of accessing the file directly via a **`File_Type`** element, you use a `Stream_Access` element. To read and write information, you use the `'Read` or `'Write` attributes of the data types you're reading or writing.

Let's look at a version of the `Show_Dir_Float_IO` procedure from the previous section that makes use of stream I/O instead of direct I/O:

Listing 9: show_float_stream.adb

```
with Ada.Text_IO;

with Ada.Streams.Stream_IO;
use  Ada.Streams.Stream_IO;

procedure Show_Float_Stream is
   F         : File_Type;
   S         : Stream_Access;
   File_Name : constant String :=
                 "float_file.bin";
begin
   Create (F, Out_File, File_Name);
   S := Stream (F);

   Float'Write (S, 1.5);
   Float'Write (S, 2.4);
   Float'Write (S, 6.7);

   Close (F);

   declare
      Value : Float;
   begin
      Open (F, In_File, File_Name);
      S := Stream (F);

      while not End_Of_File (F) loop
         Float'Read (S, Value);
         Ada.Text_IO.Put_Line
           (Float'Image (Value));
      end loop;
      Close (F);
   end;
end Show_Float_Stream;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Float_Stream
MD5: 34ccf04b0821074a332019ac0e38bb3e
```

Runtime output

```
 1.50000E+00
 2.40000E+00
 6.70000E+00
```

After the call to `Create`, we retrieve the corresponding `Stream_Access` element by calling the `Stream` function. We then use this stream to write information to the file via the `'Write` attribute of the **`Float`** type. After closing the file and reopening it for reading, we again retrieve the corresponding `Stream_Access` element and processed to read information from the file via the `'Read` attribute of the **`Float`** type.

You can use streams to create and process files containing different data types within the same file. You can also read and write unbounded data types such as strings. However, when using unbounded data types you must call the `'Input` and `'Output` attributes of the unbounded data type: these attributes write information about bounds or discriminants in addition to the object's actual data.

The following example shows file I/O that mixes both strings of different lengths and floating-point values:

Listing 10: show_string_stream.adb

```
1  with Ada.Text_IO;
2
3  with Ada.Streams.Stream_IO;
4  use  Ada.Streams.Stream_IO;
5
6  procedure Show_String_Stream is
7     F         : File_Type;
8     S         : Stream_Access;
9     File_Name : constant String :=
10                  "float_file.bin";
11
12    procedure Output (S  : Stream_Access;
13                      FV : Float;
14                      SV : String) is
15    begin
16       String'Output (S, SV);
17       Float'Output (S,  FV);
18    end Output;
19
20    procedure Input_Display (S : Stream_Access) is
21       SV : String := String'Input (S);
22       FV : Float  := Float'Input (S);
23    begin
24       Ada.Text_IO.Put_Line (Float'Image (FV)
25                             & " --- " & SV);
26    end Input_Display;
27
28 begin
29    Create (F, Out_File, File_Name);
30    S := Stream (F);
31
32    Output (S, 1.5, "Hi!!");
33    Output (S, 2.4, "Hello world!");
34    Output (S, 6.7, "Something longer here...");
35
36    Close (F);
37
38    Open (F, In_File, File_Name);
39    S := Stream (F);
```

(continues on next page)

(continued from previous page)

```
40
41    while not End_Of_File (F) loop
42       Input_Display (S);
43    end loop;
44    Close (F);
45
46 end Show_String_Stream;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_String_Stream
MD5: 3ae8276ada5f24cab49994e368e0fa34
```

Runtime output

```
 1.50000E+00 --- Hi!!
 2.40000E+00 --- Hello world!
 6.70000E+00 --- Something longer here...
```

When you use Stream I/O, no information is written into the file indicating the type of the data that you wrote. If a file contains data from different types, you must reference types in the same order when reading a file as when you wrote it. If not, the information you get will be corrupted. Unfortunately, strong data typing doesn't help you in this case. Writing simple procedures for file I/O (as in the example above) may help ensuring that the file format is consistent.

Like direct I/O, stream I/O support also allows you to access any location in the file. However, when doing so, you need to be extremely careful that the position of the new index is consistent with the data types you're expecting.

CHAPTER

TWENTYTHREE

STANDARD LIBRARY: NUMERICS

The standard library provides support for common numeric operations on floating-point types as well as on complex types and matrices. In the sections below, we present a brief introduction to these numeric operations.

23.1 Elementary Functions

The `Ada.Numerics.Elementary_Functions` package provides common operations for floating-point types, such as square root, logarithm, and the trigonometric functions (e.g., sin, cos). For example:

Listing 1: show_elem_math.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with Ada.Numerics; use Ada.Numerics;

with Ada.Numerics.Elementary_Functions;
use  Ada.Numerics.Elementary_Functions;

procedure Show_Elem_Math is
   X : Float;
begin
   X := 2.0;
   Put_Line ("Square root of "
             & Float'Image (X)
             & " is "
             & Float'Image (Sqrt (X)));

   X := e;
   Put_Line ("Natural log of "
             & Float'Image (X)
             & " is "
             & Float'Image (Log (X)));

   X := 10.0 ** 6.0;
   Put_Line ("Log_10      of "
             & Float'Image (X)
             & " is "
             & Float'Image (Log (X, 10.0)));

   X := 2.0 ** 8.0;
   Put_Line ("Log_2       of "
             & Float'Image (X)
             & " is "
             & Float'Image (Log (X, 2.0)));

```

(continues on next page)

(continued from previous page)

```
34    X := Pi;
35    Put_Line ("Cos         of "
36              & Float'Image (X)
37              & " is "
38              & Float'Image (Cos (X)));
39
40    X := -1.0;
41    Put_Line ("Arccos      of "
42              & Float'Image (X)
43              & " is "
44              & Float'Image (Arccos (X)));
45 end Show_Elem_Math;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Elem_Math
MD5: 17511d7e17cd98d4b6e49ad302d6dcb6
```

Runtime output

```
Square root of  2.00000E+00 is  1.41421E+00
Natural log of  2.71828E+00 is  1.00000E+00
Log_10      of  1.00000E+06 is  6.00000E+00
Log_2       of  2.56000E+02 is  8.00000E+00
Cos         of  3.14159E+00 is -1.00000E+00
Arccos      of -1.00000E+00 is  3.14159E+00
```

Here we use the standard e and Pi constants from the `Ada.Numerics` package.

The `Ada.Numerics.Elementary_Functions` package provides operations for the **`Float`** type. Similar packages are available for **`Long_Float`** and **`Long_Long_Float`** types. For example, the `Ada.Numerics.Long_Elementary_Functions` package offers the same set of operations for the **`Long_Float`** type. In addition, the `Ada.Numerics.` **`Generic_`**`Elementary_Functions` package is a generic version of the package that you can instantiate for custom floating-point types. In fact, the `Elementary_Functions` package can be defined as follows:

```
package Elementary_Functions is new
  Ada.Numerics.Generic_Elementary_Functions (Float);
```

23.2 Random Number Generation

The `Ada.Numerics.Float_Random` package provides a simple random number generator for the range between 0.0 and 1.0. To use it, declare a generator `G`, which you pass to `Random`. For example:

Listing 2: show_float_random_num.adb

```
1  with Ada.Text_IO;  use Ada.Text_IO;
2
3  with Ada.Numerics.Float_Random;
4  use  Ada.Numerics.Float_Random;
5
6  procedure Show_Float_Random_Num is
7     G : Generator;
8     X : Uniformly_Distributed;
9  begin
```

(continues on next page)

(continued from previous page)

```
   Reset (G);

   Put_Line ("Some random numbers between "
             & Float'Image
                (Uniformly_Distributed'First)
             & " and "
             & Float'Image
                (Uniformly_Distributed'Last)
             & ":");
   for I in 1 .. 15 loop
      X := Random (G);
      Put_Line (Float'Image (X));
   end loop;
end Show_Float_Random_Num;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Float_Random_Num
MD5: cf38ab00e27bad4309010e678113dd36
```

Runtime output

```
Some random numbers between  0.00000E+00 and  1.00000E+00:
 4.86132E-01
 5.09969E-01
 7.07772E-01
 6.30244E-01
 1.20325E-01
 4.17811E-01
 1.36088E-01
 9.58633E-01
 4.56740E-02
 1.57614E-01
 2.42813E-01
 6.01065E-01
 6.82998E-01
 9.47318E-01
 8.03689E-01
```

The standard library also includes a random number generator for discrete numbers, which is part of the `Ada.Numerics.Discrete_Random` package. Since it's a generic package, you have to instantiate it for the desired discrete type. This allows you to specify a range for the generator. In the following example, we create an application that displays random integers between 1 and 10:

Listing 3: show_discrete_random_num.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with Ada.Numerics.Discrete_Random;

procedure Show_Discrete_Random_Num is

   subtype Random_Range is Integer range 1 .. 10;

   package R is new
     Ada.Numerics.Discrete_Random (Random_Range);
   use R;

   G : Generator;
   X : Random_Range;
begin
```

(continues on next page)

(continued from previous page)

```
   Reset (G);

   Put_Line ("Some random numbers between "
             & Integer'Image (Random_Range'First)
             & " and "
             & Integer'Image (Random_Range'Last)
             & ":");

   for I in 1 .. 15 loop
      X := Random (G);
      Put_Line (Integer'Image (X));
   end loop;
end Show_Discrete_Random_Num;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Discrete_Random_Num
MD5: 892f6525477f9a2c56f88885de011fba
```

Runtime output

```
Some random numbers between  1 and  10:
 7
 2
 1
 6
 3
 3
 1
 4
 9
 4
 7
 3
 8
 3
 7
```

Here, package R is instantiated with the Random_Range type, which has a constrained range between 1 and 10. This allows us to control the range used for the random numbers. We could easily modify the application to display random integers between 0 and 20 by changing the specification of the Random_Range type. We can also use floating-point or fixed-point types.

23.3 Complex Types

The Ada.Numerics.Complex_Types package provides support for complex number types and the Ada.Numerics.Complex_Elementary_Functions package provides support for common operations on complex number types, similar to the Ada.Numerics.Elementary_Functions package. Finally, you can use the Ada.Text_IO.Complex_IO package to perform I/O operations on complex numbers. In the following example, we declare variables of the Complex type and initialize them using an aggregate:

Listing 4: show_elem_math.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with Ada.Numerics; use Ada.Numerics;
```

(continues on next page)

(continued from previous page)

```
3
4  with Ada.Numerics.Complex_Types;
5  use  Ada.Numerics.Complex_Types;
6
7  with Ada.Numerics.Complex_Elementary_Functions;
8  use  Ada.Numerics.Complex_Elementary_Functions;
9
10 with Ada.Text_IO.Complex_IO;
11
12 procedure Show_Elem_Math is
13
14    package C_IO is new
15      Ada.Text_IO.Complex_IO (Complex_Types);
16    use C_IO;
17
18    X, Y  : Complex;
19    R, Th : Float;
20 begin
21    X := (2.0, -1.0);
22    Y := (3.0,  4.0);
23
24    Put (X);
25    Put (" * ");
26    Put (Y);
27    Put (" is ");
28    Put (X * Y);
29    New_Line;
30    New_Line;
31
32    R  := 3.0;
33    Th := Pi / 2.0;
34    X  := Compose_From_Polar (R, Th);
35    --  Alternatively:
36    --  X := R * Exp ((0.0, Th));
37    --  X := R * e ** Complex'(0.0, Th);
38
39    Put ("Polar form:    "
40         & Float'Image (R)  & " * e**(i * "
41         & Float'Image (Th) & ")");
42    New_Line;
43
44    Put ("Modulus     of ");
45    Put (X);
46    Put (" is ");
47    Put (Float'Image (abs (X)));
48    New_Line;
49
50    Put ("Argument    of ");
51    Put (X);
52    Put (" is ");
53    Put (Float'Image (Argument (X)));
54    New_Line;
55    New_Line;
56
57    Put ("Sqrt        of ");
58    Put (X);
59    Put (" is ");
60    Put (Sqrt (X));
61    New_Line;
62 end Show_Elem_Math;
```

Code block metadata

```
Project: Courses.Intro_To_Ada.Standard_Library.Show_Elem_Math
MD5: 24fd48ab69aeac28286e6ec8065899c5
```

Runtime output

```
( 2.00000E+00,-1.00000E+00) * ( 3.00000E+00, 4.00000E+00) is ( 1.00000E+01, 5.
↪00000E+00)

Polar form:     3.00000E+00 * e**(i *  1.57080E+00)
Modulus     of (-1.31134E-07, 3.00000E+00) is  3.00000E+00
Argument    of (-1.31134E-07, 3.00000E+00) is  1.57080E+00

Sqrt        of (-1.31134E-07, 3.00000E+00) is ( 1.22474E+00, 1.22474E+00)
```

As we can see from this example, all the common operators, such as * and +, are available for complex types. You also have typical operations on complex numbers, such as Argument and Exp. In addition to initializing complex numbers in the cartesian form using aggregates, you can do so from the polar form by calling the Compose_From_Polar function.

The Ada.Numerics.Complex_Types and Ada.Numerics.Complex_Elementary_Functions packages provide operations for the **Float** type. Similar packages are available for **Long_Float** and **Long_Long_Float** types. In addition, the Ada.Numerics.**Generic**_Complex_Types and Ada.Numerics.**Generic**_Complex_Elementary_Functions packages are generic versions that you can instantiate for custom or pre-defined floating-point types. For example:

```
with Ada.Numerics.Generic_Complex_Types;
with Ada.Numerics.Generic_Complex_Elementary_Functions;
with Ada.Text_IO.Complex_IO;

procedure Show_Elem_Math is

   package Complex_Types is new
     Ada.Numerics.Generic_Complex_Types (Float);
   use Complex_Types;

   package Elementary_Functions is new
     Ada.Numerics.Generic_Complex_Elementary_Functions
       (Complex_Types);
   use Elementary_Functions;

   package C_IO is new Ada.Text_IO.Complex_IO
     (Complex_Types);
   use C_IO;

   X, Y  : Complex;
   R, Th : Float;
```

23.4 Vector and Matrix Manipulation

The Ada.Numerics.Real_Arrays package provides support for vectors and matrices. It includes common matrix operations such as inverse, determinant, eigenvalues in addition to simpler operators such as matrix addition and multiplication. You can declare vectors and matrices using the Real_Vector and Real_Matrix types, respectively.

The following example uses some of the operations from the Ada.Numerics.Real_Arrays package:

Listing 5: show_matrix.adb

```
with Ada.Text_IO;  use Ada.Text_IO;

with Ada.Numerics.Real_Arrays;
use  Ada.Numerics.Real_Arrays;

procedure Show_Matrix is

   procedure Put_Vector (V : Real_Vector) is
   begin
      Put ("    (");
      for I in V'Range loop
         Put (Float'Image (V (I)) & " ");
      end loop;
      Put_Line (")");
   end Put_Vector;

   procedure Put_Matrix (M : Real_Matrix) is
   begin
      for I in M'Range (1) loop
         Put ("    (");
         for J in M'Range (2) loop
            Put (Float'Image (M (I, J)) & " ");
         end loop;
         Put_Line (")");
      end loop;
   end Put_Matrix;

   V1       : Real_Vector := (1.0, 3.0);
   V2       : Real_Vector := (75.0, 11.0);

   M1       : Real_Matrix :=
                ((1.0, 5.0, 1.0),
                 (2.0, 2.0, 1.0));
   M2       : Real_Matrix :=
                ((31.0, 11.0, 10.0),
                 (34.0, 16.0, 11.0),
                 (32.0, 12.0, 10.0),
                 (31.0, 13.0, 10.0));
   M3       : Real_Matrix := ((1.0, 2.0),
                              (2.0, 3.0));
begin
   Put_Line ("V1");
   Put_Vector (V1);
   Put_Line ("V2");
   Put_Vector (V2);
   Put_Line ("V1 * V2 =");
   Put_Line ("    "
             & Float'Image (V1 * V2));
   Put_Line ("V1 * V2 =");
   Put_Matrix (V1 * V2);
   New_Line;

   Put_Line ("M1");
   Put_Matrix (M1);
   Put_Line ("M2");
   Put_Matrix (M2);
   Put_Line ("M2 * Transpose(M1) =");
   Put_Matrix (M2 * Transpose (M1));
   New_Line;

```

(continues on next page)

(continued from previous page)

```
61    Put_Line ("M3");
62    Put_Matrix (M3);
63    Put_Line ("Inverse (M3) =");
64    Put_Matrix (Inverse (M3));
65    Put_Line ("abs Inverse (M3) =");
66    Put_Matrix (abs Inverse (M3));
67    Put_Line ("Determinant (M3) =");
68    Put_Line ("    "
69              & Float'Image (Determinant (M3)));
70    Put_Line ("Solve (M3, V1) =");
71    Put_Vector (Solve (M3, V1));
72    Put_Line ("Eigenvalues (M3) =");
73    Put_Vector (Eigenvalues (M3));
74    New_Line;
75 end Show_Matrix;
```

Code block metadata

```

(continued from previous page)

```
    ( 4.23607E+00 -2.36068E-01 )
```

Matrix dimensions are automatically determined from the aggregate used for initialization when you don't specify them. You can, however, also use explicit ranges. For example:

```
M1       : Real_Matrix (1 .. 2, 1 .. 3) :=
             ((1.0, 5.0, 1.0),
              (2.0, 2.0, 1.0));
```

The `Ada.Numerics.Real_Arrays` package implements operations for the **`Float`** type. Similar packages are available for **`Long_Float`** and **`Long_Long_Float`** types. In addition, the `Ada.Numerics.`**`Generic`**`_Real_Arrays` package is a generic version that you can instantiate with custom floating-point types. For example, the `Real_Arrays` package can be defined as follows:

```
package Real_Arrays is new
  Ada.Numerics.Generic_Real_Arrays (Float);
```

CHAPTER

TWENTYFOUR

APPENDICES

24.1 Appendix A: Generic Formal Types

The following tables contain examples of available formal types for generics:

Formal type	Actual type
Incomplete type **Format**: `type T;`	Any type
Discrete type **Format**: `type T is (<>);`	Any integer, modular or enumeration type
Range type **Format**: `type T is range <>;`	Any signed integer type
Modular type **Format**: `type T is mod <>;`	Any modular type
Floating-point type **Format**: `type T is digits <>;`	Any floating-point type
Binary fixed-point type **Format**: `type T is delta <>;`	Any binary fixed-point type
Decimal fixed-point type **Format**: `type T is delta <> digits <>;`	Any decimal fixed-point type
Definite nonlimited private type **Format**: `type T is private;`	Any nonlimited, definite type
Nonlimited Private type with discriminant **Format**: `type T (D : DT) is private;`	Any nonlimited type with discriminant
Access type **Format**: `type A is access T;`	Any access type for type T
Definite derived type **Format**: `type T is new B;`	Any concrete type derived from base type B
Limited private type **Format**: `type T is limited private;`	Any definite type, limited or not
Incomplete tagged type **Format**: `type T is tagged;`	Any concrete, definite, tagged type
Definite tagged private type **Format**: `type T is tagged private;`	Any concrete, definite, tagged type
Definite tagged limited private type **Format**: `type T is tagged limited private;`	Any concrete definite tagged type, limited or not
Definite abstract tagged private type **Format**: `type T is abstract tagged private;`	Any nonlimited, definite tagged type, abstract or concrete

continues on next page

Table 1 – continued from previous page

Formal type	Actual type
Definite abstract tagged limited private type **Format**: `type T is abstract tagged limited private;`	Any definite tagged type, limited or not, abstract or concrete
Definite derived tagged type **Format**: `type T is new B with private;`	Any concrete tagged type derived from base type B
Definite abstract derived tagged type **Format**: `type T is abstract new B with private;`	Any tagged type derived from base type B abstract or concrete
Array type **Format**: `type A is array (R) of T;`	Any array type with range R containing elements of type T
Interface type **Format**: `type T is interface;`	Any interface type T
Limited interface type **Format**: `type T is limited interface;`	Any limited interface type T
Task interface type **Format**: `type T is task interface;`	Any task interface type T
Synchronized interface type **Format**: `type T is synchronized interface;`	Any synchronized interface type T
Protected interface type **Format**: `type T is protected interface;`	Any protected interface type T
Derived interface type **Format**: `type T is new B and I with private;`	Any type T derived from base type B and interface I
Derived type with multiple interfaces **Format**: `type T is new B and I1 and I2 with private;`	Any type T derived from base type B and interfaces I1 and I2
Abstract derived interface type **Format**: `type T is abstract new B and I with private;`	Any type T derived from abstract base type B and interface I
Limited derived interface type **Format**: `type T is limited new B and I with private;`	Any type T derived from limited base type B and limited interface I
Abstract limited derived interface type **Format**: `type T is abstract limited new B and I with private;`	Any type T derived from abstract limited base type B and limited interface I
Synchronized interface type **Format**: `type T is synchronized new SI with private;`	Any type T derived from synchronized interface SI
Abstract synchronized interface type **Format**: `type T is abstract synchronized new SI with private;`	Any type T derived from synchronized interface SI

24.1.1 Indefinite version

Many of the examples above can be used for formal indefinite types:

Formal type	Actual type
Indefinite incomplete type **Format**: `type T (<>);`	Any type
Indefinite nonlimited private type **Format**: `type T (<>) is private;`	Any nonlimited type indefinite or definite
Indefinite limited private type **Format**: `type T (<>) is limited private;`	Any type, limited or not, indefinite or definite
Incomplete indefinite tagged private type **Format**: `type T (<>) is tagged;`	Any concrete tagged type, indefinite or definite
Indefinite tagged private type **Format**: `type T (<>) is tagged private;`	Any concrete, nonlimited tagged type, indefinite or definite
Indefinite tagged limited private type **Format**: `type T (<>) is tagged limited private;`	Any concrete tagged type, limited or not, indefinite or definite
Indefinite abstract tagged private type **Format**: `type T (<>) is abstract tagged private;`	Any nonlimited tagged type, indefinite or definite, abstract or concrete
Indefinite abstract tagged limited private type **Format**: `type T (<>) is abstract tagged limited private;`	Any tagged type, limited or not, indefinite or definite abstract or concrete
Indefinite derived tagged type **Format**: `type T (<>) is new B with private;`	Any tagged type derived from base type B, indefinite or definite
Indefinite abstract derived tagged type **Format**: `type T (<>) is abstract new B with private;`	Any tagged type derived from base type B, indefinite or definite abstract or concrete

The same examples could also contain discriminants. In this case, `(<>)` is replaced by a list of discriminants, e.g.: `(D: DT)`.

24.2 Appendix B: Containers

The following table shows all containers available in Ada, including their versions (standard, bounded, unbounded, indefinite):

Category	Container	Std	Bounded	Unbounded	Indefinite
Vector	`Vectors`	Y	Y		Y
List	`Doubly Linked Lists`	Y	Y		Y
Map	`Hashed Maps`	Y	Y		Y
Map	`Ordered Maps`	Y	Y		Y
Set	`Hashed Sets`	Y	Y		Y
Set	`Ordered Sets`	Y	Y		Y
Tree	`Multiway Trees`	Y	Y		Y
Generic	`Holders`				Y
Queue	`Synchronized Queue Interfaces`	Y			
Queue	`Synchronized Queues`		Y	Y	
Queue	`Priority Queues`		Y	Y	

Note: To get the correct container name, replace the whitespace by _ in the names above. (For example, `Hashed Maps` becomes `Hashed_Maps`.)

The following table presents the prefixing applied to the container name that depends on its version. As indicated in the table, the standard version does not have a prefix associated with it.

Version	Naming prefix
Std	
Bounded	`Bounded_`
Unbounded	`Unbounded_`
Indefinite	`Indefinite_`

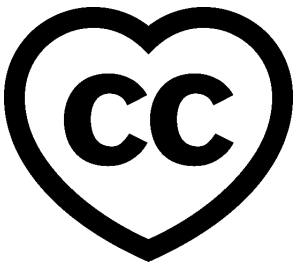
Advanced Journey With Ada: A Flight In Progress

Warning: This version of the website contains UNPUBLISHED contents. Please do not share it externally!

Copyright © 2019 – 2023, AdaCore

This book is published under a CC BY-SA license, which means that you can copy, redistribute, remix, transform, and build upon the content for any purpose, even commercially, as long as you give appropriate credit, provide a link to the license, and indicate if changes were made. If you remix, transform, or build upon the material, you must distribute your contributions under the same license as the original. You can find license details on this page[24]



Warning: This is work in progress!

Information in this document is subject to change at any time without prior notification.

Note: The code examples in this course use a 50-column limit, which greatly improves the readability of the code on devices with a small screen size. This constraint, however, leads to an unusual coding style. For instance, instead of calling `Put_Line` in a single line, we have this:

```
Put_Line
  (" is in the northeast quadrant");
```

or this:

```
Put_Line ("  (X => "
          & Integer'Image (P.X)
          & ")");
```

Note that typical Ada code uses a limit of at least 79 columns. Therefore, please don't take the coding style from this course as a reference!

Note: Each code example from this book has an associated "code block metadata", which contains the name of the "project" and an MD5 hash value. This information is used to identify a single code example.

You can find all code examples in a zip file, which you can download from the learn website[25]. The directory structure in the zip file is based on the code block metadata. For example, if you're searching for a code example with this metadata:

- Project: Courses.Intro_To_Ada.Imperative_Language.Greet
- MD5: cba89a34b87c9dfa71533d982d05e6ab

[24] http://creativecommons.org/licenses/by-sa/4.0
[25] https://learn.adacore.com/zip/learning-ada_code.zip

you will find it in this directory:

```
projects/Courses/Intro_To_Ada/Imperative_Language/Greet/
cba89a34b87c9dfa71533d982d05e6ab/
```

In order to use this code example, just follow these steps:

1. Unpack the zip file;
2. Go to target directory;
3. Start GNAT Studio on this directory;
4. Build (or compile) the project;
5. Run the application (if a main procedure is available in the project).

This course will teach you advanced topics of the Ada programming language. The *Introduction to Ada* (page 5) course is a prerequisite for this course.

This document was written by Gustavo A. Hoffmann, with major contributions from Robert A. Duff. The document also includes contributions from Arnaud Charlet, Emmanuel Briot, Franco Gasperoni, Gary Dismukes, Javier Miranda, Patrick Rogers, Quentin Ochem, Robert Dewar, and Yannick Moy.

These contributions are clearly indicated in the document, together with the original publication source.

Special thanks to Patrick Rogers for all comments and suggestions. In particular, thanks for sharing the training slides on access types: many ideas from those slides were integrated into this course.

This document was reviewed by Patrick Rogers and Tucker Taft.

CHANGELOG

Changes are being tracked on the CHANGELOG page.

CHAPTER

TWENTYFIVE

DATA TYPES

25.1 Types

25.1.1 Scalar Types

In general terms, scalar types are the most basic types that we can get. As we know, we can classify them as follows:

Category	Discrete	Numeric
Enumeration	Yes	No
Integer	Yes	Yes
Real	No	Yes

Many attributes exist for scalar types. For example, we can use the `Image` and `Value` attributes to convert between a given type and a string type. The following table presents the main attributes for scalar types:

Category	Attribute	Returned value
Ranges	`First`	First value of the discrete subtype's range.
	`Last`	Last value of the discrete subtype's range.
	`Range`	Range of the discrete subtype (corresponds to `Subtype'First .. Subtype'Last`).
Iterators	`Pred`	Predecessor of the input value.
	`Succ`	Successor of the input value.
Comparison	`Min`	Minimum of two values.
	`Max`	Maximum of two values.
String conversion	`Image`	String representation of the input value.
	`Value`	Value of a subtype based on input string.

We already discussed some of these attributes in the Introduction to Ada course (in the sections about *range and related attributes* (page 76) and *image attribute* (page 13)). In this section, we'll discuss some aspects that have been left out of the previous course.

In the Ada Reference Manual

- 3.5 Scalar types[26]

[26] http://www.ada-auth.org/standards/22rm/html/RM-3-5.html

Ranges

We've seen that the `First` and `Last` attributes can be used with discrete types. Those attributes are also available for real types. Here's an example using the **`Float`** type and a subtype of it:

Listing 1: show_first_last_real.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_First_Last_Real is
   subtype Norm is Float range 0.0 .. 1.0;
begin
   Put_Line ("Float'First: " & Float'First'Image);
   Put_Line ("Float'Last:  " & Float'Last'Image);
   Put_Line ("Norm'First:  " & Norm'First'Image);
   Put_Line ("Norm'Last:   " & Norm'Last'Image);
end Show_First_Last_Real;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Scalar_Types.Ranges_Real_Types
MD5: 89745a94fbdc41a2880ba14e50401acb
```

Runtime output

```
Float'First: -3.40282E+38
Float'Last:   3.40282E+38
Norm'First:   0.00000E+00
Norm'Last:    1.00000E+00
```

This program displays the first and last values of both the **`Float`** type and the `Norm` subtype. In the case of the **`Float`** type, we see the full range, while for the `Norm` subtype, we get the values we used in the declaration of the subtype (i.e. 0.0 and 1.0).

Predecessor and Successor

We can use the `Pred` and `Succ` attributes to get the predecessor and successor of a specific value. For discrete types, this is simply the next discrete value. For example, `Pred (2)` is 1 and `Succ (2)` is 3. Let's look at a complete source-code example:

Listing 2: show_succ_pred_discrete.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Succ_Pred_Discrete is
   type State is (Idle, Started,
                  Processing, Stopped);

   Machine_State : constant State := Started;

   I : constant Integer := 2;
begin
   Put_Line ("State                      : "
             & Machine_State'Image);
   Put_Line ("State'Pred (Machine_State): "
             & State'Pred (Machine_State)'Image);
   Put_Line ("State'Succ (Machine_State): "
             & State'Succ (Machine_State)'Image);
   Put_Line ("----------");
```

(continues on next page)

(continued from previous page)

```
18
19    Put_Line ("I               : "
20              & I'Image);
21    Put_Line ("Integer'Pred (I): "
22              & Integer'Pred (I)'Image);
23    Put_Line ("Integer'Succ (I): "
24              & Integer'Succ (I)'Image);
25 end Show_Succ_Pred_Discrete;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Scalar_Types.Show_Succ_Pred_Discrete
MD5: e11d0f50105864fdc1594b3bb72d927e
```

Runtime output

```
State                     : STARTED
State'Pred (Machine_State): IDLE
State'Succ (Machine_State): PROCESSING
----------
I               :  2
Integer'Pred (I):  1
Integer'Succ (I):  3
```

In this example, we use the `Pred` and `Succ` attributes for a variable of enumeration type (`State`) and a variable of **`Integer`** type.

We can also use the `Pred` and `Succ` attributes with real types. In this case, however, the value we get depends on the actual type we're using:

- for fixed-point types, the value is calculated using the smallest value (`Small`), which is derived from the declaration of the fixed-point type;
- for floating-point types, the value used in the calculation depends on representation constraints of the actual target machine.

Let's look at this example with a decimal type (`Decimal`) and a floating-point type (`My_Float`):

Listing 3: show_succ_pred_real.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Succ_Pred_Real is
4     subtype My_Float is
5       Float range 0.0 .. 0.5;
6
7     type Decimal is
8       delta 0.1 digits 2
9       range 0.0 .. 0.5;
10
11    D : Decimal;
12    N : My_Float;
13 begin
14    Put_Line ("---- DECIMAL -----");
15    Put_Line ("Small: " & Decimal'Small'Image);
16    Put_Line ("----- Succ -------");
17    D := Decimal'First;
18    loop
19       Put_Line (D'Image);
20       D := Decimal'Succ (D);
21
```

(continues on next page)

(continued from previous page)

```
      exit when D = Decimal'Last;
   end loop;
   Put_Line ("----- Pred -------");

   D := Decimal'Last;
   loop
      Put_Line (D'Image);
      D := Decimal'Pred (D);

      exit when D = Decimal'First;
   end loop;
   Put_Line ("==================");

   Put_Line ("---- MY_FLOAT ----");
   Put_Line ("----- Succ -------");
   N := My_Float'First;
   for I in 1 .. 5 loop
      Put_Line (N'Image);
      N := My_Float'Succ (N);
   end loop;
   Put_Line ("----- Pred -------");

   for I in 1 .. 5 loop
      Put_Line (N'Image);
      N := My_Float'Pred (N);
   end loop;
end Show_Succ_Pred_Real;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Scalar_Types.Show_Succ_Pred_Real
MD5: f426d6539c3ce863101f1e6afb21c08f
```

Runtime output

```
---- DECIMAL -----
Small:  1.00000000000000000E-01
----- Succ -------
 0.0
 0.1
 0.2
 0.3
 0.4
----- Pred -------
 0.5
 0.4
 0.3
 0.2
 0.1
==================
---- MY_FLOAT ----
----- Succ -------
 0.00000E+00
 1.40130E-45
 2.80260E-45
 4.20390E-45
 5.60519E-45
----- Pred -------
 7.00649E-45
 5.60519E-45
 4.20390E-45
```

(continues on next page)

(continued from previous page)

```
2.80260E-45
1.40130E-45
```

As the output of the program indicates, the smallest value (see `Decimal'Small` in the example) is used to calculate the previous and next values of `Decimal` type.

In the case of the `My_Float` type, the difference between the current and the previous or next values is 1.40130E-45 (or 2^{-149}) on a standard PC.

Scalar To String Conversion

We've seen that we can use the `Image` and `Value` attributes to perform conversions between values of a given subtype and a string:

Listing 4: show_image_value_attr.adb

```
1 with Ada.Text_IO; use Ada.Text_IO;
2
3 procedure Show_Image_Value_Attr is
4    I : constant Integer := Integer'Value ("42");
5 begin
6    Put_Line (I'Image);
7 end Show_Image_Value_Attr;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Scalar_Types.Image_Value_Attr
MD5: 9daa13b1f05511fac7e108eb9b8eefa7
```

Runtime output

```
 42
```

The `Image` and `Value` attributes are used for the **`String`** type specifically. In addition to them, there are also attributes for different string types — namely **`Wide_String`** and `Wide_Wide_String`. This is the complete list of available attributes:

Conversion type	Attribute	String type
Conversion to string	`Image`	**`String`**
	`Wide_Image`	**`Wide_String`**
	`Wide_Wide_Image`	`Wide_Wide_String`
Conversion to subtype	`Value`	**`String`**
	`Wide_Value`	**`Wide_String`**
	`Wide_Wide_Value`	`Wide_Wide_String`

We discuss more about **`Wide_String`** and `Wide_Wide_String` in *another section* (page 495).

Width attribute

When converting a value to a string by using the Image attribute, we get a string with variable width. We can assess the maximum width of that string for a specific subtype by using the Width attribute. For example, **Integer**'Width gives us the maximum width returned by the Image attribute when converting a value of **Integer** type to a string of **String** type.

This attribute is useful when we're using bounded strings in our code to store the string returned by the Image attribute. For example:

Listing 5: show_width_attr.adb

```
with Ada.Text_IO;          use Ada.Text_IO;
with Ada.Strings;          use Ada.Strings;
with Ada.Strings.Bounded;

procedure Show_Width_Attr is
   package B_Str is new
     Ada.Strings.Bounded.Generic_Bounded_Length
       (Max => Integer'Width);
   use B_Str;

   Str_I : Bounded_String;

   I : constant Integer := 42;
   J : constant Integer := 103;
begin
   Str_I := To_Bounded_String (I'Image);
   Put_Line ("Value:          "
             & To_String (Str_I));
   Put_Line ("String Length: "
             & Length (Str_I)'Image);
   Put_Line ("----");

   Str_I := To_Bounded_String (J'Image);
   Put_Line ("Value:          "
             & To_String (Str_I));
   Put_Line ("String Length: "
             & Length (Str_I)'Image);
end Show_Width_Attr;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Scalar_Types.Width_Attr
MD5: 82cff0cf4fecfdecce3020135cf98fd2
```

Runtime output

```
Value:          42
String Length:  3
----
Value:          103
String Length:  4
```

In this example, we're storing the string returned by Image in the Str_I variable of Bounded_String type.

Similar to the Image and Value attributes, the Width attribute is also available for string types other than **String**. In fact, we can use:

- the Wide_Width attribute for strings returned by Wide_Image; and
- the Wide_Wide_Width attribute for strings returned by Wide_Wide_Image.

Base

The Base attribute gives us the unconstrained underlying hardware representation selected for a given numeric type. As an example, let's say we declared a subtype of the **Integer** type named One_To_Ten:

Listing 6: my_integers.ads

```
package My_Integers is

   subtype One_To_Ten is Integer
     range 1 .. 10;

end My_Integers;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Scalar_Types.Base_Attr
MD5: e3f8310ed742e61a65728fecb6caa557
```

If we then use the Base attribute — by writing One_To_Ten'Base —, we're actually referring to the unconstrained underlying hardware representation selected for One_To_Ten. As One_To_Ten is a subtype of the **Integer** type, this also means that One_To_Ten'Base is equivalent to **Integer**'Base, i.e. they refer to the same base type. (This base type is the underlying hardware type representing the **Integer** type — but is not the **Integer** type itself.)

For further reading...

The Ada standard defines that the minimum range of the **Integer** type is -2**15 + 1 .. 2**15 - 1. In modern 64-bit systems — where wider types such as **Long_Integer** are defined — the range is at least -2**31 + 1 .. 2**31 - 1. Therefore, we could think of the **Integer** type as having the following declaration:

```
type Integer is
  range -2 ** 31 .. 2 ** 31 - 1;
```

However, even though **Integer** is a predefined Ada type, it's actually a subtype of an anonymous type. That anonymous "type" is the hardware's representation for the numeric type as chosen by the compiler based on the requested range (for the signed integer types) or digits of precision (for floating-point types). In other words, these types are actually subtypes of something that does not have a specific name in Ada, and that is not constrained.

In effect,

```
type Integer is
  range -2 ** 31 .. 2 ** 31 - 1;
```

is really as if we said this:

```
subtype Integer is
  Some_Hardware_Type_With_Sufficient_Range
  range -2 ** 31 .. 2 ** 31 - 1;
```

Since the Some_Hardware_Type_With_Sufficient_Range type is anonymous and we therefore cannot refer to it in the code, we just say that **Integer** is a type rather than a subtype.

Let's focus on signed integers — as the other numerics work the same way. When we declare a signed integer type, we have to specify the required range, statically. If the compiler cannot find a hardware-defined or supported signed integer type with at least the

range requested, the compilation is rejected. For example, in current architectures, the code below most likely won't compile:

Listing 7: int_def.ads

```
package Int_Def is

   type Too_Big_To_Fail is
     range -2 ** 255 .. 2 ** 255 - 1;

end Int_Def;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Scalar_Types.Very_Big_Range
MD5: 29f54776dc814dc8a5d245105b527992
```

Build output

```
int_def.ads:4:06: error: integer type definition bounds out of range
gprbuild: *** compilation phase failed
```

Otherwise, the compiler maps the named Ada type to the hardware "type", presumably choosing the smallest one that supports the requested range. (That's why the range has to be static in the source code, unlike for explicit subtypes.)

The following example shows how the Base attribute affects the bounds of a variable:

Listing 8: show_base.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with My_Integers; use My_Integers;

procedure Show_Base is
   C : constant One_To_Ten := One_To_Ten'Last;
begin
   Using_Constrained_Subtype : declare
      V : One_To_Ten := C;
   begin
      Put_Line
        ("Increasing value for One_To_Ten...");

      V := One_To_Ten'Succ (V);
   exception
      when others =>
         Put_Line ("Exception raised!");
   end Using_Constrained_Subtype;

   Using_Base : declare
      V : One_To_Ten'Base := C;
   begin
      Put_Line
      ("Increasing value for One_To_Ten'Base...");

      V := One_To_Ten'Succ (V);
   exception
      when others =>
         Put_Line ("Exception raised!");
   end Using_Base;

   Put_Line ("One_To_Ten'Last: "
```

(continues on next page)

(continued from previous page)

```
            & One_To_Ten'Last'Image);
   Put_Line ("One_To_Ten'Base'Last: "
            & One_To_Ten'Base'Last'Image);
end Show_Base;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Scalar_Types.Base_Attr
MD5: ce3e9fb3ff1619e835e9108ae0a787e7
```

Build output

```
show_base.adb:13:22: warning: value not in range of type "One_To_Ten" defined at␣
↪my_integers.ads:3 [enabled by default]
show_base.adb:13:22: warning: Constraint_Error will be raised at run time [enabled␣
↪by default]
```

Runtime output

```
Increasing value for One_To_Ten...
Exception raised!
Increasing value for One_To_Ten'Base...
One_To_Ten'Last:  10
One_To_Ten'Base'Last:  2147483647
```

In the first block of the example (`Using_Constrained_Subtype`), we're asking for the next value after the last value of a range — in this case, `One_To_Ten'Succ (One_To_Ten'Last)`. As expected, since the last value of the range doesn't have a successor, a constraint exception is raised.

In the `Using_Base` block, we're declaring a variable `V` of `One_To_Ten'Base` subtype. In this case, the next value exists — because the condition `One_To_Ten'Last + 1 <= One_To_Ten'Base'Last` is true —, so we can use the `Succ` attribute without having an exception being raised.

In the following example, we adjust the result of additions and subtractions to avoid constraint errors:

Listing 9: my_integers.ads

```
package My_Integers is

   subtype One_To_Ten is Integer range 1 .. 10;

   function Sat_Add (V1, V2 : One_To_Ten'Base)
                     return One_To_Ten;

   function Sat_Sub (V1, V2 : One_To_Ten'Base)
                     return One_To_Ten;

end My_Integers;
```

Listing 10: my_integers.adb

```
--  with Ada.Text_IO; use Ada.Text_IO;

package body My_Integers is

   function Saturate (V : One_To_Ten'Base)
                      return One_To_Ten is
   begin
```

(continues on next page)

(continued from previous page)

```
      --  Put_Line ("SATURATE " & V'Image);

      if V < One_To_Ten'First then
         return One_To_Ten'First;
      elsif V > One_To_Ten'Last then
         return One_To_Ten'Last;
      else
         return V;
      end if;
   end Saturate;

   function Sat_Add (V1, V2 : One_To_Ten'Base)
                     return One_To_Ten is
   begin
      return Saturate (V1 + V2);
   end Sat_Add;

   function Sat_Sub (V1, V2 : One_To_Ten'Base)
                     return One_To_Ten is
   begin
      return Saturate (V1 - V2);
   end Sat_Sub;

end My_Integers;
```

Listing 11: show_base.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with My_Integers; use My_Integers;

procedure Show_Base is

   type Display_Saturate_Op is (Add, Sub);

   procedure Display_Saturate
     (V1, V2 : One_To_Ten;
      Op     : Display_Saturate_Op)
   is
      Res : One_To_Ten;
   begin
      case Op is
      when Add =>
         Res := Sat_Add (V1, V2);
      when Sub =>
         Res := Sat_Sub (V1, V2);
      end case;
      Put_Line ("SATURATE " & Op'Image
                & " (" & V1'Image
                & ", " & V2'Image
                & ") = " & Res'Image);
   end Display_Saturate;

begin
   Display_Saturate (1,  1, Add);
   Display_Saturate (10, 8, Add);
   Display_Saturate (1,  8, Sub);
end Show_Base;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Scalar_Types.Base_Attr_Sat
MD5: e9b31345c2efc056bdb71824072852d0
```

Runtime output

```
SATURATE ADD ( 1,  1) =  2
SATURATE ADD ( 10,  8) =  10
SATURATE SUB ( 1,  8) =  1
```

In this example, we're using the Base attribute to declare the parameters of the Sat_Add, Sat_Sub and Saturate functions. Note that the parameters of the Display_Saturate procedure are of One_To_Ten type, while the parameters of the Sat_Add, Sat_Sub and Saturate functions are of the (unconstrained) base subtype (One_To_Ten'Base). In those functions, we perform operations using the parameters of unconstrained subtype and adjust the result — in the Saturate function — before returning it as a constrained value of One_To_Ten subtype.

The code in the body of the My_Integers package contains lines that were commented out — to be more precise, a call to Put_Line call in the Saturate function. If you uncomment them, you'll see the value of the input parameter V (of One_To_Ten'Base type) in the runtime output of the program before it's adapted to fit the constraints of the One_To_Ten subtype.

25.1.2 Enumerations

We've introduced enumerations back in the *Introduction to Ada course* (page 51). In this section, we'll discuss a few useful features of enumerations, such as enumeration renaming, enumeration overloading and representation clauses.

In the Ada Reference Manual

- 3.5.1 Enumeration Types[27]

Enumerations as functions

If you have used programming language such as C in the past, you're familiar with the concept of enumerations being constants with integer values. In Ada, however, enumerations are not integers. In fact, they're actually parameterless functions! Let's consider this example:

Listing 12: days.ads

```
1  package Days is
2
3     type Day is (Mon, Tue, Wed,
4                  Thu, Fri,
5                  Sat, Sun);
6
7     --  Essentially, we're declaring
8     --  these functions:
9     --
10    --  function Mon return Day;
11    --  function Tue return Day;
12    --  function Wed return Day;
```

(continues on next page)

[27] http://www.ada-auth.org/standards/22rm/html/RM-3-5-1.html

(continued from previous page)

```
   --  function Thu return Day;
   --  function Fri return Day;
   --  function Sat return Day;
   --  function Sun return Day;

end Days;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Enumerations.Enumeration_As_Function
MD5: fa3e58b58edffa5a3e04b060a7f8cb8b
```

In the package Days, we're declaring the enumeration type Day. When we do this, we're essentially declaring seven parameterless functions, one for each enumeration. For example, the Mon enumeration corresponds to `function Mon return Day`. You can see all seven function declarations in the comments of the example above.

Note that this has no direct relation to how an Ada compiler generates machine code for enumeration. Even though enumerations are parameterless functions, a typical Ada compiler doesn't generate function calls for code that deals with enumerations.

Enumeration renaming

The idea that enumerations are parameterless functions can be used when we want to rename enumerations. For example, we could rename the enumerations of the Day type like this:

Listing 13: enumeration_example.ads

```
package Enumeration_Example is

   type Day is (Mon, Tue, Wed,
                Thu, Fri,
                Sat, Sun);

   function Monday    return Day renames Mon;
   function Tuesday   return Day renames Tue;
   function Wednesday return Day renames Wed;
   function Thursday  return Day renames Thu;
   function Friday    return Day renames Fri;
   function Saturday  return Day renames Sat;
   function Sunday    return Day renames Sun;

end Enumeration_Example;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Enumerations.Enumeration_Renaming
MD5: e2e12bb3bfcb0b6e94769ced9a4b80f9
```

Now, we can use both Monday or Mon to refer to Monday of the Day type:

Listing 14: show_renaming.adb

```
with Ada.Text_IO;         use Ada.Text_IO;
with Enumeration_Example; use Enumeration_Example;

procedure Show_Renaming is
   D1 : constant Day := Mon;
```

(continues on next page)

(continued from previous page)

```
   D2 : constant Day := Monday;
begin
   if D1 = D2 then
      Put_Line ("D1 = D2");
      Put_Line (Day'Image (D1)
                & " =  "
                & Day'Image (D2));
   end if;
end Show_Renaming;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Enumerations.Enumeration_Renaming
MD5: 2d7177def2c9e9fb11c7dc5e036c3be3
```

Runtime output

```
D1 = D2
MON =  MON
```

When running this application, we can confirm that D1 is equal to D2. Also, even though we've assigned Monday to D2 (instead of Mon), the application displays Mon = Mon, since Monday is just another name to refer to the actual enumeration (Mon).

Hint

If you just want to have a single (renamed) enumeration visible in your application — and make the original enumeration invisible —, you can use a separate package. For example:

Listing 15: enumeration_example.ads

```
package Enumeration_Example is

   type Day is (Mon, Tue, Wed,
                Thu, Fri,
                Sat, Sun);

end Enumeration_Example;
```

Listing 16: enumeration_renaming.ads

```
with Enumeration_Example;

package Enumeration_Renaming is

   subtype Day is Enumeration_Example.Day;

   function Monday    return Day renames
     Enumeration_Example.Mon;
   function Tuesday   return Day renames
     Enumeration_Example.Tue;
   function Wednesday return Day renames
     Enumeration_Example.Wed;
   function Thursday  return Day renames
     Enumeration_Example.Thu;
   function Friday    return Day renames
     Enumeration_Example.Fri;
   function Saturday  return Day renames
     Enumeration_Example.Sat;
   function Sunday    return Day renames
```

(continues on next page)

(continued from previous page)

```
20      Enumeration_Example.Sun;
21
22  end Enumeration_Renaming;
```

Listing 17: show_renaming.adb

```
1   with Ada.Text_IO; use Ada.Text_IO;
2
3   with Enumeration_Renaming;
4   use  Enumeration_Renaming;
5
6   procedure Show_Renaming is
7      D1 : constant Day := Monday;
8   begin
9      Put_Line (Day'Image (D1));
10  end Show_Renaming;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Enumerations.Enumeration_Renaming
MD5: 87fe75026f0fc118921eaee45fe55a8a
```

Runtime output

```
MON
```

Note that the call to Put_Line still display Mon instead of Monday.

Enumeration overloading

Enumerations can be overloaded. In simple terms, this means that the same name can be used to declare an enumeration of different types. A typical example is the declaration of colors:

Listing 18: colors.ads

```
1   package Colors is
2
3      type Color is
4        (Salmon,
5         Firebrick,
6         Red,
7         Darkred,
8         Lime,
9         Forestgreen,
10        Green,
11        Darkgreen,
12        Blue,
13        Mediumblue,
14        Darkblue);
15
16     type Primary_Color is
17       (Red,
18        Green,
19        Blue);
20
21  end Colors;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Enumerations.Enumeration_Overloading
MD5: b808f90d9164f044b6b7a8931863726f
```

Note that we have Red as an enumeration of type `Color` and of type `Primary_Color`. The same applies to Green and Blue. Because Ada is a strongly-typed language, in most cases, the enumeration that we're referring to is clear from the context. For example:

Listing 19: red_colors.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Colors;      use Colors;

procedure Red_Colors is
   C1 : constant Color         := Red;
   --  Using Red from Color

   C2 : constant Primary_Color := Red;
   --  Using Red from Primary_Color
begin
   if C1 = Red then
      Put_Line ("C1 = Red");
   end if;
   if C2 = Red then
      Put_Line ("C2 = Red");
   end if;
end Red_Colors;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Enumerations.Enumeration_Overloading
MD5: dd590eab88164773e974e748d77a51af
```

Runtime output

```
C1 = Red
C2 = Red
```

When assigning Red to C1 and C2, it is clear that, in the first case, we're referring to Red of `Color` type, while in the second case, we're referring to Red of the `Primary_Color` type. The same logic applies to comparisons such as the one in `if C1 = Red:` because the type of C1 is defined (`Color`), it's clear that the Red enumeration is the one of `Color` type.

Enumeration subtypes

Note that enumeration overloading is not the same as enumeration subtypes. For example, we could define the following subtype:

Listing 20: colors-shades.ads

```
package Colors.Shades is

   subtype Blue_Shades is
     Colors range Blue .. Darkblue;

end Colors.Shades;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Enumerations.Enumeration_Overloading
MD5: 9c13508bda487cae02dbf8b403271540
```

In this case, `Blue` of `Blue_Shades` and `Blue` of `Colors` are the same enumeration.

Enumeration ambiguities

A situation where enumeration overloading might lead to ambiguities is when we use them in ranges. For example:

Listing 21: colors.ads

```
package Colors is

   type Color is
     (Salmon,
      Firebrick,
      Red,
      Darkred,
      Lime,
      Forestgreen,
      Green,
      Darkgreen,
      Blue,
      Mediumblue,
      Darkblue);

   type Primary_Color is
     (Red,
      Green,
      Blue);

end Colors;
```

Listing 22: color_loop.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Colors;      use Colors;

procedure Color_Loop is
begin
   for C in Red .. Blue loop
   --       ^^^^^^^^^^^
   --  ERROR: range is ambiguous!
      Put_Line (Color'Image (C));
   end loop;
end Color_Loop;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Enumerations.Enumeration_Ambiguities
MD5: 82d0d3f28f1faf6b296a4f44db71f41b
```

Build output

```
color_loop.adb:6:17: error: ambiguous bounds in range of iteration
color_loop.adb:6:17: error: possible interpretations:
color_loop.adb:6:17: error: type "Primary_Color" defined at colors.ads:16
color_loop.adb:6:17: error: type "Color" defined at colors.ads:3
color_loop.adb:6:17: error: ambiguous bounds in discrete range
color_loop.adb:9:30: error: expected type "Color" defined at colors.ads:3
color_loop.adb:9:30: error: found type "Primary_Color" defined at colors.ads:16
gprbuild: *** compilation phase failed
```

Here, it's not clear whether the range in the loop is of `Color` type or of `Primary_Color` type. Therefore, we get a compilation error for this code example. The next line in the code example — the one with the call to `Put_Line` — gives us a hint about the developer's intention to refer to the `Color` type. In this case, we can use qualification — for example, `Color'(Red)` — to resolve the ambiguity:

Listing 23: color_loop.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Colors;      use Colors;

procedure Color_Loop is
begin
   for C in Color'(Red) .. Color'(Blue) loop
      Put_Line (Color'Image (C));
   end loop;
end Color_Loop;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Enumerations.Enumeration_Ambiguities
MD5: c3e946d330bb6aed258bcd005a540794
```

Runtime output

```
RED
DARKRED
LIME
FORESTGREEN
GREEN
DARKGREEN
BLUE
```

Note that, in the case of ranges, we can also rewrite the loop by using a range declaration:

Listing 24: color_loop.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Colors;      use Colors;

procedure Color_Loop is
begin
   for C in Color range Red .. Blue loop
      Put_Line (Color'Image (C));
   end loop;
end Color_Loop;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Enumerations.Enumeration_Ambiguities
MD5: 23f8db4fcb5710f7bda6b511234e0448
```

Runtime output

```
RED
DARKRED
LIME
FORESTGREEN
GREEN
DARKGREEN
BLUE
```

Alternatively, `Color range Red .. Blue` could be used in a subtype declaration, so we could rewrite the example above using a subtype (such as `Red_To_Blue`) in the loop:

Listing 25: color_loop.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Colors;      use Colors;

procedure Color_Loop is
   subtype Red_To_Blue is Color range Red .. Blue;
begin
   for C in Red_To_Blue loop
      Put_Line (Color'Image (C));
   end loop;
end Color_Loop;
```

Position and Internal Code

As we've said above, a typical Ada compiler doesn't generate function calls for code that deals with enumerations. On the contrary, each enumeration has values associated with it, and the compiler uses those values instead.

Each enumeration has:

- a position value, which is a natural value indicating the position of the enumeration in the enumeration type; and
- an internal code, which, by default, in most cases, is the same as the position value.

Also, by default, the value of the first position is zero, the value of the second position is one, and so on. We can see this by listing each enumeration of the `Day` type and displaying the value of the corresponding position:

Listing 26: days.ads

```
package Days is

   type Day is (Mon, Tue, Wed,
                Thu, Fri,
                Sat, Sun);

end Days;
```

Listing 27: show_days.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Days;        use Days;

procedure Show_Days is
begin
   for D in Day loop
      Put_Line (Day'Image (D)
                & " position      = "
                & Integer'Image (Day'Pos (D)));
      Put_Line (Day'Image (D)
                & " internal code = "
                & Integer'Image
                    (Day'Enum_Rep (D)));
   end loop;
end Show_Days;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Enumerations.Enumeration_Values
MD5: d6c5cb99b9770893b7277c470f40e805
```

Runtime output

```
MON position      =  0
MON internal code =  0
TUE position      =  1
TUE internal code =  1
WED position      =  2
WED internal code =  2
THU position      =  3
THU internal code =  3
FRI position      =  4
FRI internal code =  4
SAT position      =  5
SAT internal code =  5
SUN position      =  6
SUN internal code =  6
```

Note that this application also displays the internal code, which, in this case, is equivalent to the position value for all enumerations.

We may, however, change the internal code of an enumeration using a representation clause. We discuss this topic *in another section* (page 347).

25.1.3 Definite and Indefinite Subtypes

Indefinite types were mentioned back in the *Introduction to Ada course* (page 81). In this section, we'll recapitulate and extend on both definite and indefinite types.

Definite types are the basic kind of types we commonly use when programming applications. For example, we can only declare variables of definite types; otherwise, we get a compilation error. Interestingly, however, to be able to explain what definite types are, we need to first discuss indefinite types.

Indefinite types include:

- unconstrained arrays;
- record types with unconstrained discriminants without defaults.

Let's see some examples of indefinite types:

Listing 28: unconstrained_types.ads

```
1  package Unconstrained_Types is
2
3     type Integer_Array is
4       array (Positive range <>) of Integer;
5
6     type Simple_Record (Extended : Boolean) is
7     record
8        V : Integer;
9        case Extended is
10          when False =>
11             null;
12          when True  =>
13             V_Float : Float;
14       end case;
15    end record;
```

(continues on next page)

(continued from previous page)

```

 ↪Indefinite_Types
MD5: e569dc73150b834c9315b14d46c0ac79
```

In this example, both `Integer_Array` and `Simple_Record` are indefinite types.

Important

Note that we cannot use indefinite subtypes as discriminants. For example, the following code won't compile:

Listing 29: unconstrained_types.ads

```
1  package Unconstrained_Types is
2
3     type Integer_Array is
4       array (Positive range <>) of Integer;
5
6     type Simple_Record (Arr : Integer_Array) is
7     record
8        L : Natural := Arr'Length;
9     end record;
10
11 end Unconstrained_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Definite_Indefinite_Subtypes.
 ↪Indefinite_Types_Error
MD5: cf73d308ddb4a8c2503146ecd550a791
```

Build output

```
unconstrained_types.ads:6:30: error: discriminants must have a discrete or access␣
 ↪type
gprbuild: *** compilation phase failed
```

`Integer_Array` is a correct type declaration — although the type itself is indefinite after the declaration. However, we cannot use it as the discriminant in the declaration of `Simple_Record`. We could, however, have a correct declaration by using discriminants as access values:

Listing 30: unconstrained_types.ads

```
1  package Unconstrained_Types is
2
3     type Integer_Array is
4       array (Positive range <>) of Integer;
5
6     type Integer_Array_Access is
7       access Integer_Array;
8
9     type Simple_Record
10      (Arr : Integer_Array_Access) is
11    record
```

(continues on next page)

(continued from previous page)

```
12       L : Natural := Arr'Length;
13    end record;
14
15 end Unconstrained_Types;
```

Code block metadata

```

 ↪Indefinite_Types_Error
MD5: dc8193e3684b172e8503e1c5427cf93d
```

By adding the `Integer_Array_Access` type and using it in `Simple_Record`'s type declaration, we can indirectly use an indefinite type in the declaration of another indefinite type. We discuss this topic later *in another chapter* (page 745).

As we've just mentioned, we cannot declare variable of indefinite types:

Listing 31: using_unconstrained_type.adb

```
1  with Unconstrained_Types; use Unconstrained_Types;
2
3  procedure Using_Unconstrained_Type is
4
5     A : Integer_Array;
6
7     R : Simple_Record;
8
9  begin
10    null;
11 end Using_Unconstrained_Type;
```

gprbuild: *** compilation phase failed
```

As we can see when we try to build this example, the compiler complains about the declaration of A and R because we're trying to use indefinite types to declare variables. The main reason we cannot use indefinite types here is that the compiler needs to know at this point how much memory it should allocate. Therefore, we need to provide the information that is missing. In other words, we need to change the declaration so the type becomes definite. We can do this by either declaring a definite type or providing constraints in the variable declaration. For example:

Listing 32: using_unconstrained_type.adb

```
with Unconstrained_Types; use Unconstrained_Types;

procedure Using_Unconstrained_Type is

   subtype Integer_Array_5 is
     Integer_Array (1 .. 5);

   A1 : Integer_Array_5;
   A2 : Integer_Array (1 .. 5);

   subtype Simple_Record_Ext is
     Simple_Record (Extended => True);

   R1 : Simple_Record_Ext;
   R2 : Simple_Record (Extended => True);

begin
   null;
end Using_Unconstrained_Type;
```

Code block metadata

```

 ↪assigned [-gnatwv]
using_unconstrained_type.adb:9:04: warning: variable "A2" is never read and never␣
 ↪assigned [-gnatwv]
using_unconstrained_type.adb:14:04: warning: variable "R1" is never read and never␣
 ↪assigned [-gnatwv]
using_unconstrained_type.adb:15:04: warning: variable "R2" is never read and never␣
 ↪assigned [-gnatwv]
```

In this example, we declare the `Integer_Array_5` subtype, which is definite because we're constraining it to a range from 1 to 5, thereby defining the information that was missing in the indefinite type `Integer_Array`. Because we now have a definite type, we can use it to declare the `A1` variable. Similarly, we can use the indefinite type `Integer_Array` directly in the declaration of `A2` by specifying the previously unknown range.

Similarly, in this example, we declare the `Simple_Record_Ext` subtype, which is definite because we're initializing the record discriminant `Extended`. We can therefore use it in the declaration of the `R1` variable. Alternatively, we can simply use the indefinite type `Simple_Record` and specify the information required for the discriminants. This is what we do in the declaration of the `R2` variable.

Although we cannot use indefinite types directly in variable declarations, they're very useful to generalize algorithms. For example, we can use them as parameters of a subprogram:

Listing 33: show_integer_array.ads

```
with Unconstrained_Types; use Unconstrained_Types;

procedure Show_Integer_Array (A : Integer_Array);
```

Listing 34: show_integer_array.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Integer_Array (A : Integer_Array)
is
begin
   for I in A'Range loop
      Put_Line (Positive'Image (I)
                & ": "
                & Integer'Image (A (I)));
   end loop;
   Put_Line ("--------");
end Show_Integer_Array;
```

Listing 35: using_unconstrained_type.adb

```
with Unconstrained_Types; use Unconstrained_Types;
with Show_Integer_Array;

procedure Using_Unconstrained_Type is
   A_5  : constant Integer_Array (1 .. 5)  :=
            (1, 2, 3, 4, 5);
   A_10 : constant Integer_Array (1 .. 10) :=
            (1, 2, 3, 4, 5, others => 99);
begin
   Show_Integer_Array (A_5);
   Show_Integer_Array (A_10);
end Using_Unconstrained_Type;
```

```

In this particular example, the compiler doesn't know a priori which range is used for the A parameter of Show_Integer_Array. It could be a range from 1 to 5 as used for variable A_5 of the Using_Unconstrained_Type procedure, or it could be a range from 1 to 10 as used for variable A_10, or it could be anything else. Although the parameter A of Show_Integer_Array is unconstrained, both calls to Show_Integer_Array — in Us-

ing_Unconstrained_Type procedure — use constrained objects.

Note that we could call the Show_Integer_Array procedure above with another unconstrained parameter. For example:

Listing 36: show_integer_array_header.ads

```
with Unconstrained_Types; use Unconstrained_Types;

procedure Show_Integer_Array_Header
  (AA : Integer_Array;
   HH : String);
```

Listing 37: show_integer_array_header.adb

```
with Ada.Text_IO;         use Ada.Text_IO;
with Show_Integer_Array;

procedure Show_Integer_Array_Header
  (AA : Integer_Array;

 6:  99
 7:  99
 8:  99
 9:  99
 10:  99
--------
```

In this case, we're calling the Show_Integer_Array procedure with another unconstrained parameter (the AA parameter). However, although we could have a long *chain* of procedure calls using indefinite types in their parameters, we still use a (definite) object at the beginning of this chain. For example, for the A_5 object, we have this chain:

```
A_5

    ==> Show_Integer_Array_Header (AA => A_5,
                                   ...);

        ==> Show_Integer_Array (A => AA);
```

Therefore, at this specific call to Show_Integer_Array, even though A is declared as a parameter of indefinite type, the actual argument is of definite type because A_5 is constrained — and, thus, of definite type.

Note that we can declare variables based on parameters of indefinite type. For example:

Listing 39: show_integer_array_plus.ads

```
with Unconstrained_Types; use Unconstrained_Types;

procedure Show_Integer_Array_Plus
  (A : Integer_Array;
   V : Integer);
```

Listing 40: show_integer_array_plus.adb

```
with Show_Integer_Array;

procedure Show_Integer_Array_Plus
  (A : Integer_Array;
   V : Integer)
is
   A_Plus : Integer_Array (A'Range);
begin
   for I in A_Plus'Range loop
      A_Plus (I) := A (I) + V;
   end loop;
   Show_Integer_Array (A_Plus);
end Show_Integer_Array_Plus;
```

Listing 41: using_unconstrained_type.adb

```
with Unconstrained_Types; use Unconstrained_Types;

with Show_Integer_Array_Plus;

 4:  9
 5:  10
--------
```

In the `Show_Integer_Array_Plus` procedure, we're declaring `A_Plus` based on the range of `A`, which is itself of indefinite type. However, since the object passed as an argument to `Show_Integer_Array_Plus` must have a constraint, `A_Plus` will also be constrained. For example, in the call to `Show_Integer_Array_Plus` using `A_5` as an argument, the declaration of `A_Plus` becomes `A_Plus : Integer_Array (1 .. 5);`. Therefore, it becomes clear that the compiler needs to allocate five elements for `A_Plus`.

We'll see later how definite and indefinite types apply to *formal parameters* (page 1921).

In the Ada Reference Manual

- 3.3 Objects and Named Numbers[28]

Constrained Attribute

We can use the `Constrained` attribute to verify whether an object of discriminated type is constrained or not. Let's start our discussion by reusing the `Simple_Record` type from previous examples. In this version of the `Unconstrained_Types` package, we're adding a `Reset` procedure for the discriminated record type:

Listing 42: unconstrained_types.ads

```
package Unconstrained_Types is

   type Simple_Record
     (Extended : Boolean := False) is
   record
      V : Integer;
      case Extended is
         when False =>
            null;
         when True  =>
            V_Float : Float;
      end case;
   end record;
```

(continues on next page)

[28] http://www.ada-auth.org/standards/22rm/html/RM-3-3.html

(continued from previous page)

```
14
15    procedure Reset (R : in out Simple_Record);
16
17 end Unconstrained_Types;
```

Listing 43: unconstrained_types.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Unconstrained_Types is
4
5     procedure Reset (R : in out Simple_Record) is
6        Zero_Not_Extended : constant
7          Simple_Record := (Extended => False,
8                            V        => 0);
9
10       Zero_Extended : constant
11         Simple_Record := (Extended => True,
12                           V        => 0,
13                           V_Float  => 0.0);
14    begin
15       Put_Line ("---- Reset: R'Constrained => "
16                 & R'Constrained'Image);
17
18       if not R'Constrained then
19          R := Zero_Extended;
20       else
21          if R.Extended then
22             R := Zero_Extended;
23          else
24             R := Zero_Not_Extended;
25          end if;
26       end if;
27    end Reset;
28
29 end Unconstrained_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Definite_Indefinite_Subtypes.
 ↪Constrained_Attribute
MD5: b56e6d71fd4f05e8490412d7fe40b923
```

As the name indicates, the `Reset` procedure initializes all record components with zero. Note that we use the `Constrained` attribute to verify whether objects are constrained before assigning to them. For objects that are not constrained, we can simply assign another object to it — as we do with the `R := Zero_Extended` statement. When an object is constrained, however, the discriminants must match. If we assign an object to R, the discriminant of that object must match the discriminant of R. This is the kind of verification that we do in the **`else`** part of that procedure: we check the state of the `Extended` discriminant before assigning an object to the R parameter.

The `Using_Constrained_Attribute` procedure below declares two objects of `Simple_Record` type: R1 and R2. Because the `Simple_Record` type has a default value for its discriminant, we can declare objects of this type without specifying a value for the discriminant. This is exactly what we do in the declaration of R1. Here, we don't specify any constraints, so that it takes the default value (`Extended => False`). In the declaration of R2, however, we explicitly set `Extended` to **`False`**:

Listing 44: using_constrained_attribute.adb

```
with Ada.Text_IO;         use Ada.Text_IO;

with Unconstrained_Types; use Unconstrained_Types;

procedure Using_Constrained_Attribute is
   R1 : Simple_Record;
   R2 : Simple_Record (Extended => False);

   procedure Show_Rs is
   begin
      Put_Line ("R1'Constrained => "
                & R1'Constrained'Image);
      Put_Line ("R1.Extended => "
                & R1.Extended'Image);
      Put_Line ("--");
      Put_Line ("R2'Constrained => "
                & R2'Constrained'Image);
      Put_Line ("R2.Extended => "
                & R2.Extended'Image);
      Put_Line ("----------------");
   end Show_Rs;
begin
   Show_Rs;

   Reset (R1);
   Reset (R2);
   Put_Line ("----------------");

   Show_Rs;
end Using_Constrained_Attribute;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Definite_Indefinite_Subtypes.
 ↪Constrained_Attribute
MD5: f7517fcd3c68a784f55064f188d4e7bb
```

Runtime output

```
R1'Constrained => FALSE
R1.Extended => FALSE
--
R2'Constrained => TRUE
R2.Extended => FALSE
----------------
---- Reset: R'Constrained => FALSE
---- Reset: R'Constrained => TRUE
----------------
R1'Constrained => FALSE
R1.Extended => TRUE
--
R2'Constrained => TRUE
R2.Extended => FALSE
----------------
```

When we run this code, the user messages from Show_Rs indicate to us that R1 is not constrained, while R2 is constrained. Because we declare R1 without specifying a value for the Extended discriminant, R1 is not constrained. In the declaration of R2, on the other hand, the explicit value for the Extended discriminant makes this object constrained. Note that, for both R1 and R2, the value of Extended is **False** in the declarations.

As we were just discussing, the Reset procedure includes checks to avoid mismatches in discriminants. When we don't have those checks, we might get exceptions at runtime. We can force this situation by replacing the implementation of the Reset procedure with the following lines:

```
--  [...]
begin
   Put_Line ("---- Reset: R'Constrained => "
             & R'Constrained'Image);
   R := Zero_Extended;
end Reset;
```

Running the code now generates a runtime exception:

```
raised CONSTRAINT_ERROR : unconstrained_types.adb:12 discriminant check failed
```

This exception is raised during the call to Reset (R2). As see in the code, R2 is constrained. Also, its Extended discriminant is set to **False**, which means that it doesn't have the V_Float component. Therefore, R2 is not compatible with the constant Zero_Extended object, so we cannot assign Zero_Extended to R2. Also, because R2 is constrained, its Extended discriminant cannot be modified.

The behavior is different for the call to Reset (R1), which works fine. Here, when we pass R1 as an argument to the Reset procedure, its Extended discriminant is **False** by default. Thus, R1 is also not compatible with the Zero_Extended object. However, because R1 is not constrained, the assignment modifies R1 (by changing the value of the Extended discriminant). Therefore, with the call to Reset, the Extended discriminant of R1 changes from **False** to **True**.

In the Ada Reference Manual

- 3.7.2 Operations of Discriminated Types[29]

25.1.4 Incomplete types

Incomplete types — as the name suggests — are types that have missing information in their declaration. This is a simple example:

```
type Incomplete;
```

Because this type declaration is incomplete, we need to provide the missing information at some later point. Consider the incomplete type R in the following example:

Listing 45: incomplete_type_example.ads

```
1  package Incomplete_Type_Example is
2
3     type R;
4     --  Incomplete type declaration!
5
6     type R is record
7        I : Integer;
8     end record;
9     --  type R is now complete!
10
11 end Incomplete_Type_Example;
```

[29] http://www.ada-auth.org/standards/22rm/html/RM-3-7-2.html

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Incomplete_Types.Incomplete_Types
MD5: 5ca250595f2b0cc101df286ab319982f
```

The first declaration of type R is incomplete. However, in the second declaration of R, we specify that R is a record. By providing this missing information, we're completing the type declaration of R.

It's also possible to declare an incomplete type in the private part of a package specification and its complete form in the package body. Let's rewrite the example above accordingly:

Listing 46: incomplete_type_example.ads

```
package Incomplete_Type_Example is

private

   type R;
   --  Incomplete type declaration!

end Incomplete_Type_Example;
```

Listing 47: incomplete_type_example.adb

```
package body Incomplete_Type_Example is

   type R is record
      I : Integer;
   end record;
   --  type R is now complete!

end Incomplete_Type_Example;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Incomplete_Types.Incomplete_Types_2
MD5: fd2f0301b4a63887add1cb2093692ddb
```

A typical application of incomplete types is to create linked lists using access types based on those incomplete types. This kind of type is called a recursive type. For example:

Listing 48: linked_list_example.ads

```
package Linked_List_Example is

   type Integer_List;

   type Next is access Integer_List;

   type Integer_List is record
      I : Integer;
      N : Next;
   end record;

end Linked_List_Example;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Incomplete_Types.Linked_List_Example
MD5: b2d3a048473d498bbe691bc6e38ca1e9
```

Here, the N component of `Integer_List` is essentially giving us access to the next element

of `Integer_List` type. Because the `Next` type is both referring to the `Integer_List` type and being used in the declaration of the `Integer_List` type, we need to start with an incomplete declaration of the `Integer_List` type and then complete it after the declaration of `Next`.

Incomplete types are useful to declare *mutually dependent types* (page 418), as we'll see later on. Also, we can also have formal incomplete types, as we'll discuss *later* (page 1926).

In the Ada Reference Manual

- 3.10.1 Incomplete Type Declarations[30]

25.1.5 Type view

Ada distinguishes between the partial and the full view of a type. The full view is a type declaration that contains all the information needed by the compiler. For example, the following declaration of type R represents the full view of this type:

Listing 49: full_view.ads

```
package Full_View is

   --  Full view of the R type:
   type R is record
      I : Integer;
   end record;

end Full_View;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_View.Full_View
MD5: d37792287d08f9aa3d32499e233516df
```

As soon as we start applying encapsulation and information hiding — via the **private** keyword — to a specific type, we are introducing a partial view and making only that view compile-time visible to clients. Doing so requires us to introduce the private part of the package (unless already present). For example:

Listing 50: partial_full_views.ads

```
package Partial_Full_Views is

   --  Partial view of the R type:
   type R is private;

private

   --  Full view of the R type:
   type R is record
      I : Integer;
   end record;

end Partial_Full_Views;
```

Code block metadata

[30] http://www.ada-auth.org/standards/22rm/html/RM-3-10-1.html

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_View.Partial_Full_View
MD5: b0cf748e43b23ea6c845e283c4266ff3
```

As indicated in the example, the `type R is private` declaration is the partial view of the R type, while the `type R is record [...]` declaration in the private part of the package is the full view.

Although the partial view doesn't contain the full type declaration, it contains very important information for the users of the package where it's declared. In fact, the partial view of a private type is all that users actually need to know to effectively use this type, while the full view is only needed by the compiler.

In the previous example, the partial view indicates that R is a private type, which means that, even though users cannot directly access any information stored in this type — for example, read the value of the I component of R —, they can use the R type to declare objects. For example:

Listing 51: main.adb

```
with Partial_Full_Views; use Partial_Full_Views;

procedure Main is
   --  Partial view of R indicates that
   --  R exists as a private type, so we
   --  can declare objects of this type:
   C : R;
begin
   --  But we cannot directly access any
   --  information declared in the full
   --  view of R:
   --
   --  C.I := 42;
   --
   null;
end Main;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_View.Partial_Full_View
MD5: 05bc9a75406d0a46f6d009d97885d010
```

Build output

```
main.adb:7:04: warning: variable "C" is never read and never assigned [-gnatwv]
```

In many cases, the restrictions applied to the partial and full views must match. For example, if we declare a limited type in the full view of a private type, its partial view must also be limited:

Listing 52: limited_private_example.ads

```
package Limited_Private_Example is

   --  Partial view must be limited,
   --  since the full view is limited.
   type R is limited private;

private

   type R is limited record
      I : Integer;
   end record;
```

(continues on next page)

(continued from previous page)

```
12
13 end Limited_Private_Example;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_View.Limited_Private
MD5: 23d01b93fe052a500c8ca6ff76a2fd51
```

There are, however, situations where the full view may contain additional requirements that aren't mentioned in the partial view. For example, a type may be declared as non-tagged in the partial view, but, at the same time, be tagged in the full view:

Listing 53: tagged_full_view_example.ads

```
1  package Tagged_Full_View_Example is
2
3     --  Partial view using non-tagged type:
4     type R is private;
5
6  private
7
8     --  Full view using tagged type:
9     type R is tagged record
10       I : Integer;
11    end record;
12
13 end Tagged_Full_View_Example;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_View.Tagged_Full_View
MD5: 0ff9142b1ee086695b98b72a9d0f50ac
```

In this case, from a user's perspective, the R type is non-tagged, so that users cannot use any object-oriented programming features for this type. In the package body of Tagged_Full_View_Example, however, this type is tagged, so that all object-oriented programming features are available for subprograms of the package body that make use of this type. Again, the partial view of the private type contains the most important information for users that want to declare objects of this type.

In the Ada Reference Manual

- 7.3 Private Types and Private Extensions[31]

Non-Record Private Types

Although it's very common to declare private types as record types, this is not the only option. In fact, we could declare any type in the full view — scalars, for example —, so we could declare a "private integer" type:

Listing 54: private_integers.ads

```
1  package Private_Integers is
2
3     --  Partial view of private Integer type:
```

(continues on next page)

[31] http://www.ada-auth.org/standards/22rm/html/RM-7-3.html

(continued from previous page)

```
   type Private_Integer is private;

private

   --  Full view of private Integer type:
   type Private_Integer is new Integer;

end Private_Integers;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_View.Private_Integer
MD5: f1fcbed95e0f66a6f67d1bfd9ba9df1c
```

This code compiles as expected, but isn't very useful. We can improve it by adding operators to it, for example:

Listing 55: private_integers.ads

```
package Private_Integers is

   --  Partial view of private Integer type:
   type Private_Integer is private;

   function "+" (Left, Right : Private_Integer)
                 return Private_Integer;

private

   --  Full view of private Integer type:
   type Private_Integer is new Integer;

end Private_Integers;
```

Listing 56: private_integers.adb

```
package body Private_Integers is

   function "+" (Left, Right : Private_Integer)
                 return Private_Integer
   is
      Res : constant Integer :=
               Integer (Left) + Integer (Right);
      --  Note that we're converting Left
      --  and Right to Integer, which calls
      --  the "+" operator of the Integer
      --  type. Writing "Left + Right" would
      --  have called the "+" operator of
      --  Private_Integer, which leads to
      --  recursive calls, as this is the
      --  operator we're currently in.
   begin
      return Private_Integer (Res);
   end "+";

end Private_Integers;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_View.Private_Integer
MD5: ac161cb5debfde16465c45949cf682d7
```

Now, let's use the new operator in a test application:

Listing 57: show_private_integers.adb

```
with Private_Integers; use Private_Integers;

procedure Show_Private_Integers is
   A, B : Private_Integer;
begin
   A := A + B;
end Show_Private_Integers;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_View.Private_Integer
MD5: 5933779ce5f0802b448df96c42e65a8d
```

Build output

```
show_private_integers.adb:4:07: warning: variable "B" is read but never assigned [-
↪gnatwv]
show_private_integers.adb:6:09: warning: "A" may be referenced before it has a␣
↪value [enabled by default]
```

In this example, we use the + operator as if we were adding two common integer variables of **Integer** type.

Unconstrained Types

There are, however, some limitations: we cannot use unconstrained types such as arrays or even discriminants for arrays in the same way as we did for scalars. For example, the following declarations won't work:

Listing 58: private_arrays.ads

```
package Private_Arrays is

   type Private_Unconstrained_Array is private;

   type Private_Constrained_Array
     (L : Positive) is private;

private

   type Integer_Array is
     array (Positive range <>) of Integer;

   type Private_Unconstrained_Array is
     array (Positive range <>) of Integer;

   type Private_Constrained_Array
     (L : Positive) is
       array (1 .. 2) of Integer;

   --  NOTE: using an array type fails as well:
   --
   --  type Private_Constrained_Array
   --    (L : Positive) is
   --      Integer_Array (1 .. L);

end Private_Arrays;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_View.Private_Array
MD5: b873c2d381c159532b429101e4533c05
```

Build output

```
private_arrays.ads:13:09: error: full view of "Private_Unconstrained_Array" not␣
 ↪compatible with declaration at line 3
private_arrays.ads:13:09: error: one is constrained, the other unconstrained
private_arrays.ads:17:07: error: elementary or array type cannot have discriminants
gprbuild: *** compilation phase failed
```

Completing the private type with an unconstrained array type in the full view is not allowed because clients could expect, according to their view, to declare objects of the type. But doing so would not be allowed according to the full view. So this is another case of the partial view having to present clients with a sufficiently *true* view of the type's capabilities.

One solution is to rewrite the declaration of `Private_Constrained_Array` using a record type:

Listing 59: private_arrays.ads

```
1  package Private_Arrays is
2
3     type Private_Constrained_Array
4       (L : Positive) is private;
5
6  private
7
8     type Integer_Array is
9       array (Positive range <>) of Integer;
10
11    type Private_Constrained_Array
12      (L : Positive) is
13    record
14       Arr : Integer_Array  (1 .. 2);
15    end record;
16
17 end Private_Arrays;
```

Listing 60: declare_private_array.adb

```
1  with Private_Arrays; use Private_Arrays;
2
3  procedure Declare_Private_Array is
4    Arr : Private_Constrained_Array (5);
5  begin
6    null;
7  end Declare_Private_Array;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_View.Private_Array
MD5: 3830721499a59d85efddd4989aa7c288
```

Build output

```
declare_private_array.adb:4:03: warning: variable "Arr" is never read and never␣
 ↪assigned [-gnatwv]
```

Now, the code compiles fine — but we had to use a record type in the full view to make it work.

Another solution is to make the private type indefinite. In this case, the client's partial view would be consistent with a completion as an indefinite type in the private part:

Listing 61: private_arrays.ads

```
package Private_Arrays is

   type Private_Constrained_Array (<>) is
     private;

   function Init
     (L : Positive)
      return Private_Constrained_Array;

private

   type Private_Constrained_Array is
     array (Positive range <>) of Integer;

end Private_Arrays;
```

Listing 62: private_arrays.adb

```
package body Private_Arrays is

   function Init
     (L : Positive)
      return Private_Constrained_Array
   is
      PCA : Private_Constrained_Array (1 .. L);
   begin
      return PCA;
   end Init;

end Private_Arrays;
```

Listing 63: declare_private_array.adb

```
with Private_Arrays; use Private_Arrays;

procedure Declare_Private_Array is
  Arr : Private_Constrained_Array := Init (5);
begin
  null;
end Declare_Private_Array;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_View.Private_Array
MD5: cd170a1e44fffb93314776a68f1cb413
```

Build output

```
private_arrays.adb:7:07: warning: variable "PCA" is read but never assigned [-
↪gnatwv]
```

The bounds for the object's declaration come from the required initial value when an object is declared. In this case, we initialize the object with a call to the `Init` function.

25.1.6 Type conversion

An important operation when dealing with objects of different types is type conversion, which we already discussed in the *Introduction to Ada course* (page 56). In fact, we can convert an object `Obj_X` of an *operand* type X to a similar, closely related *target* type Y by simply indicating the target type: `Y (Obj_X)`. In this section, we discuss type conversions for different kinds of types.

Ada distinguishes between two kinds of conversion: value conversion and view conversion. The main difference is the way how the operand (argument) of the conversion is evaluated:

- in a value conversion, the operand is evaluated as an *expression* (page 581);
- in a view conversion, the operand is evaluated as a name.

In other words, we cannot use expressions such as `2 * A` in a view conversion, but only A. In a value conversion, we could use both forms.

In the Ada Reference Manual

- 4.6 Type Conversions[32]

Value conversion

Value conversions are possible for various types. In this section, we see some examples, starting with types derived from scalar types up to array conversions.

Root and derived types

Let's start with the conversion between a scalar type and its derived types. For example, we can convert back-and-forth between the **Integer** type and the derived `Int` type:

Listing 64: custom_integers.ads

```
package Custom_Integers is

   type Int is new Integer
     with Dynamic_Predicate => Int /= 0;

   function Double (I : Integer)
                    return Integer is
     (I * 2);

end Custom_Integers;
```

Listing 65: show_conversion.adb

```
with Ada.Text_IO;     use Ada.Text_IO;
with Custom_Integers; use Custom_Integers;

procedure Show_Conversion is
   Int_Var     : Int     := 1;
   Integer_Var : Integer := 2;
begin
   --  Int to Integer conversion
   Integer_Var := Integer (Int_Var);
```

(continues on next page)

[32] http://www.ada-auth.org/standards/22rm/html/RM-4-6.html

(continued from previous page)

```
10
11    Put_Line ("Integer_Var : "
12              & Integer_Var'Image);
13
14    --  Int to Integer conversion
15    --  as an actual parameter
16    Integer_Var := Double (Integer (Int_Var));
17
18    Put_Line ("Integer_Var : "
19              & Integer_Var'Image);
20
21    --  Integer to Int conversion
22    --  using an expression
23    Int_Var     := Int (Integer_Var * 2);
24
25    Put_Line ("Int_Var :     "
26              & Int_Var'Image);
27 end Show_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Root_Derived_Type_
 ↪Conversion
MD5: 7cd324f308edc34de3bc4bccce63f1ee
```

Runtime output

```
Integer_Var :  1
Integer_Var :  2
Int_Var :      4
```

In the `Show_Conversion` procedure from this example, we first convert from `Int` to **`Integer`**. Then, we do the same conversion while providing the resulting value as an actual parameter for the `Double` function. Finally, we convert the `Integer_Var * 2` expression from **`Integer`** to `Int`.

Note that the converted value must conform to any constraints that the target type might have. In the example above, `Int` has a predicate that dictates that its value cannot be zero. This (dynamic) predicate is checked at runtime, so an exception is raised if it fails:

Listing 66: show_conversion.adb

```
1  with Ada.Text_IO;     use Ada.Text_IO;
2  with Custom_Integers; use Custom_Integers;
3
4  procedure Show_Conversion is
5     Int_Var     : Int;
6     Integer_Var : Integer;
7  begin
8     Integer_Var := 0;
9     Int_Var     := Int (Integer_Var);
10
11    Put_Line ("Int_Var : "
12              & Int_Var'Image);
13 end Show_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Root_Derived_Type_
 ↪Conversion
MD5: 4150cdffd4c1fed39fa1728a77fa599f
```

Runtime output

```
raised ADA.ASSERTIONS.ASSERTION_ERROR : Dynamic_Predicate failed at show_
 ↪conversion.adb:9
```

In this case, the conversion from `Integer` to `Int` fails because, while zero is a valid integer value, it doesn't obey `Int`'s predicate.

Numeric type conversion

A typical conversion is the one between integer and floating-point values. For example:

Listing 67: show_conversion.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Conversion is
   F : Float   := 1.0;
   I : Integer := 2;
begin
   I := Integer (F);

   Put_Line ("I : "
             & I'Image);

   I := 4;
   F := Float (I);

   Put_Line ("F :   "
             & F'Image);
end Show_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Numeric_Type_
 ↪Conversion
MD5: f64649c786377617b0bc9ff49475ba55
```

Runtime output

```
I :  1
F :    4.00000E+00
```

Also, we can convert between fixed-point types and floating-point or integer types:

Listing 68: fixed_point_defs.ads

```
package Fixed_Point_Defs is
   S     : constant := 32;
   Exp   : constant := 15;
   D     : constant := 2.0 ** (-S + Exp + 1);

   type TQ15_31 is delta D
     range -1.0 * 2.0 ** Exp ..
            1.0 * 2.0 ** Exp - D;

   pragma Assert (TQ15_31'Size = S);
end Fixed_Point_Defs;
```

Listing 69: show_conversion.adb

```
with Fixed_Point_Defs; use Fixed_Point_Defs;
with Ada.Text_IO;      use Ada.Text_IO;

procedure Show_Conversion is
   F  : Float;
   FP : TQ15_31;
   I  : Integer;
begin
   FP := TQ15_31 (10.25);
   I  := Integer (FP);

   Put_Line ("FP : "
             & FP'Image);
   Put_Line ("I : "
             & I'Image);

   I  := 128;
   FP := TQ15_31 (I);
   F  := Float (FP);

   Put_Line ("FP : "
             & FP'Image);
   Put_Line ("F :   "
             & F'Image);
end Show_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Numeric_Type_
 ↪Conversion
MD5: 70714ba396b03469397b982e00299561
```

Runtime output

```
FP :  10.25000
I :  10
FP :  128.00000
F :    1.28000E+02
```

As we can see in the examples above, converting between different numeric types works in all directions. (Of course, rounding is applied when converting from floating-point to integer types, but this is expected.)

Enumeration conversion

We can also convert between an enumeration type and a type derived from it:

Listing 70: custom_enumerations.ads

```
package Custom_Enumerations is

   type Priority is (Low, Mid, High);

   type Important_Priority is new
     Priority range Mid .. High;

end Custom_Enumerations;
```

Listing 71: show_conversion.adb

```
with Ada.Text_IO;         use Ada.Text_IO;
with Custom_Enumerations; use Custom_Enumerations;

procedure Show_Conversion is
   P  : Priority           := Low;
   IP : Important_Priority := High;
begin
   P := Priority (IP);

   Put_Line ("P:  "
             & P'Image);

   P  := Mid;
   IP := Important_Priority (P);

   Put_Line ("IP: "
             & IP'Image);
end Show_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Enumeration_Type_
 ↪Conversion
MD5: b1e42cbd8b57291d3b3a9968c41efdd7
```

Runtime output

```
P:  HIGH
IP: MID
```

In this example, we have the `Priority` type and the derived type `Important_Priority`. As expected, the conversion works fine when the converted value is in the range of the target type. If not, an exception is raised:

Listing 72: show_conversion.adb

```
with Ada.Text_IO;         use Ada.Text_IO;
with Custom_Enumerations; use Custom_Enumerations;

procedure Show_Conversion is
   P  : Priority;
   IP : Important_Priority;
begin
   P  := Low;
   IP := Important_Priority (P);

   Put_Line ("IP: "
             & IP'Image);
end Show_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Enumeration_Type_
 ↪Conversion
MD5: 6bbc777d4b44023bf572ca5dc6c2b4f8
```

Build output

```
show_conversion.adb:9:10: warning: value not in range of type "Important_Priority"␣
 ↪defined at custom_enumerations.ads:5 [enabled by default]
show_conversion.adb:9:10: warning: Constraint_Error will be raised at run time␣
 ↪[enabled by default]
```

Runtime output

```
raised CONSTRAINT_ERROR : show_conversion.adb:9 range check failed
```

In this example, an exception is raised because Low is not in the Important_Priority type's range.

Array conversion

Similarly, we can convert between array types. For example, if we have the array type Integer_Array and its derived type Derived_Integer_Array, we can convert between those array types:

Listing 73: custom_arrays.ads

```
package Custom_Arrays is

   type Integer_Array is
     array (Positive range <>) of Integer;

   type Derived_Integer_Array is new
     Integer_Array;

end Custom_Arrays;
```

Listing 74: show_conversion.adb

```
pragma Ada_2022;

with Ada.Text_IO;   use Ada.Text_IO;
with Custom_Arrays; use Custom_Arrays;

procedure Show_Conversion is
   subtype Common_Range is Positive range 1 .. 3;

   AI : Integer_Array (Common_Range);
   AI_D : Derived_Integer_Array (Common_Range);
begin
   AI_D := [1, 2, 3];
   AI := Integer_Array (AI_D);

   Put_Line ("AI: "
             & AI'Image);

   AI   := [4, 5, 6];
   AI_D := Derived_Integer_Array (AI);

   Put_Line ("AI_D: "
             & AI_D'Image);
end Show_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Array_Type_
 ↪Conversion
MD5: e0a9fd519685b418a06dc7a3d0dab1c0
```

Runtime output

```
AI:
[ 1,  2,  3]
AI_D:
[ 4,  5,  6]
```

Note that both arrays must have the same number of components in order for the conversion to be successful. (Sliding is fine, though.) In this example, both arrays have the same range: Common_Range.

We can also convert between array types that aren't derived one from the other. As long as the components and the index subtypes are of the same type, the conversion between those types is possible. To be more precise, these are the requirements for the array conversion to be accepted:

- The component types must be the same type.
- The index types (or subtypes) must be the same or, at least, convertible.
- The dimensionality of the arrays must be the same.
- The bounds must be compatible (but not necessarily equal).

Converting between different array types can be very handy, especially when we're dealing with array types that were not declared in the same package. For example:

Listing 75: custom_arrays_1.ads

```
1  package Custom_Arrays_1 is
2
3     type Integer_Array_1 is
4       array (Positive range <>) of Integer;
5
6     type Float_Array_1 is
7       array (Positive range <>) of Float;
8
9  end Custom_Arrays_1;
```

Listing 76: custom_arrays_2.ads

```
1  package Custom_Arrays_2 is
2
3     type Integer_Array_2 is
4       array (Positive range <>) of Integer;
5
6     type Float_Array_2 is
7       array (Positive range <>) of Float;
8
9  end Custom_Arrays_2;
```

Listing 77: show_conversion.adb

```
1  pragma Ada_2022;
2
3  with Ada.Text_IO;      use Ada.Text_IO;
4  with Custom_Arrays_1; use Custom_Arrays_1;
5  with Custom_Arrays_2; use Custom_Arrays_2;
6
```

(continues on next page)

(continued from previous page)

```
procedure Show_Conversion is
   subtype Common_Range is Positive range 1 .. 3;

   AI_1 : Integer_Array_1 (Common_Range);
   AI_2 : Integer_Array_2 (Common_Range);
   AF_1 : Float_Array_1 (Common_Range);
   AF_2 : Float_Array_2 (Common_Range);
begin
   AI_2 := [1, 2, 3];
   AI_1 := Integer_Array_1 (AI_2);

   Put_Line ("AI_1: "
             & AI_1'Image);

   AI_1 := [4, 5, 6];
   AI_2 := Integer_Array_2 (AI_1);

   Put_Line ("AI_2: "
             & AI_2'Image);

   --  ERROR: Cannot convert arrays whose
   --         components have different types:
   --
   --  AF_1 := Float_Array_1 (AI_1);
   --
   --  Instead, use array aggregate where each
   --  component is converted from integer to
   --  float:
   --
   AF_1 := [for I in AF_1'Range =>
               Float (AI_1 (I))];

   Put_Line ("AF_1: "
             & AF_1'Image);

   AF_2 := Float_Array_2 (AF_1);

   Put_Line ("AF_2: "
             & AF_2'Image);
end Show_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Array_Type_
↪Conversion
MD5: 5c62f7cf94eedf8b0b223c24a83cc8d3
```

Runtime output

```
AI_1:
[ 1,  2,  3]
AI_2:
[ 4,  5,  6]
AF_1:
[ 4.00000E+00,  5.00000E+00,  6.00000E+00]
AF_2:
[ 4.00000E+00,  5.00000E+00,  6.00000E+00]
```

As we can see in this example, the fact that `Integer_Array_1` and `Integer_Array_2` have the same component type (**`Integer`**) allows us to convert between them. The same applies to the `Float_Array_1` and `Float_Array_2` types.

A conversion is not possible when the component types don't match. Even though we can convert between integer and floating-point types, we cannot convert an array of integers to an array of floating-point directly. Therefore, we cannot write a statement such as `AF_1 := Float_Array_1 (AI_1);`.

However, when the components don't match, we can of course implement the array conversion by converting the individual components. For the example above, we used an iterated component association in an array aggregate: `[for I in AF_1'Range => Float (AI_1 (I))];`. (We discuss this topic later *in another chapter* (page 450).)

We may also encounter array types originating from the instantiation of generic packages. In this case as well, we can use array conversions. Consider the following generic package:

Listing 78: custom_arrays.ads

```
generic
   type T is private;
package Custom_Arrays is
   type T_Array is
     array (Positive range <>) of T;
end Custom_Arrays;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Generic_Array_Type_
 ↪Conversion
MD5: 8b3a963a1292a90d99d83c6d81ce3995
```

We could instantiate this generic package and reuse parts of the previous code example:

Listing 79: show_conversion.adb

```
pragma Ada_2022;

with Ada.Text_IO;   use Ada.Text_IO;
with Custom_Arrays;

procedure Show_Conversion is
   package CA_Int_1 is
     new Custom_Arrays (T => Integer);
   package CA_Int_2 is
     new Custom_Arrays (T => Integer);

   subtype Common_Range is Positive range 1 .. 3;

   AI_1 : CA_Int_1.T_Array (Common_Range);
   AI_2 : CA_Int_2.T_Array (Common_Range);
begin
   AI_2 := [1, 2, 3];
   AI_1 := CA_Int_1.T_Array (AI_2);

   Put_Line ("AI_1: "
             & AI_1'Image);

   AI_1 := [4, 5, 6];
   AI_2 := CA_Int_2.T_Array (AI_1);

   Put_Line ("AI_2: "
             & AI_2'Image);
end Show_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Generic_Array_Type_
 ↪Conversion
MD5: 956186d864763924b93b6a9d807525b6
```

Runtime output

```
AI_1:
[ 1,  2,  3]
AI_2:
[ 4,  5,  6]
```

As we can see in this example, each of the instantiated `CA_Int_1` and `CA_Int_2` packages has a `T_Array` type. Even though these `T_Array` types have the same name, they're actually completely unrelated types. However, we can still convert between them in the same way as we did in the previous code examples.

View conversion

As mentioned before, view conversions just allow names to be converted. Thus, we cannot use expressions in this case.

Note that a view conversion never changes the value during the conversion. We could say that a view conversion is simply making us *view* an object from a different angle. The object itself is still the same for both the original and the target types.

For example, consider this package:

Listing 80: some_tagged_types.ads

```
1  package Some_Tagged_Types is
2
3     type T is tagged record
4        A : Integer;
5     end record;
6
7     type T_Derived is new T with record
8        B : Float;
9     end record;
10
11    Obj : T_Derived;
12
13 end Some_Tagged_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Tagged_Types_View
MD5: 2e18ba972682f1ae1d38e38842fde48e
```

Here, `Obj` is an object of type `T_Derived`. When we *view* this object, we notice that it has two components: `A` and `B`. However, we could *view* this object as being of type `T`. From that perspective, this object only has one component: `A`. (Note that changing the perspective doesn't change the object itself.) Therefore, a view conversion from `T_Derived` to `T` just makes us *view* the object `Obj` from a different angle.

In this sense, a view conversion changes the view of a given object to the target type's view, both in terms of components that exist and operations that are available. It doesn't really change anything at all in the value itself.

There are basically two kinds of view conversions: the ones using tagged types and the ones using untagged types. We discuss these kinds of conversion in this section.

View conversion of tagged types

A conversion between tagged types is a view conversion. Let's consider a typical code example that declares one, two and three-dimensional points:

Listing 81: points.ads

```
package Points is

   type Point_1D is tagged record
      X : Float;
   end record;

   procedure Display (P : Point_1D);

   type Point_2D is new Point_1D with record
      Y : Float;
   end record;

   procedure Display (P : Point_2D);

   type Point_3D is new Point_2D with record
      Z : Float;
   end record;

   procedure Display (P : Point_3D);

end Points;
```

Listing 82: points.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Points is

   procedure Display (P : Point_1D) is
   begin
      Put_Line ("(X => " & P.X'Image & ")");
   end Display;

   procedure Display (P : Point_2D) is
   begin
      Put_Line ("(X => " & P.X'Image
                & ", Y => " & P.Y'Image & ")");
   end Display;

   procedure Display (P : Point_3D) is
   begin
      Put_Line ("(X => " & P.X'Image
                & ", Y => " & P.Y'Image
                & ", Z => " & P.Z'Image & ")");
   end Display;

end Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Tagged_Type_
 ↪Conversion
MD5: 0acc05ae2310ab4ba038dfdb6bae0495
```

We can use the types from the `Points` package and convert between each other:

Listing 83: show_conversion.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Points;      use Points;

procedure Show_Conversion is
   P_1D : Point_1D;
   P_3D : Point_3D;
begin
   P_3D := (X => 0.1, Y => 0.5, Z => 0.3);
   P_1D := Point_1D (P_3D);

   Put ("P_3D : ");
   Display (P_3D);

   Put ("P_1D : ");
   Display (P_1D);
end Show_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Tagged_Type_
 ↪Conversion
MD5: fb8e07c8f2399cfae935179d8f413150
```

Runtime output

```
P_3D : (X =>  1.00000E-01, Y =>  5.00000E-01, Z =>  3.00000E-01)
P_1D : (X =>  1.00000E-01)
```

In this example, as expected, we're able to convert from the `Point_3D` type (which has three components) to the `Point_1D` type, which has only one component.

View conversion of untagged types

For untagged types, a view conversion is the one that happens when we have an object of an untagged type as an actual parameter for a formal **`in out`** or **`out`** parameter.

Let's see a code example. Consider the following simple procedure:

Listing 84: double.ads

```
procedure Double (X : in out Float);
```

Listing 85: double.adb

```
procedure Double (X : in out Float) is
begin
   X := X * 2.0;
end Double;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Untagged_Type_View_
 ↪Conversion
MD5: 31f4409d9faeaf213c5940de65eeb014
```

The `Double` procedure has an **`in out`** parameter of **`Float`** type. We can call this procedure using an integer variable `I` as the actual parameter. For example:

Listing 86: show_conversion.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Double;

procedure Show_Conversion is
   I : Integer;
begin
   I := 2;
   Put_Line ("I : "
             & I'Image);

   --  Calling Double with
   --  Integer parameter:
   Double (Float (I));
   Put_Line ("I : "
             & I'Image);
end Show_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Untagged_Type_View_
 ↪Conversion
MD5: 2256d3c120d569789dcd4c9959ed9d0f
```

Runtime output

```
I :  2
I :  4
```

In this case, the `Float (I)` conversion in the call to `Double` creates a temporary floating-point variable. This is the same as if we had written the following code:

Listing 87: show_conversion.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Double;

procedure Show_Conversion is
   I : Integer;
begin
   I := 2;
   Put_Line ("I : "
             & I'Image);

   declare
      F : Float := Float (I);
   begin
      Double (F);
      I := Integer (F);
   end;
   Put_Line ("I : "
             & I'Image);
end Show_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Untagged_Type_View_
 ↪Conversion
MD5: 3b90caf789952710ece42141a7b60968
```

Runtime output

```
I :  2
I :  4
```

In this sense, the view conversion that happens in `Double (Float (I))` can be considered syntactic sugar, as it allows us to elegantly write two conversions in a single statement.

Implicit conversions

Implicit conversions are only possible when we have a type T and a subtype S related to the T type. For example:

Listing 88: custom_integers.ads

```
package Custom_Integers is

   type Int is new Integer
     with Dynamic_Predicate => Int /= 0;

   subtype Sub_Int_1 is Integer
     with Dynamic_Predicate => Sub_Int_1 /= 0;

   subtype Sub_Int_2 is Sub_Int_1
     with Dynamic_Predicate => Sub_Int_2 /= 1;

end Custom_Integers;
```

Listing 89: show_conversion.adb

```
with Ada.Text_IO;     use Ada.Text_IO;
with Custom_Integers; use Custom_Integers;

procedure Show_Conversion is
   Int_Var       : Int;
   Sub_Int_1_Var : Sub_Int_1;
   Sub_Int_2_Var : Sub_Int_2;
   Integer_Var   : Integer;
begin
   Integer_Var := 5;
   Int_Var     := Int (Integer_Var);

   Put_Line ("Int_Var :       "
             & Int_Var'Image);

   --  Implicit conversions:
   --  no explicit conversion required!
   Sub_Int_1_Var := Integer_Var;
   Sub_Int_2_Var := Integer_Var;

   Put_Line ("Sub_Int_1_Var : "
             & Sub_Int_1_Var'Image);
   Put_Line ("Sub_Int_2_Var : "
             & Sub_Int_2_Var'Image);
end Show_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Implicit_Subtype_
 ↪Conversion
MD5: dbbe498fa66701ca94f48119b1bc1a91
```

Runtime output

```
Int_Var :        5
Sub_Int_1_Var :  5
Sub_Int_2_Var :  5
```

In this example, we declare the `Int` type and the `Sub_Int_1` and `Sub_Int_2` subtypes:

- the `Int` type is derived from the **`Integer`** type,
- `Sub_Int_1` is a subtype of the **`Integer`** type, and
- `Sub_Int_2` is a subtype of the `Sub_Int_1` subtype.

We need an explicit conversion when converting between the **`Integer`** and `Int` types. However, as the conversion is implicit for subtypes, we can simply write `Sub_Int_1_Var := Integer_Var;`. (Of course, writing the explicit conversion `Sub_Int_1 (Integer_Var)` in the assignment is possible as well.) Also, the same applies to the `Sub_Int_2` subtype: we can write an implicit conversion in the `Sub_Int_2_Var := Integer_Var;` statement.

Conversion of other types

For other kinds of types, such as records, a direct conversion as we've seen so far isn't possible. In this case, we have to write a conversion function ourselves. A common convention in Ada is to name this function `To_Typename`. For example, if we want to convert from any type to **`Integer`** or **`Float`**, we implement the `To_Integer` and `To_Float` functions, respectively. (Obviously, because Ada supports subprogram overloading, we can have multiple `To_Typename` functions for different operand types.)

Let's see a code example:

Listing 90: custom_rec.ads

```
package Custom_Rec is

   type Rec is record
      X : Integer;
   end record;

   function To_Integer (R : Rec)
                        return Integer is
     (R.X);

end Custom_Rec;
```

Listing 91: show_conversion.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Custom_Rec;  use Custom_Rec;

procedure Show_Conversion is
   R : Rec;
   I : Integer;
begin
   R := (X => 2);
   I := To_Integer (R);

   Put_Line ("I : " & I'Image);
end Show_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Other_Type_
 ↪Conversions
MD5: d52a4fde48243a7dd6942f0b2b91ce62
```

Runtime output

```
I :  2
```

In this example, we have the `To_Integer` function that converts from the Rec type to the **`Integer`** type.

In other languages

In C++, you can define conversion operators to cast between objects of different classes. Also, you can overload the `=` operator. Consider this example:

```cpp
#include <iostream>

class T1 {
public:
    T1 (float x) :
      x(x) {}

    // If class T3 is declared before class
    // T1, we can overload the "=" operator.
    //
    // void operator=(T3 v) {
    //     x = static_cast<float>(v);
    // }

    void display();
private:
   float x;
};

class T3 {
public:
    T3 (float x, float y, float z) :
      x(x), y(y), z(z) {}

    // implicit conversion
    operator float() const {
        return (x + y + z) / 3.0;
    }

    // implicit conversion
    //
    // operator T1() const {
    //     return T1((x + y + z) / 3.0);
    // }

    // explicit conversion (C++11)
    explicit operator T1() const {
        return T1(float(*this));
    }

    void display();

private:
    float x, y, z;
};
```

(continues on next page)

(continued from previous page)

```
void T1::display()
{
    std::cout << "(x => " << x
              << ")" << std::endl;
}

void T3::display()
{
    std::cout << "(x => " << x
              << "y => "  << y
              << "z => "  << z
              << ")" << std::endl;
}

int main ()
{
    const T3 t_3 (0.5, 0.4, 0.6);
    T1 t_1 (0.0);
    float f;

    // Implicit conversion
    f = t_3;

    std::cout << "f : " << f
              << std::endl;

    // Explicit conversion
    f = static_cast<float>(t_3);

    // f = (float)t_3;

    std::cout << "f : " << f
              << std::endl;

    // Explicit conversion
    t_1 = static_cast<T1>(t_3);

    // t_1 = (T1)t_3;

    std::cout << "t_1 : ";
    t_1.display();
    std::cout << std::endl;
}
```

Here, we're using `operator float()` and `operator T1()` to cast from an object of class T3 to a floating-point value and an object of class T1, respectively. (If we switch the order and declare the T3 class before the T1 class, we could overload the `=` operator, as you can see in the commented-out lines.)

In Ada, this kind of conversions isn't available. Instead, we have to implement conversion functions such as the `To_Integer` function from the previous code example. This is the corresponding implementation:

Listing 92: custom_defs.ads

```
1  package Custom_Defs is
2
3     type T1 is private;
4
5     function Init (X : Float)
```

(continues on next page)

(continued from previous page)

```
                  return T1;

   procedure Display (Obj : T1);

   type T3 is private;

   function Init (X, Y, Z : Float)
                  return T3;

   function To_Float (Obj : T3)
                      return Float;

   function To_T1 (Obj : T3)
                   return T1;

   procedure Display (Obj : T3);

private
   type T1 is record
      X : Float;
   end record;

   function Init (X : Float)
                  return T1 is
     (X => X);

   type T3 is record
      X, Y, Z : Float;
   end record;

   function Init (X, Y, Z : Float)
                  return T3 is
     (X => X, Y => Y, Z => Z);

end Custom_Defs;
```

Listing 93: custom_defs.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Custom_Defs is

   procedure Display (Obj : T1) is
   begin
      Put_Line ("(X => "
                & Obj.X'Image & ")");
   end Display;

   function To_Float (Obj : T3)
                      return Float is
     ((Obj.X + Obj.Y + Obj.Z) / 3.0);

   function To_T1 (Obj : T3)
                   return T1 is
     (Init (To_Float (Obj)));

   procedure Display (Obj : T3) is
   begin
      Put_Line ("(X => "    & Obj.X'Image
                & ", Y => " & Obj.Y'Image
                & ", Z => " & Obj.Z'Image
```

(continues on next page)

(continued from previous page)

```
                & ")");
   end Display;

end Custom_Defs;
```

Listing 94: show_conversion.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Custom_Defs; use Custom_Defs;

procedure Show_Conversion is
   T_3 : constant T3 := Init (0.5, 0.4, 0.6);
   T_1 :          T1 := Init (0.0);
   F   : Float;
begin
   --  Explicit conversion from
   --  T3 to Float type
   F := To_Float (T_3);

   Put_Line ("F : " & F'Image);

   --  Explicit conversion from
   --  T3 to T1 type
   T_1 := To_T1 (T_3);

   Put ("T_1 : ");
   Display (T_1);
end Show_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Type_Conversion.Explicit_Rec_
 ↪Conversion
MD5: b3e7be5488fb8026b4386063ba16aaeb
```

Runtime output

```
F :  5.00000E-01
T_1 : (X =>  5.00000E-01)
```

In this example, we *translate* the casting operators from the C++ version by implementing the `To_Float` and `To_T1` functions. (In addition to that, we replace the C++ constructors by `Init` functions.)

25.1.7 Qualified Expressions

We already saw qualified expressions in the *Introduction to Ada* (page 91) course. As mentioned there, a qualified expression specifies the exact type or subtype that the target expression will be resolved to, and it can be either any expression in parentheses, or an aggregate:

Listing 95: simple_integers.ads

```
package Simple_Integers is

   type Int is new Integer;

```

(continues on next page)

(continued from previous page)

```
   subtype Int_Not_Zero is Int
     with Dynamic_Predicate => Int_Not_Zero /= 0;

end Simple_Integers;
```

Listing 96: show_qualified_expressions.adb

```
with Simple_Integers; use Simple_Integers;

procedure Show_Qualified_Expressions is
   I : Int;
begin
   --  Using qualified expression Int'(N)
   I := Int'(0);
end Show_Qualified_Expressions;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Qualified_Expressions.Example
MD5: 0a83e10b51c72827e322984bd5c8009d
```

Here, the qualified expression `Int'(0)` indicates that the value zero is of `Int` type.

In the Ada Reference Manual

- 4.7 Qualified Expressions[33]

Verifying subtypes

Note: This feature was introduced in Ada 2022.

We can use qualified expressions to verify a subtype's predicate:

Listing 97: show_qualified_expressions.adb

```
with Simple_Integers; use Simple_Integers;

procedure Show_Qualified_Expressions is
   I : Int;
begin
   I := Int_Not_Zero'(0);
end Show_Qualified_Expressions;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Qualified_Expressions.Example
MD5: 3c4ab8ad7bf75ae029047f673aa15d70
```

Build output

```
show_qualified_expressions.adb:6:23: warning: expression fails predicate check on
 ↪"Int_Not_Zero" [enabled by default]
show_qualified_expressions.adb:6:23: warning: check will fail at run time [-gnatw.
 ↪a]
```

[33] http://www.ada-auth.org/standards/22rm/html/RM-4-7.html

Runtime output

```
raised ADA.ASSERTIONS.ASSERTION_ERROR : Dynamic_Predicate failed at show_qualified_
↪expressions.adb:6
```

Here, the qualified expression `Int_Not_Zero'(0)` checks the dynamic predicate of the subtype. (This predicate check fails at runtime.)

25.1.8 Default initial values

In the *Introduction to Ada course* (page 65), we've seen that record components can have default values. For example:

Listing 98: defaults.ads

```
1  package Defaults is
2
3     type R is record
4       X : Positive := 1;
5       Y : Positive := 10;
6     end record;
7
8  end Defaults;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Default_Initial_Values.Defaults_1
MD5: e230be602cbb24a854e71c8176c7148c
```

In this section, we'll extend the concept of default values to other kinds of type declarations, such as scalar types and arrays.

To assign a default value for a scalar type declaration — such as an enumeration and a new integer —, we use the `Default_Value` aspect:

Listing 99: defaults.ads

```
1  package Defaults is
2
3     type E is (E1, E2, E3)
4       with Default_Value => E1;
5
6     type T is new Integer
7       with Default_Value => -1;
8
9  end Defaults;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Default_Initial_Values.Defaults_2
MD5: e6cd8261b099278ceeb5fda91d318f6e
```

Note that we cannot specify a default value for a subtype:

Listing 100: defaults.ads

```
1  package Defaults is
2
3     subtype T is Integer
4       with Default_Value => -1;
```

(continues on next page)

(continued from previous page)

```
   --  ERROR!!

end Defaults;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Default_Initial_Values.Defaults_3
MD5: beef68e4a7a3714cfa3e547bdcda9a0c
```

Build output

```
defaults.ads:4:11: error: aspect "Default_Value" cannot apply to subtype
gprbuild: *** compilation phase failed
```

For array types, we use the `Default_Component_Value` aspect:

Listing 101: defaults.ads

```
package Defaults is

   type Arr is
     array (Positive range <>) of Integer
       with Default_Component_Value => -1;

end Defaults;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Default_Initial_Values.Defaults_4
MD5: 2c390e3900e4af42498381025a37955e
```

This is a package containing the declarations we've just seen:

Listing 102: defaults.ads

```
package Defaults is

   type E is (E1, E2, E3)
     with Default_Value => E1;

   type T is new Integer
     with Default_Value => -1;

   --  We cannot specify default
   --  values for subtypes:
   --
   --  subtype T is Integer
   --    with Default_Value => -1;

   type R is record
     X : Positive := 1;
     Y : Positive := 10;
   end record;

   type Arr is
     array (Positive range <>) of Integer
       with Default_Component_Value => -1;

end Defaults;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Default_Initial_Values.Defaults
MD5: e9263ff5b96523c129a3d2d9bbb5a4dd
```

In the example below, we declare variables of the types from the `Defaults` package:

Listing 103: use_defaults.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Defaults; use Defaults;

procedure Use_Defaults is
   E1 : E;
   T1 : T;
   R1 : R;
   A1 : Arr (1 .. 5);
begin
   Put_Line ("Enumeration:  "
             & E'Image (E1));
   Put_Line ("Integer type: "
             & T'Image (T1));
   Put_Line ("Record type:  "
             & Positive'Image (R1.X)
             & ", "
             & Positive'Image (R1.Y));

   Put ("Array type:   ");
   for V of A1 loop
      Put (Integer'Image (V) & " ");
   end loop;
   New_Line;
end Use_Defaults;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Default_Initial_Values.Defaults
MD5: f8e55d31cbda2447fe14eb07eaad1975
```

Runtime output

```
Enumeration:  E1
Integer type: -1
Record type:   1,  10
Array type:   -1 -1 -1 -1 -1
```

As we see in the `Use_Defaults` procedure, all variables still have their default values, since we haven't assigned any value to them.

In the Ada Reference Manual

- 3.5 Scalar Types[34]
- 3.6 Array Types[35]

[34] http://www.ada-auth.org/standards/22rm/html/RM-3-5.html
[35] http://www.ada-auth.org/standards/22rm/html/RM-3-6.html

25.1.9 Deferred Constants

Deferred constants are declarations where the value of the constant is not specified immediately, but rather *deferred* to a later point. In that sense, if a constant declaration is deferred, it is actually declared twice:

1. in the deferred constant declaration, and
2. in the full constant declaration.

The simplest form of deferred constant is the one that has a full constant declaration in the private part of the package specification. For example:

Listing 104: deferred_constants.ads

```
package Deferred_Constants is

   type Speed is new Long_Float;

   Light : constant Speed;
   --      ^ deferred constant declaration

private

   Light : constant Speed := 299_792_458.0;
   --      ^ full constant declaration

end Deferred_Constants;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Deferred_Constants.Deferred_
 ↪Constant_Private
MD5: f76e42326889f70fa7e1e216576f9771
```

Another form of deferred constant is the one that imports a constant from an external implementation — using the `Import` keyword. We can use this to import a constant declaration from an implementation in C. For example, we can declare the `light` constant in a C file:

Listing 105: constants.c

```
double light = 299792458.0;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Deferred_Constants.Deferred_
 ↪Constant_C
MD5: 71194a329dc5adaac3e01aff143a9943
```

Then, we can import this constant in the `Deferred_Constants` package:

Listing 106: deferred_constants.ads

```
package Deferred_Constants is

   type Speed is new Long_Float;

   Light : constant Speed with
     Import, Convention => C;
   --  ^^^^ deferred constant
   --       declaration; imported
   --       from C file
```

(continues on next page)

(continued from previous page)

```
10
11 end Deferred_Constants;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Deferred_Constants.Deferred_
 ↪Constant_C
MD5: 9355d194e973c6c6540485178b2259c9
```

In this case, we don't have a full declaration in the `Deferred_Constants` package, as the `Light` constant is imported from the `constants.c` file.

As a rule, the deferred and the full declarations should match — except, of course, for the actual value that is missing in the deferred declaration. For instance, we're not allowed to use different types in both declarations. However, we may use a subtype in the full declaration — as long as it's compatible with the type that was used in the deferred declaration. For example:

Listing 107: deferred_constants.ads

```
1  package Deferred_Constants is
2
3     type Speed is new Long_Float;
4
5     subtype Positive_Speed is
6       Speed range 0.0 .. Speed'Last;
7
8     Light : constant Speed;
9     --      ^ deferred constant declaration
10
11 private
12
13    Light : constant Positive_Speed :=
14              299_792_458.0;
15    --      ^ full constant declaration
16    --        using a subtype
17
18 end Deferred_Constants;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Deferred_Constants.Deferred_
 ↪Constant_Subtype
MD5: ad6e13e30bacb6d97ccfa6c7345ffb67
```

Here, we're using the Speed type in the deferred declaration of the `Light` constant, but we're using the `Positive_Speed` subtype in the full declaration.

A useful application of deferred constants is when the value of the constant is calculated using entities not meant to be compile-time visible to clients. As such, these other entities are only visible in the private part of the package, so that's where the value of the deferred constant must be computed. For example, the full constant declaration may be computed by a call to an expression function:

Listing 108: deferred_constants.ads

```
1  package Deferred_Constants is
2
3     type Speed is new Long_Float;
4
5     Light : constant Speed;
```

(continues on next page)

(continued from previous page)

```
   --       ^ deferred constant declaration

private

   function Calculate_Light return Speed is
     (299_792_458.0);

   Light : constant Speed := Calculate_Light;
   --       ^ full constant declaration
   --         calling a private function

end Deferred_Constants;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.Deferred_Constants.Deferred_
 ↪Constant_Function
MD5: f0b1a9521af31a4b48bbd54891f1c32b
```

Here, we call the `Calculate_Light` function — declared in the private part of the `Deferred_Constants` package — for the full declaration of the `Light` constant.

In the Ada Reference Manual

- 7.4 Deferred Constants[36]

25.1.10 User-defined literals

Note: This feature was introduced in Ada 2022.

Any type definition has a kind of literal associated with it. For example, integer types are associated with integer literals. Therefore, we can initialize an object of integer type with an integer literal:

Listing 109: simple_integer_literal.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Simple_Integer_Literal is
   V : Integer;
begin
   V := 10;

   Put_Line (Integer'Image (V));
end Simple_Integer_Literal;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.User-Defined_Literals.Simple_
 ↪Integer_Literal
MD5: 9f65e7c319be2b292dc1fdf02dd7cfb4
```

Runtime output

[36] http://www.ada-auth.org/standards/22rm/html/RM-7-4.html

```
10
```

Here, `10` is the integer literal that we use to initialize the integer variable V. Other examples of literals are real literals and string literals, as we'll see later.

When we declare an enumeration type, we limit the set of literals that we can use to initialize objects of that type:

Listing 110: simple_enumeration.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Simple_Enumeration is
   type Activation_State is (Unknown, Off, On);

   S : Activation_State;
begin
   S := On;
   Put_Line (Activation_State'Image (S));
end Simple_Enumeration;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.User-Defined_Literals.Simple_
 ↪Enumeration
MD5: 075df146fcb567817dadfdb245659773
```

Runtime output

```
ON
```

For objects of `Activation_State` type, such as S, the only possible literals that we can use are `Unknown`, `Off` and `On`. In this sense, types have a constrained set of literals that can be used for objects of that type.

User-defined literals allow us to extend this set of literals. We could, for example, extend the type declaration of `Activation_State` and allow the use of integer literals for objects of that type. In this case, we need to use the `Integer_Literal` aspect and specify a function that implements the conversion from literals to the type we're declaring. For this conversion from integer literals to the `Activation_State` type, we could specify that 0 corresponds to `Off`, 1 corresponds to `On` and other values correspond to `Unknown`. We'll see the corresponding implementation later.

These are the three kinds of literals and their corresponding aspect:

Literal	Example	Aspect
Integer	1	`Integer_Literal`
Real	1.0	`Real_Literal`
String	"On"	`String_Literal`

For our previous `Activation_States` type, we could declare a function `Integer_To_Activation_State` that converts integer literals to one of the enumeration literals that we've specified for the `Activation_States` type:

Listing 111: activation_states.ads

```
package Activation_States is

   type Activation_State is (Unknown, Off, On)
```

(continues on next page)

(continued from previous page)

```
     with Integer_Literal =>
            Integer_To_Activation_State;

   function Integer_To_Activation_State
     (S : String)
      return Activation_State;

end Activation_States;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.User-Defined_Literals.User_Defined_
↪Literals
MD5: 67b6d96f049ab6cde962aefda96bffca
```

Based on this specification, we can now use an integer literal to initialize an object S of Activation_State type:

```
S : Activation_State := 1;
```

Note that we have a string parameter in the declaration of the Integer_To_Activation_State function, even though the function itself is only used to convert integer literals (but not string literals) to the Activation_State type. It's our job to process that string parameter in the implementation of the Integer_To_Activation_State function and convert it to an integer value — using Integer'Value, for example:

Listing 112: activation_states.adb

```
package body Activation_States is

   function Integer_To_Activation_State
     (S : String)
      return Activation_State is
   begin
      case Integer'Value (S) is
         when 0      => return Off;
         when 1      => return On;
         when others => return Unknown;
      end case;
   end Integer_To_Activation_State;

end Activation_States;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.User-Defined_Literals.User_Defined_
↪Literals
MD5: 104a835915b93ea3b860bce03fd709a3
```

Let's look at a complete example that makes use of all three kinds of literals:

Listing 113: activation_states.ads

```
package Activation_States is

   type Activation_State is (Unknown, Off, On)
     with String_Literal  =>
            To_Activation_State,
          Integer_Literal =>
            Integer_To_Activation_State,
          Real_Literal    =>
```

(continues on next page)

(continued from previous page)

```
            Real_To_Activation_State;

   function To_Activation_State
     (S : Wide_Wide_String)
      return Activation_State;

   function Integer_To_Activation_State
     (S : String)
      return Activation_State;

   function Real_To_Activation_State
     (S : String)
      return Activation_State;

end Activation_States;
```

Listing 114: activation_states.adb

```
package body Activation_States is

   function To_Activation_State
     (S : Wide_Wide_String)
      return Activation_State
   is
   begin
      if S = "Off" then
         return Off;
      elsif S = "On" then
         return On;
      else
         return Unknown;
      end if;
   end To_Activation_State;

   function Integer_To_Activation_State
     (S : String)
      return Activation_State
   is
   begin
      case Integer'Value (S) is
         when 0      => return Off;
         when 1      => return On;
         when others => return Unknown;
      end case;
   end Integer_To_Activation_State;

   function Real_To_Activation_State
     (S : String)
      return Activation_State
   is
      V : constant Float := Float'Value (S);
   begin
      if V < 0.0 then
         return Unknown;
      elsif V < 1.0 then
         return Off;
      else
         return On;
      end if;
   end Real_To_Activation_State;

```

(continues on next page)

(continued from previous page)

```
44 end Activation_States;
```

Listing 115: activation_examples.adb

```
1  with Ada.Text_IO;       use Ada.Text_IO;
2  with Activation_States; use Activation_States;
3
4  procedure Activation_Examples is
5     S : Activation_State;
6  begin
7     S := "Off";
8     Put_Line ("String: Off  => "
9               & Activation_State'Image (S));
10
11    S := 1;
12    Put_Line ("Integer: 1   => "
13              & Activation_State'Image (S));
14
15    S := 1.5;
16    Put_Line ("Real:    1.5 => "
17              & Activation_State'Image (S));
18 end Activation_Examples;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.User-Defined_Literals.Activation_
↪States
MD5: 186b7b898e4c16bfd8dcd683e8f0379d
```

Runtime output

```
String: Off  => OFF
Integer: 1   => ON
Real:    1.5 => ON
```

In this example, we're extending the declaration of the `Activation_State` type to include string and real literals. For string literals, we use the `To_Activation_State` function, which converts:

- the `"Off"` string to `Off`,
- the `"On"` string to `On`, and
- any other string to `Unknown`.

For real literals, we use the `Real_To_Activation_State` function, which converts:

- any negative number to `Unknown`,
- a value in the interval [0, 1) to `Off`, and
- a value equal or above 1.0 to `On`.

Note that the string parameter of `To_Activation_State` function — which converts string literals — is of `Wide_Wide_String` type, and not of **`String`** type, as it's the case for the other conversion functions.

In the `Activation_Examples` procedure, we show how we can initialize an object of `Activation_State` type with all kinds of literals (string, integer and real literals).

With the definition of the `Activation_State` type that we've seen in the complete example, we can initialize an object of this type with an enumeration literal or a string, as both forms are defined in the type specification:

Listing 116: using_string_literal.adb

```
with Ada.Text_IO;       use Ada.Text_IO;
with Activation_States; use Activation_States;

procedure Using_String_Literal is
   S1 : constant Activation_State := On;
   S2 : constant Activation_State := "On";
begin
   Put_Line (Activation_State'Image (S1));
   Put_Line (Activation_State'Image (S2));
end Using_String_Literal;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.User-Defined_Literals.Activation_
 ↪States
MD5: 6ca6aa79b88058801688fc2dfb186091
```

Runtime output

```
ON
ON
```

Note we need to be very careful when designing conversion functions. For example, the use of string literals may limit the kind of checks that we can do. Consider the following misspelling of the `Off` literal:

Listing 117: misspelling_example.adb

```
with Ada.Text_IO;       use Ada.Text_IO;
with Activation_States; use Activation_States;

procedure Misspelling_Example is
   S : constant Activation_State :=
         Offf;
   --    ^ Error: Off is misspelled.
begin
   Put_Line (Activation_State'Image (S));
end Misspelling_Example;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.User-Defined_Literals.Activation_
 ↪States
MD5: ebc1036a58e460a9212106606461b014
```

Build output

```
misspelling_example.adb:6:10: error: "Offf" is undefined
misspelling_example.adb:6:10: error: possible misspelling of "Off"
gprbuild: *** compilation phase failed
```

As expected, the compiler detects this error. However, this error is accepted when using the corresponding string literal:

Listing 118: misspelling_example.adb

```
with Ada.Text_IO;       use Ada.Text_IO;
with Activation_States; use Activation_States;

```

(continues on next page)

(continued from previous page)

```
procedure Misspelling_Example is
   S : constant Activation_State :=
         "Offf";
   --     ^ Error: Off is misspelled.
begin
   Put_Line (Activation_State'Image (S));
end Misspelling_Example;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.User-Defined_Literals.Activation_
↪States
MD5: 99f74c67712a9b55c146b9d57405e47f
```

Runtime output

```
UNKNOWN
```

Here, our implementation of `To_Activation_State` simply returns `Unknown`. In some cases, this might be exactly the behavior that we want. However, let's assume that we'd prefer better error handling instead. In this case, we could change the implementation of `To_Activation_State` to check all literals that we want to allow, and indicate an error otherwise — by raising an exception, for example. Alternatively, we could specify this in the preconditions of the conversion function:

```
function To_Activation_State
  (S : Wide_Wide_String)
   return Activation_State
     with Pre => S = "Off"  or
                 S = "On"   or
                 S = "Unknown";
```

In this case, the precondition explicitly indicates which string literals are allowed for the `To_Activation_State` type.

User-defined literals can also be used for more complex types, such as records. For example:

Listing 119: silly_records.ads

```
package Silly_Records is

   type Silly is record
      X : Integer;
      Y : Float;
   end record
     with String_Literal => To_Silly;

   function To_Silly (S : Wide_Wide_String)
                      return Silly;
end Silly_Records;
```

Listing 120: silly_records.adb

```
package body Silly_Records is

   function To_Silly (S : Wide_Wide_String)
                      return Silly
   is
   begin
```

(continues on next page)

(continued from previous page)

```
      if S = "Magic" then
         return (X => 42, Y => 42.0);
      else
         return (X => 0, Y => 0.0);
      end if;
   end To_Silly;

end Silly_Records;
```

Listing 121: silly_magic.adb

```
with Ada.Text_IO;   use Ada.Text_IO;
with Silly_Records; use Silly_Records;

procedure Silly_Magic is
   R1 : Silly;
begin
   R1 := "Magic";
   Put_Line (R1.X'Image & ", " & R1.Y'Image);
end Silly_Magic;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Types.User-Defined_Literals.Record_
 ↪Literals
MD5: 2a077045f058a8d5c09c43f66fc128be
```

Runtime output

```
 42,  4.20000E+01
```

In this example, when we initialize an object of `Silly` type with a string, its components are:

- set to 42 when using the "Magic" string; or
- simply set to zero when using any other string.

Obviously, this example isn't particularly useful. However, the goal is to show that this approach is useful for more complex types where a string literal (or a numeric literal) might simplify handling those types. Used-defined literals let you design types in ways that, otherwise, would only be possible when using a preprocessor or a domain-specific language.

In the Ada Reference Manual

- 4.2.1 User-Defined Literals[37]

[37] http://www.ada-auth.org/standards/22rm/html/RM-4-2-1.html

25.2 Types and Representation

25.2.1 Enumeration Representation Clauses

We have talked about the internal code of an enumeration *in another section* (page 294). We may change this internal code by using a representation clause, which has the following format:

```
for Primary_Color is (Red   =>    1,
                      Green =>    5,
                      Blue  => 1000);
```

The value of each code in a representation clause must be distinct. However, as you can see above, we don't need to use sequential values — the values must, however, increase for each enumeration.

We can rewrite the previous example using a representation clause:

Listing 122: days.ads

```
1  package Days is
2
3     type Day is (Mon, Tue, Wed,
4                  Thu, Fri,
5                  Sat, Sun);
6
7     for Day use (Mon => 2#00000001#,
8                  Tue => 2#00000010#,
9                  Wed => 2#00000100#,
10                 Thu => 2#00001000#,
11                 Fri => 2#00010000#,
12                 Sat => 2#00100000#,
13                 Sun => 2#01000000#);
14
15 end Days;
```

Listing 123: show_days.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2  with Days;        use Days;
3
4  procedure Show_Days is
5  begin
6     for D in Day loop
7        Put_Line (Day'Image (D)
8                  & " position      = "
9                  & Integer'Image (Day'Pos (D)));
10       Put_Line (Day'Image (D)
11                 & " internal code = "
12                 & Integer'Image
13                     (Day'Enum_Rep (D)));
14    end loop;
15 end Show_Days;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Enumeration_
↪Representation_Clauses.Enumeration_Values
MD5: a70c3f8a967c355a4bf8f2d669f9c541
```

Runtime output

```
MON position      =  0
MON internal code =  1
TUE position      =  1
TUE internal code =  2
WED position      =  2
WED internal code =  4
THU position      =  3
THU internal code =  8
FRI position      =  4
FRI internal code =  16
SAT position      =  5
SAT internal code =  32
SUN position      =  6
SUN internal code =  64
```

Now, the value of the internal code is the one that we've specified in the representation clause instead of being equivalent to the value of the enumeration position.

In the example above, we're using binary values for each enumeration — basically viewing the integer value as a bit-field and assigning one bit for each enumeration. As long as we maintain an increasing order, we can use totally arbitrary values as well. For example:

Listing 124: days.ads

```
1  package Days is
2
3     type Day is (Mon, Tue, Wed,
4                  Thu, Fri,
5                  Sat, Sun);
6
7     for Day use (Mon =>  5,
8                  Tue =>  9,
9                  Wed => 42,
10                 Thu => 49,
11                 Fri => 50,
12                 Sat => 66,
13                 Sun => 99);
14
15 end Days;
```

25.2.2 Data Representation

This section provides a glimpse on attributes and aspects used for data representation. They are usually used for embedded applications because of strict requirements that are often found there. Therefore, unless you have very specific requirements for your application, in most cases, you won't need them. However, you should at least have a rudimentary understanding of them. To read a thorough overview on this topic, please refer to the *Introduction to Embedded Systems Programming* (page 1117) course.

In the Ada Reference Manual

- 13.2 Packed Types[38]
- 13.3 Operational and Representation Attributes[39]
- 13.5.3 Bit Ordering[40]

[39] http://www.ada-auth.org/standards/22rm/html/RM-13-3.html
[40] http://www.ada-auth.org/standards/22rm/html/RM-13-5-3.html

Sizes

Ada offers multiple attributes to retrieve the size of a type or an object:

Attribute	Description
`Size`	Size of the representation of a subtype or an object (in bits).
`Object_Size`	Size of a component or an aliased object (in bits).
`Component_Size`	Size of a component of an array (in bits).
`Storage_Size`	Number of storage elements reserved for an access type or a task object.

For the first three attributes, the size is measured in bits. In the case of `Storage_Size`, the size is measured in storage elements. Note that the size information depends your target architecture. We'll discuss some examples to better understand the differences among those attributes.

Important

A storage element is the smallest element we can use to store data in memory. As we'll see soon, a storage element corresponds to a byte in many architectures.

The size of a storage element is represented by the `System.Storage_Unit` constant. In other words, the storage unit corresponds to the number of bits used for a single storage element.

In typical architectures, `System.Storage_Unit` is 8 bits. In this specific case, a storage element is equal to a byte in memory. Note, however, that `System.Storage_Unit` might have a value different than eight in certain architectures.

Size attribute and aspect

Let's start with a code example using the `Size` attribute:

Listing 125: custom_types.ads

```
package Custom_Types is

   type UInt_7 is range 0 .. 127;

   type UInt_7_S32 is range 0 .. 127
     with Size => 32;

end Custom_Types;
```

Listing 126: show_sizes.adb

```
with Ada.Text_IO;  use Ada.Text_IO;

with Custom_Types; use Custom_Types;

procedure Show_Sizes is
   V1 : UInt_7;
   V2 : UInt_7_S32;
begin
   Put_Line ("UInt_7'Size:           "
```

(continues on next page)

(continued from previous page)

```
10              & UInt_7'Size'Image);
11    Put_Line ("UInt_7'Object_Size:     "
12              & UInt_7'Object_Size'Image);
13    Put_Line ("V1'Size:                "
14              & V1'Size'Image);
15    New_Line;
16
17    Put_Line ("UInt_7_S32'Size:        "
18              & UInt_7_S32'Size'Image);
19    Put_Line ("UInt_7_S32'Object_Size: "
20              & UInt_7_S32'Object_Size'Image);
21    Put_Line ("V2'Size:                "
22              & V2'Size'Image);
23 end Show_Sizes;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Data_Representation.
 ↪Sizes
MD5: e0da7cd23dc6989bea3d2902221f033e
```

Build output

```
show_sizes.adb:6:04: warning: variable "V1" is read but never assigned [-gnatwv]
show_sizes.adb:7:04: warning: variable "V2" is read but never assigned [-gnatwv]
```

Runtime output

```
UInt_7'Size:             7
UInt_7'Object_Size:      8
V1'Size:                 8

UInt_7_S32'Size:         32
UInt_7_S32'Object_Size:  32
V2'Size:                 32
```

Depending on your target architecture, you may see this output:

```
UInt_7'Size:             7
UInt_7'Object_Size:      8
V1'Size:                 8

UInt_7_S32'Size:         32
UInt_7_S32'Object_Size:  32
V2'Size:                 32
```

When we use the `Size` attribute for a type T, we're retrieving the minimum number of bits necessary to represent objects of that type. Note that this is not the same as the actual size of an object of type T because the compiler will select an object size that is appropriate for the target architecture.

In the example above, the size of the `UInt_7` is 7 bits, while the most appropriate size to store objects of this type in the memory of our target architecture is 8 bits. To be more specific, the range of `UInt_7` (0 .. 127) can be perfectly represented in 7 bits. However, most target architectures don't offer 7-bit registers or 7-bit memory storage, so 8 bits is the most appropriate size in this case.

We can retrieve the size of an object of type T by using the `Object_Size`. Alternatively, we can use the `Size` attribute directly on objects of type T to retrieve their actual size — in our example, we write `V1'Size` to retrieve the size of `V1`.

In the example above, we've used both the `Size` attribute (for example, `UInt_7'Size`) and

the Size aspect (`with Size => 32`). While the size attribute is a function that returns the size, the size aspect is a request to the compiler to verify that the expected size can be used on the target platform. You can think of this attribute as a dialog between the developer and the compiler:

> (Developer) "I think that UInt_7_S32 should be stored using at least 32 bits. Do you agree?"
>
> (Ada compiler) "For the target platform that you selected, I can confirm that this is indeed the case."

Depending on the target platform, however, the conversation might play out like this:

> (Developer) "I think that UInt_7_S32 should be stored using at least 32 bits. Do you agree?"
>
> (Ada compiler) "For the target platform that you selected, I cannot possibly do it! COMPILATION ERROR!"

Component size

Let's continue our discussion on sizes with an example that makes use of the Component_Size attribute:

Listing 127: custom_types.ads

```
1  package Custom_Types is
2
3     type UInt_7 is range 0 .. 127;
4
5     type UInt_7_Array is
6       array (Positive range <>) of UInt_7;
7
8     type UInt_7_Array_Comp_32 is
9       array (Positive range <>) of UInt_7
10        with Component_Size => 32;
11
12 end Custom_Types;
```

Listing 128: show_sizes.adb

```
1  with Ada.Text_IO;  use Ada.Text_IO;
2
3  with Custom_Types; use Custom_Types;
4
5  procedure Show_Sizes is
6     Arr_1 : UInt_7_Array (1 .. 20);
7     Arr_2 : UInt_7_Array_Comp_32 (1 .. 20);
8  begin
9     Put_Line
10      ("UInt_7_Array'Size:                  "
11       & UInt_7_Array'Size'Image);
12    Put_Line
13      ("UInt_7_Array'Object_Size:           "
14       & UInt_7_Array'Object_Size'Image);
15    Put_Line
16      ("UInt_7_Array'Component_Size:        "
17       & UInt_7_Array'Component_Size'Image);
18    Put_Line
19      ("Arr_1'Component_Size:               "
20       & Arr_1'Component_Size'Image);
```

(continues on next page)

(continued from previous page)

```
   Put_Line
     ("Arr_1'Size:                          "
      & Arr_1'Size'Image);
   New_Line;

   Put_Line
     ("UInt_7_Array_Comp_32'Object_Size:    "
      & UInt_7_Array_Comp_32'Size'Image);
   Put_Line
     ("UInt_7_Array_Comp_32'Object_Size:    "
      & UInt_7_Array_Comp_32'Object_Size'Image);
   Put_Line
     ("UInt_7_Array_Comp_32'Component_Size: "
      &
      UInt_7_Array_Comp_32'Component_Size'Image);
   Put_Line
     ("Arr_2'Component_Size:                "
      & Arr_2'Component_Size'Image);
   Put_Line
     ("Arr_2'Size:                          "
      & Arr_2'Size'Image);
   New_Line;
end Show_Sizes;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Data_Representation.
↪Sizes
MD5: e316bcb827e014075dfbf044935827ae
```

Build output

```
show_sizes.adb:6:04: warning: variable "Arr_1" is read but never assigned [-gnatwv]
show_sizes.adb:7:04: warning: variable "Arr_2" is read but never assigned [-gnatwv]
```

Runtime output

```
UInt_7_Array'Size:                    17179869176
UInt_7_Array'Object_Size:             17179869176
UInt_7_Array'Component_Size:          8
Arr_1'Component_Size:                 8
Arr_1'Size:                           160

UInt_7_Array_Comp_32'Object_Size:     68719476704
UInt_7_Array_Comp_32'Object_Size:     68719476704
UInt_7_Array_Comp_32'Component_Size:  32
Arr_2'Component_Size:                 32
Arr_2'Size:                           640
```

Depending on your target architecture, you may see this output:

```
UInt_7_Array'Size:                    17179869176
UInt_7_Array'Object_Size:             17179869176
UInt_7_Array'Component_Size:          8
Arr_1'Component_Size:                 8
Arr_1'Size:                           160

UInt_7_Array_Comp_32'Size:            68719476704
UInt_7_Array_Comp_32'Object_Size:     68719476704
UInt_7_Array_Comp_32'Component_Size:  32
```

(continues on next page)

(continued from previous page)

```
Arr_2'Component_Size:                  32
Arr_2'Size:                            640
```

Here, the value we get for `Component_Size` of the `UInt_7_Array` type is 8 bits, which matches the `UInt_7'Object_Size` — as we've seen in the previous subsection. In general, we expect the component size to match the object size of the underlying type.

However, we might have component sizes that aren't equal to the object size of the component's type. For example, in the declaration of the `UInt_7_Array_Comp_32` type, we're using the `Component_Size` aspect to query whether the size of each component can be 32 bits:

```
type UInt_7_Array_Comp_32 is
  array (Positive range <>) of UInt_7
    with Component_Size => 32;
```

If the code compiles, we see this value when we use the `Component_Size` attribute. In this case, even though `UInt_7'Object_Size` is 8 bits, the component size of the array type (`UInt_7_Array_Comp_32'Component_Size`) is 32 bits.

Note that we can use the `Component_Size` attribute with data types, as well as with actual objects of that data type. Therefore, we can write `UInt_7_Array'Component_Size` and `Arr_1'Component_Size`, for example.

This big number (17179869176 bits) for `UInt_7_Array'Size` and `UInt_7_Array'Object_Size` might be surprising for you. This is due to the fact that Ada is reporting the size of the `UInt_7_Array` type for the case when the complete range is used. Considering that we specified a positive range in the declaration of the `UInt_7_Array` type, the maximum length on this machine is 2^{31} - 1. The object size of an array type is calculated by multiplying the maximum length by the component size. Therefore, the object size of the `UInt_7_Array` type corresponds to the multiplication of 2^{31} - 1 components (maximum length) by 8 bits (component size).

Storage size

To complete our discussion on sizes, let's look at this example of storage sizes:

Listing 129: custom_types.ads

```
1  package Custom_Types is
2
3     type UInt_7 is range 0 .. 127;
4
5     type UInt_7_Access is access UInt_7;
6
7  end Custom_Types;
```

Listing 130: show_sizes.adb

```
1  with Ada.Text_IO;  use Ada.Text_IO;
2  with System;
3
4  with Custom_Types; use Custom_Types;
5
6  procedure Show_Sizes is
7     AV1, AV2 : UInt_7_Access;
8  begin
9     Put_Line
10      ("UInt_7_Access'Storage_Size:          "
```

(continues on next page)

(continued from previous page)

```
      & UInt_7_Access'Storage_Size'Image);
   Put_Line
     ("UInt_7_Access'Storage_Size (bits):   "
      & Integer'Image (UInt_7_Access'Storage_Size
                       * System.Storage_Unit));

   Put_Line
     ("UInt_7'Size:                "
      & UInt_7'Size'Image);
   Put_Line
     ("UInt_7_Access'Size:         "
      & UInt_7_Access'Size'Image);
   Put_Line
     ("UInt_7_Access'Object_Size: "
      & UInt_7_Access'Object_Size'Image);
   Put_Line
     ("AV1'Size:                   "
      & AV1'Size'Image);
   New_Line;

   Put_Line ("Allocating AV1...");
   AV1 := new UInt_7;
   Put_Line ("Allocating AV2...");
   AV2 := new UInt_7;
   New_Line;

   Put_Line
     ("AV1.all'Size:               "
      & AV1.all'Size'Image);
   New_Line;
end Show_Sizes;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Data_Representation.
 ↪Sizes
MD5: 5e652ee25b8550ac331f3ce98e24f7ba
```

Runtime output

```
UInt_7_Access'Storage_Size:           0
UInt_7_Access'Storage_Size (bits):    0
UInt_7'Size:                 7
UInt_7_Access'Size:          64
UInt_7_Access'Object_Size:   64
AV1'Size:                    64

Allocating AV1...
Allocating AV2...

AV1.all'Size:                8
```

Depending on your target architecture, you may see this output:

```
UInt_7_Access'Storage_Size:           0
UInt_7_Access'Storage_Size (bits):    0

UInt_7'Size:                 7
UInt_7_Access'Size:          64
UInt_7_Access'Object_Size:   64
```

(continues on next page)

(continued from previous page)

```
AV1'Size:                   64

Allocating AV1...
Allocating AV2...

AV1.all'Size:               8
```

As we've mentioned earlier on, `Storage_Size` corresponds to the number of storage elements reserved for an access type or a task object. In this case, we see that the storage size of the `UInt_7_Access` type is zero. This is because we haven't indicated that memory should be reserved for this data type. Thus, the compiler doesn't reserve memory and simply sets the size to zero.

Because `Storage_Size` gives us the number of storage elements, we have to multiply this value by `System.Storage_Unit` to get the total storage size in bits. (In this particular example, however, the multiplication doesn't make any difference, as the number of storage elements is zero.)

Note that the size of our original data type `UInt_7` is 7 bits, while the size of its corresponding access type `UInt_7_Access` (and the access object `AV1`) is 64 bits. This is due to the fact that the access type doesn't contain an object, but rather memory information about an object. You can retrieve the size of an object allocated via **new** by first dereferencing it — in our example, we do this by writing `AV1.all'Size`.

Now, let's use the `Storage_Size` aspect to actually reserve memory for this data type:

Listing 131: custom_types.ads

```
package Custom_Types is

   type UInt_7 is range 0 .. 127;

   type UInt_7_Reserved_Access is access UInt_7
     with Storage_Size => 8;

end Custom_Types;
```

Listing 132: show_sizes.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with System;

with Custom_Types; use Custom_Types;

procedure Show_Sizes is
   RAV1, RAV2 : UInt_7_Reserved_Access;
begin
   Put_Line
   ("UInt_7_Reserved_Access'Storage_Size:        "
    & UInt_7_Reserved_Access'Storage_Size'Image);

   Put_Line
   ("UInt_7_Reserved_Access'Storage_Size (bits): "
    & Integer'Image
        (UInt_7_Reserved_Access'Storage_Size
         * System.Storage_Unit));

   Put_Line
     ("UInt_7_Reserved_Access'Size:        "
      & UInt_7_Reserved_Access'Size'Image);
   Put_Line
```

(continues on next page)

(continued from previous page)

```
23       ("UInt_7_Reserved_Access'Object_Size: "
24        & UInt_7_Reserved_Access'Object_Size'Image);
25     Put_Line
26       ("RAV1'Size:                          "
27        & RAV1'Size'Image);
28     New_Line;
29
30     Put_Line ("Allocating RAV1...");
31     RAV1 := new UInt_7;

Allocating RAV1...
Allocating RAV2...

raised STORAGE_ERROR : s-poosiz.adb:108 explicit raise
```

In this case, we're reserving 8 storage elements in the declaration of `UInt_7_Reserved_Access`.

```
type UInt_7_Reserved_Access is access UInt_7
  with Storage_Size => 8;
```

Since each storage element corresponds to one byte (8 bits) in this architecture, we're reserving a maximum of 64 bits (or 8 bytes) for the `UInt_7_Reserved_Access` type.

This example raises an exception at runtime — a storage error, to be more specific. This is because the maximum reserved size is 64 bits, and the size of a single access object is 64 bits as well. Therefore, after the first allocation, the reserved storage space is already consumed, so we cannot allocate a second access object.

This behavior might be quite limiting in many cases. However, for certain applications

where memory is very constrained, this might be exactly what we want to see. For example, having an exception being raised when the allocated memory for this data type has reached its limit might allow the application to have enough memory to at least handle the exception gracefully.

Alignment

For many algorithms, it's important to ensure that we're using the appropriate alignment. This can be done by using the `Alignment` attribute and the `Alignment` aspect. Let's look at this example:

Listing 133: custom_types.ads

```
package Custom_Types is

   type UInt_7 is range 0 .. 127;

   type Aligned_UInt_7 is new UInt_7
     with Alignment => 4;

end Custom_Types;
```

Listing 134: show_alignment.adb

```
with Ada.Text_IO;  use Ada.Text_IO;

with Custom_Types; use Custom_Types;

procedure Show_Alignment is
   V         : constant UInt_7         := 0;
   Aligned_V : constant Aligned_UInt_7 := 0;
begin
   Put_Line
     ("UInt_7'Alignment:           "
      & UInt_7'Alignment'Image);
   Put_Line
     ("UInt_7'Size:                "
      & UInt_7'Size'Image);
   Put_Line
     ("UInt_7'Object_Size:         "
      & UInt_7'Object_Size'Image);
   Put_Line
     ("V'Alignment:                "
      & V'Alignment'Image);
   Put_Line
     ("V'Size:                     "
      & V'Size'Image);
   New_Line;

   Put_Line
     ("Aligned_UInt_7'Alignment:   "
      & Aligned_UInt_7'Alignment'Image);
   Put_Line
     ("Aligned_UInt_7'Size:        "
      & Aligned_UInt_7'Size'Image);
   Put_Line
     ("Aligned_UInt_7'Object_Size: "
      & Aligned_UInt_7'Object_Size'Image);
   Put_Line
     ("Aligned_V'Alignment:        "
```

(continues on next page)

(continued from previous page)

```
      & Aligned_V'Alignment'Image);
   Put_Line
     ("Aligned_V'Size:             "
      & Aligned_V'Size'Image);
   New_Line;
end Show_Alignment;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Data_Representation.
↪Alignment
MD5: a2fea340559193c293ccaee226de2558
```

Runtime output

```
UInt_7'Alignment:            1
UInt_7'Size:                 7
UInt_7'Object_Size:          8
V'Alignment:                 1
V'Size:                      8

Aligned_UInt_7'Alignment:    4
Aligned_UInt_7'Size:         7
Aligned_UInt_7'Object_Size:  32
Aligned_V'Alignment:         4
Aligned_V'Size:              32
```

Depending on your target architecture, you may see this output:

```
UInt_7'Alignment:            1
UInt_7'Size:                 7
UInt_7'Object_Size:          8
V'Alignment:                 1
V'Size:                      8

Aligned_UInt_7'Alignment:    4
Aligned_UInt_7'Size:         7
Aligned_UInt_7'Object_Size:  32
Aligned_V'Alignment:         4
Aligned_V'Size:              32
```

In this example, we're reusing the `UInt_7` type that we've already been using in previous examples. Because we haven't specified any alignment for the `UInt_7` type, it has an alignment of 1 storage unit (or 8 bits). However, in the declaration of the `Aligned_UInt_7` type, we're using the `Alignment` aspect to request an alignment of 4 storage units (or 32 bits):

```
type Aligned_UInt_7 is new UInt_7
  with Alignment => 4;
```

When using the `Alignment` attribute for the `Aligned_UInt_7` type, we can confirm that its alignment is indeed 4 storage units (bytes).

Note that we can use the `Alignment` attribute for both data types and objects — in the code above, we're using `UInt_7'Alignment` and `V'Alignment`, for example.

Because of the alignment we're specifying for the `Aligned_UInt_7` type, its size — indicated by the `Object_Size` attribute — is 32 bits instead of 8 bits as for the `UInt_7` type.

Note that you can also retrieve the alignment associated with a class using `S'Class'Alignment`. For example:

Listing 135: show_class_alignment.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Class_Alignment is

   type Point_1D is tagged record
      X : Integer;
   end record;

   type Point_2D is new Point_1D with record
      Y : Integer;
   end record
     with Alignment => 16;

   type Point_3D is new Point_2D with record
      Z : Integer;
   end record;

begin
   Put_Line ("1D_Point'Alignment:       "
             & Point_1D'Alignment'Image);
   Put_Line ("1D_Point'Class'Alignment: "
             & Point_1D'Class'Alignment'Image);
   Put_Line ("2D_Point'Alignment:       "
             & Point_2D'Alignment'Image);
   Put_Line ("2D_Point'Class'Alignment: "
             & Point_2D'Class'Alignment'Image);
   Put_Line ("3D_Point'Alignment:       "
             & Point_3D'Alignment'Image);
   Put_Line ("3D_Point'Class'Alignment: "
             & Point_3D'Class'Alignment'Image);
end Show_Class_Alignment;
```

```

Overlapping Storage

Algorithms can be designed to perform in-place or out-of-place processing. In other words, they can take advantage of the fact that input and output arrays share the same storage space or not.

We can use the `Has_Same_Storage` and the `Overlaps_Storage` attributes to retrieve more information about how the storage space of two objects related to each other:

- the `Has_Same_Storage` attribute indicates whether two objects have the exact same storage.

  - A typical example is when both objects are exactly the same, so they obviously share the same storage. For example, for array A, `A'Has_Same_Storage (A)` is always **True**.

- the `Overlaps_Storage` attribute indicates whether two objects have at least one bit in common.
  - Note that, if two objects have the same storage, this implies that their storage also overlaps. In other words, `A'Has_Same_Storage (B) = True` implies that `A'Overlaps_Storage (B) = True`.

Let's look at this example:

Listing 136: int_array_processing.ads

```
package Int_Array_Processing is

   type Int_Array is
     array (Positive range <>) of Integer;

   procedure Show_Storage (X : Int_Array;
                           Y : Int_Array);

   procedure Process (X :     Int_Array;
                      Y : out Int_Array);

end Int_Array_Processing;
```

Listing 137: int_array_processing.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Int_Array_Processing is

   procedure Show_Storage (X : Int_Array;
                           Y : Int_Array) is
   begin
      if X'Has_Same_Storage (Y) then
         Put_Line
         ("Info: X and Y have the same storage.");
      else
         Put_Line
           ("Info: X and Y don't have"
            & "the same storage.");
      end if;
      if X'Overlaps_Storage (Y) then
         Put_Line
           ("Info: X and Y overlap.");
      else
         Put_Line
           ("Info: X and Y don't overlap.");
      end if;
   end Show_Storage;

   procedure Process (X :     Int_Array;
                      Y : out Int_Array) is
   begin
      Put_Line ("==== PROCESS ====");
      Show_Storage (X, Y);

      if X'Has_Same_Storage (Y) then
         Put_Line ("In-place processing...");
      else
```

(continues on next page)

Out-of-place processing...

==== PROCESS ====
Info: X and Y don't havethe same storage.
Info: X and Y don't overlap.
Out-of-place processing...
```

In this code example, we implement two procedures:

- `Show_Storage`, which shows storage information about two arrays by using the `Has_Same_Storage` and `Overlaps_Storage` attributes.
- `Process`, which are supposed to process an input array `X` and store the processed data in the output array `Y`.
  - Note that the implementation of this procedure is actually just a mock-up, so that no processing is actually taking place.

We have four different instances of how we can call the `Process` procedure:

- in the `Process (A, A)` call, we're using the same array for the input and output arrays. This is a perfect example of in-place processing. Because the input and the output arrays arguments are actually the same object, they obviously share the exact same storage.
- in the `Process (A (1 .. 10), A (10 .. 20))` call, we're using two slices of the `A` array as input and output arguments. In this case, a single component of the `A` array is shared: `A (10)`. Because the storage space is overlapping, but not exactly the same, neither in-place nor out-of-place processing can usually be used in this case.
- in the `Process (A (1 .. 10), A (11 .. 20))` call, even though we're using the same array `A` for the input and output arguments, we're using slices that are completely independent from each other, so that the input and output arrays are not sharing any storage in this case. Therefore, we can use out-of-place processing.
- in the `Process (A, B)` call, we have two different arrays — which obviously don't share any storage space —, so we can use out-of-place processing.

Packed Representation

As we've seen previously, the minimum number of bits required to represent a data type might be less than the actual number of bits used to store an object of that same type. We've seen an example where `UInt_7'Size` was 7 bits, while `UInt_7'Object_Size` was 8 bits. The most extreme case is the one for the **`Boolean`** type: in this case, **`Boolean`**`'Size` is 1 bit, while **`Boolean`**`'Object_Size` might be 8 bits (or even more on certain architectures). In such cases, we have 7 (or more) unused bits in memory for each object of **`Boolean`** type. In other words, we're wasting memory. On the other hand, we're gaining speed of access because we can directly access each element without having to first change its internal representation back and forth. We'll come back to this point later.

The situation is even worse when implementing bit-fields, which can be declared as an array of **`Boolean`** components. For example:

Listing 139: flag_definitions.ads

```
package Flag_Definitions is

   type Flags is
     array (Positive range <>) of Boolean;

end Flag_Definitions;
```

Listing 140: show_flags.adb

```
with Ada.Text_IO;      use Ada.Text_IO;
with Flag_Definitions; use Flag_Definitions;

procedure Show_Flags is
   Flags_1 : Flags (1 .. 8);
begin
   Put_Line ("Boolean'Size:           "
             & Boolean'Size'Image);
   Put_Line ("Boolean'Object_Size:    "
             & Boolean'Object_Size'Image);
   Put_Line ("Flags_1'Size:           "
             & Flags_1'Size'Image);
   Put_Line ("Flags_1'Component_Size: "
             & Flags_1'Component_Size'Image);
end Show_Flags;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Data_Representation.
 ↪Non_Packed_Flags
MD5: 6fd7a913e3c6717e846c2e822c1cbad7
```

Build output

```
show_flags.adb:5:04: warning: variable "Flags_1" is read but never assigned [-
 ↪gnatwv]
```

Runtime output

```
Boolean'Size:           1
Boolean'Object_Size:    8
Flags_1'Size:           64
Flags_1'Component_Size: 8
```

Depending on your target architecture, you may see this output:

```
Boolean'Size:           1
Boolean'Object_Size:    8
Flags_1'Size:           64
Flags_1'Component_Size: 8
```

In this example, we're declaring the `Flags` type as an array of **`Boolean`** components. As we can see in this case, although the size of the **`Boolean`** type is just 1 bit, an object of this type has a size of 8 bits. Consequently, each component of the `Flags` type has a size of 8 bits. Moreover, an array with 8 components of **`Boolean`** type — such as the `Flags_1` array — has a size of 64 bits.

Therefore, having a way to compact the representation — so that we can store multiple objects without wasting storage space — may help us improving memory usage. This is actually possible by using the `Pack` aspect. For example, we could extend the previous example and declare a `Packed_Flags` type that makes use of this aspect:

Listing 141: flag_definitions.ads

```
package Flag_Definitions is

   type Flags is
     array (Positive range <>) of Boolean;

   type Packed_Flags is
     array (Positive range <>) of Boolean
       with Pack;

end Flag_Definitions;
```

Listing 142: show_packed_flags.adb

```
with Ada.Text_IO;      use Ada.Text_IO;
with Flag_Definitions; use Flag_Definitions;

procedure Show_Packed_Flags is
   Flags_1 : Flags (1 .. 8);
   Flags_2 : Packed_Flags (1 .. 8);
begin
   Put_Line ("Boolean'Size:           "
             & Boolean'Size'Image);
   Put_Line ("Boolean'Object_Size:    "
             & Boolean'Object_Size'Image);
   Put_Line ("Flags_1'Size:           "
             & Flags_1'Size'Image);
   Put_Line ("Flags_1'Component_Size: "
             & Flags_1'Component_Size'Image);
   Put_Line ("Flags_2'Size:           "
             & Flags_2'Size'Image);
   Put_Line ("Flags_2'Component_Size: "
             & Flags_2'Component_Size'Image);
end Show_Packed_Flags;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Data_Representation.
 ↪Packed_Flags
MD5: c71cf68dc8bc41d0df2a5e3eb61b51fd
```

Build output

```
show_packed_flags.adb:5:04: warning: variable "Flags_1" is read but never assigned␣
 ↪[-gnatwv]
show_packed_flags.adb:6:04: warning: variable "Flags_2" is read but never assigned␣
 ↪[-gnatwv]
```

Runtime output

```
Boolean'Size:            1
Boolean'Object_Size:     8
Flags_1'Size:            64
Flags_1'Component_Size:  8
Flags_2'Size:            8
Flags_2'Component_Size:  1
```

Depending on your target architecture, you may see this output:

```
Boolean'Size:             1
Boolean'Object_Size:      8
Flags_1'Size:             64
Flags_1'Component_Size:   8
Flags_2'Size:             8
Flags_2'Component_Size:   1
```

In this example, we're declaring the Flags_2 array of Packed_Flags type. Its size is 8 bits — instead of the 64 bits required for the Flags_1 array. Because the array type Packed_Flags is packed, we can now effectively use this type to store an object of **Boolean** type using just 1 bit of the memory, as indicated by the Flags_2'Component_Size attribute.

In many cases, we need to convert between a *normal* representation (such as the one used for the Flags_1 array above) to a packed representation (such as the one for the Flags_2 array). In many programming languages, this conversion may require writing custom code with manual bit-shifting and bit-masking to get the proper target representation. In Ada, however, we just need to indicate the actual type conversion, and the compiler takes care of generating code containing bit-shifting and bit-masking to performs the type conversion.

Let's modify the previous example and introduce this type conversion:

Listing 143: flag_definitions.ads

```
1  package Flag_Definitions is
2
3     type Flags is
4       array (Positive range <>) of Boolean;
5
6     type Packed_Flags is
7       array (Positive range <>) of Boolean
8         with Pack;
9
10    Default_Flags : constant Flags :=
11      (True, True, False, True,
12       False, False, True, True);
13
14 end Flag_Definitions;
```

Listing 144: show_flag_conversion.adb

```
1  with Ada.Text_IO;      use Ada.Text_IO;
2  with Flag_Definitions; use Flag_Definitions;
3
4  procedure Show_Flag_Conversion is
5     Flags_1 : Flags (1 .. 8);
6     Flags_2 : Packed_Flags (1 .. 8);
7  begin
8     Flags_1 := Default_Flags;
9     Flags_2 := Packed_Flags (Flags_1);
10
11    for I in Flags_2'Range loop
12       Put_Line (I'Image & ": "
13                 & Flags_1 (I)'Image & ", "
14                 & Flags_2 (I)'Image);
15    end loop;
16 end Show_Flag_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Data_Representation.
 ↪Flag_Conversion
MD5: faff2079f6779097b6e0f7cd6cd48612
```

Runtime output

```
1: TRUE, TRUE
2: TRUE, TRUE
3: FALSE, FALSE
4: TRUE, TRUE
5: FALSE, FALSE
6: FALSE, FALSE
7: TRUE, TRUE
8: TRUE, TRUE
```

In this extended example, we're now declaring `Default_Flags` as an array of constant flags, which we use to initialize `Flags_1`.

The actual conversion happens with `Flags_2 := Packed_Flags (Flags_1)`. Here, the type conversion `Packed_Flags()` indicates that we're converting from the normal representation (used for the `Flags` type) to the packed representation (used for `Packed_Flags` type). We don't need to write more code than that to perform the correct type conversion.

Also, by using the same strategy, we could read information from a packed representation. For example:

```
Flags_1 := Flags (Flags_2);
```

In this case, we use `Flags()` to convert from a packed representation to the normal representation.

We elaborate on the topic of converting between data representations in the section on *changing data representation* (page 376).

Trade-offs

As indicated previously, when we're using a packed representation (vs. using a standard *unpacked* representation), we're trading off speed of access for less memory consumption. The following table summarizes this:

Representation	More speed of access	Less memory consumption
Unpacked	X	
Packed		X

On one hand, we have better memory usage when we apply packed representations because we may save many bits for each object. On the other hand, there's a cost associated with accessing those packed objects because they need to be unpacked before we can actually access them. In fact, the compiler generates code — using bit-shifting and bit-masking — that converts a packed representation into an unpacked representation, which we can then access. Also, when storing a packed object, the compiler generates code that converts the unpacked representation of the object into the packed representation.

This packing and unpacking mechanism has a performance cost associated with it, which results in less speed of access for packed objects. As usual in those circumstances, before using packed representation, we should assess whether memory constraints are more important than speed in our target architecture.

25.2.3 Record Representation and storage clauses

In this section, we discuss how to use record representation clauses to specify how a record is represented in memory. Our goal is to provide a brief introduction into the topic. If you're interested in more details, you can find a thorough discussion about record representation clauses in the *Introduction to Embedded Systems Programming* (page 1117) course.

Let's start with the simple approach of declaring a record type without providing further information. In this case, we're basically asking the compiler to select a reasonable representation for that record in the memory of our target architecture.

Let's see a simple example:

Listing 145: p.ads

```
package P is

   type R is record
      A : Integer;
      B : Integer;
   end record;

end P;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Record_Representation_
 ↪Storage_Clauses.Rep_Clauses_1
MD5: 88171257118810bb7e02cea60ffb1ad9
```

Considering a typical 64-bit PC architecture with 8-bit storage units, and `Integer` defined as a 32-bit type, we get this memory representation:

position	0	1	2	3	4	5	6	7
component	A				B			

Each storage unit is a position in memory. In the graph above, the numbers on the top (0, 1, 2, ...) represent those positions for record R.

In addition, we can show the bits that are used for components A and B:

position	0	1	2	3	4	5	6	7
bits	#0 .. 7	#8 .. #15	#16 .. #23	#24 .. #31	#0 .. 7	#8 .. #15	#16 .. #23	#24 .. #31
component	A				B			

The memory representation we see in the graph above can be described in Ada using representation clauses, as you can see in the code starting at the `for R use record` line in the code example below — we'll discuss the syntax and further details right after this example.

Listing 146: p.ads

```
package P is

   type R is record
      A : Integer;
      B : Integer;
   end record;

   --  Representation clause for record R:
   for R use record
      A at 0 range 0 .. 31;
      --   ^ starting memory position
      B at 4 range 0 .. 31;
      --           ^ first bit .. last bit
   end record;

end P;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Record_Representation_
 ↪Storage_Clauses.Rep_Clauses_2
MD5: b6be86ae7e1a5c2e7d981fe37bad49ed
```

Here, we're specifying that the A component is stored in the bits #0 up to #31 starting at position #0. Note that the position itself doesn't represent an absolute address in the device's memory; instead, it's relative to the memory space reserved for that record. The B component has the same 32-bit range, but starts at position #4.

This is a generalized view of the syntax:

```
for Record_Type use record
   Component_Name at Start_Position
                  range First_Bit .. Last_Bit;
end record;
```

These are the elements we see above:

- `Component_Name`: name of the component (from the record type declaration);
- `Start_Position`: start position — in storage units — of the memory space reserved for that component;
- `First_Bit`: first bit (in the start position) of the component;
- `Last_Bit`: last bit of the component.

Note that the last bit of a component might be in a different storage unit. Since the **`Integer`** type has a larger width (32 bits) than the storage unit (8 bits), components of that type span over multiple storage units. Therefore, in our example, the first bit of component A is at position #0, while the last bit is at position #3.

Also note that the last eight bits of component A are bits #24 .. #31. If we think in terms of storage units, this corresponds to bits #0 .. #7 of position #3. However, when specifying the last bit in Ada, we always use the `First_Bit` value as a reference, not the position where those bits might end up. Therefore, we write **`range`** `0 .. 31`, well knowing that those 32 bits span over four storage units (positions #0 .. #3).

In the Ada Reference Manual

- 13.5.1 Record Representation Clauses[41]

[41] http://www.ada-auth.org/standards/22rm/html/RM-13-5-1.html

Storage Place Attributes

We can retrieve information about the start position, and the first and last bits of a component by using the storage place attributes:

- `Position`, which retrieves the start position of a component;
- `First_Bit`, which retrieves the first bit of a component;
- `Last_Bit`, which retrieves the last bit of a component.

Note, however, that these attributes can only be used with actual records, and not with record types.

We can revisit the previous example and verify how the compiler represents the R type in memory:

Listing 147: p.ads

```
package P is

   type R is record
      A : Integer;
      B : Integer;
   end record;

end P;
```

Listing 148: show_storage.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with System;

with P;           use P;

procedure Show_Storage is
   R1 : R;
begin
   Put_Line ("R'Size:              "
             & R'Size'Image);
   Put_Line ("R'Object_Size:       "
             & R'Object_Size'Image);
   New_Line;

   Put_Line ("System.Storage_Unit: "
             & System.Storage_Unit'Image);
   New_Line;

   Put_Line ("R1.A'Position  : "
             & R1.A'Position'Image);
   Put_Line ("R1.A'First_Bit : "
             & R1.A'First_Bit'Image);
   Put_Line ("R1.A'Last_Bit  : "
             & R1.A'Last_Bit'Image);
   New_Line;

   Put_Line ("R1.B'Position  : "
             & R1.B'Position'Image);
   Put_Line ("R1.B'First_Bit : "
             & R1.B'First_Bit'Image);
```

(continues on next page)

(continued from previous page)

```
31    Put_Line ("R1.B'Last_Bit  : "
32              & R1.B'Last_Bit'Image);
33 end Show_Storage;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Record_Representation_
 ↪Storage_Clauses.Storage_Place_Attributes
MD5: 05a402585ce71eb47cf972e68c02835e
```

Build output

```
show_storage.adb:7:04: warning: variable "R1" is read but never assigned [-gnatwv]
```

Runtime output

```
R'Size:               64
R'Object_Size:        64

System.Storage_Unit:  8

R1.A'Position  :  0
R1.A'First_Bit :  0
R1.A'Last_Bit  :  31

R1.B'Position  :  4
R1.B'First_Bit :  0
R1.B'Last_Bit  :  31
```

First of all, we see that the size of the R type is 64 bits, which can be explained by those two 32-bit integer components. Then, we see that components A and B start at positions #0 and #4, and each one makes use of bits in the range from #0 to #31. This matches the graph we've seen above.

In the Ada Reference Manual

- 13.5.2 Storage Place Attributes[42]

Using Representation Clauses

We can use representation clauses to change the way the compiler handles memory for a record type. For example, let's say we want to have an empty storage unit between components A and B. We can use a representation clause where we specify that component B starts at position #5 instead of #4, leaving an empty byte after component A and before component B:

position	0	1	2	3	4	5	6	7	8
bits	#0 .. 7	#8 .. #15	#16 .. #23	#24 .. #31		#0 .. 7	#8 .. #15	#16 .. #23	#24 .. #31
component	A					B			

This is the code that implements that:

[42] http://www.ada-auth.org/standards/22rm/html/RM-13-5-2.html

Listing 149: p.ads

```
package P is

   type R is record
      A : Integer;
      B : Integer;
   end record;

   for R use record
      A at 0 range 0 .. 31;
      B at 5 range 0 .. 31;
   end record;

end P;
```

Listing 150: show_empty_byte.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with P;           use P;

procedure Show_Empty_Byte is
begin
   Put_Line ("R'Size:        "
             & R'Size'Image);
   Put_Line ("R'Object_Size: "
             & R'Object_Size'Image);
end Show_Empty_Byte;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Record_Representation_
 ↪Storage_Clauses.Rep_Clauses_Empty_Byte
MD5: c616e534e95a06f2e8b3052a3e8a9aab
```

Runtime output

```
R'Size:         72
R'Object_Size:  96
```

When running the application above, we see that, due to the extra byte in the record representation, the sizes increase. On a typical 64-bit PC, R'Size is now 76 bits, which reflects the additional eight bits that we introduced between components A and B. Depending on the target architecture, you may also see that R'Object_Size is now 96 bits, which is the size the compiler selects as the most appropriate for this record type. As we've mentioned in the previous section, we can use aspects to request a specific size to the compiler. In this case, we could use the Object_Size aspect:

Listing 151: p.ads

```
package P is

   type R is record
      A : Integer;
      B : Integer;
   end record
     with Object_Size => 72;

   for R use record
      A at 0 range 0 .. 31;
```

(continues on next page)

(continued from previous page)

```
      B at 5 range 0 .. 31;
   end record;

end P;
```

Listing 152: show_empty_byte.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with P;           use P;

procedure Show_Empty_Byte is
begin
   Put_Line ("R'Size:        "
             & R'Size'Image);
   Put_Line ("R'Object_Size: "
             & R'Object_Size'Image);
end Show_Empty_Byte;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Record_Representation_
↪Storage_Clauses.Rep_Clauses_Empty_Byte
MD5: 9d7bae2b2aabeda4bc03752544cee9b9
```

Runtime output

```
R'Size:         72
R'Object_Size:  72
```

If the code compiles, `R'Size` and `R'Object_Size` should now have the same value.

Derived Types And Representation Clauses

In some cases, you might want to modify the memory representation of a record without impacting existing code. For example, you might want to use a record type that was declared in a package that you're not allowed to change. Also, you would like to modify its memory representation in your application. A nice strategy is to derive a type and use a representation clause for the derived type.

We can apply this strategy on our previous example. Let's say we would like to use record type R from package P in our application, but we're not allowed to modify package P — or the record type, for that matter. In this case, we could simply derive R as R_New and use a representation clause for R_New. This is exactly what we do in the specification of the child package P.Rep:

Listing 153: p.ads

```
package P is

   type R is record
      A : Integer;
      B : Integer;
   end record;

end P;
```

Listing 154: p-rep.ads

```
package P.Rep is

   type R_New is new R
     with Object_Size => 72;

   for R_New use record
      A at 0 range 0 .. 31;
      B at 5 range 0 .. 31;
   end record;

end P.Rep;
```

Listing 155: show_empty_byte.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with P;           use P;
with P.Rep;       use P.Rep;

procedure Show_Empty_Byte is
begin
   Put_Line ("R'Size:        "
             & R'Size'Image);
   Put_Line ("R'Object_Size: "
             & R'Object_Size'Image);

   Put_Line ("R_New'Size:        "
             & R_New'Size'Image);
   Put_Line ("R_New'Object_Size: "
             & R_New'Object_Size'Image);
end Show_Empty_Byte;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Record_Representation_
 ↪Storage_Clauses.Derived_Rep_Clauses_Empty_Byte
MD5: 3a1e0837f8bd8250f20fc7b274b869d5
```

Runtime output

```
R'Size:         64
R'Object_Size:  64
R_New'Size:         72
R_New'Object_Size:  72
```

When running this example, we see that the R type retains the memory representation selected by the compiler for the target architecture, while the R_New has the memory representation that we specified.

Representation on Bit Level

A very common application of representation clauses is to specify individual bits of a record. This is particularly useful, for example, when mapping registers or implementing protocols.

Let's consider the following fictitious register as an example:

bit	0	1	2	3	4	5	6	7
component	S		(reserved)		Error	V1		

Here, S is the current status, `Error` is a flag, and `V1` contains a value. Due to the fact that we can use representation clauses to describe individual bits of a register as records, the implementation becomes as simple as this:

Listing 156: p.ads

```
package P is

  type Status is (Ready, Waiting,
                  Processing, Done);
  type UInt_3 is range 0 .. 2 ** 3 - 1;

   type Simple_Reg is record
      S     : Status;
      Error : Boolean;
      V1    : UInt_3;
   end record;

   for Simple_Reg use record
      S     at 0 range 0 .. 1;
      --  Bit #2 and 3: reserved!
      Error at 0 range 4 .. 4;
      V1    at 0 range 5 .. 7;
   end record;

end P;
```

Listing 157: show_simple_reg.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with P;           use P;

procedure Show_Simple_Reg is
begin
   Put_Line ("Simple_Reg'Size:        "
             & Simple_Reg'Size'Image);
   Put_Line ("Simple_Reg'Object_Size: "
             & Simple_Reg'Object_Size'Image);
end Show_Simple_Reg;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Record_Representation_
 ↪Storage_Clauses.Rep_Clauses_Simple_Reg
MD5: cbac444336572460062f922767c226a5
```

Runtime output

```
Simple_Reg'Size:         8
Simple_Reg'Object_Size:  8
```

As we can see in the declaration of the `Simple_Reg` type, each component represents a field from our register, and it has a fixed location (which matches the register representation we see in the graph above). Any operation on the register is as simple as accessing the record component. For example:

Listing 158: show_simple_reg.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with P;           use P;

procedure Show_Simple_Reg is
   Default : constant Simple_Reg :=
               (S     => Ready,
                Error => False,
                V1    => 0);

   R : Simple_Reg := Default;
begin
   Put_Line ("R.S:  " & R.S'Image);

   R.V1 := 4;

   Put_Line ("R.V1: " & R.V1'Image);
end Show_Simple_Reg;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Record_Representation_
 ↪Storage_Clauses.Rep_Clauses_Simple_Reg
MD5: e442396e43d6609c1c837165bbc21641
```

Runtime output

```
R.S:  READY
R.V1:  4
```

As we can see in the example, to retrieve the current status of the register, we just have to write `R.S`. To update the *V1* field of the register with the value 4, we just have to write `R.V1 := 4`. No extra code — such as bit-masking or bit-shifting — is needed here.

In other languages

Some programming languages require that developers use complicated, error-prone approaches — which may include manually bit-shifting and bit-masking variables — to retrieve information from or store information to individual bits or registers. In Ada, however, this is efficiently handled by the compiler, so that developers only need to correctly describe the register mapping using representation clauses.

25.2.4 Changing Data Representation

Note: This section was originally written by Robert Dewar and published as Gem #27: Changing Data Representation[43] and Gem #28[44].

A powerful feature of Ada is the ability to specify the exact data layout. This is particularly important when you have an external device or program that requires a very specific format. Some examples are:

Listing 159: communication.ads

```
package Communication is

   type Com_Packet is record
      Key : Boolean;
      Id  : Character;
      Val : Integer range 100 .. 227;
   end record;

   for Com_Packet use record
      Key at 0 range 0 .. 0;
      Id  at 0 range 1 .. 8;
      Val at 0 range 9 .. 15;
   end record;

end Communication;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Changing_Data_
 ↪Representation.Com_Packet
MD5: cbd7f5547c5b0458853ac21d03aa41f8
```

Build output

```
communication.ads:12:11: warning: component clause forces biased representation␣
 ↪for "Val" [-gnatw.b]
```

which lays out the fields of a record, and in the case of `Val`, forces a biased representation in which all zero bits represents 100. Another example is:

Listing 160: array_representation.ads

```
package Array_Representation is

   type Val is (A, B, C, D, E, F, G, H);

   type Arr is array (1 .. 16) of Val
     with Component_Size => 3;

end Array_Representation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Changing_Data_
 ↪Representation.Array_Rep
MD5: 7eb17fc2cd415acb7c53a363fa336807
```

[43] https://www.adacore.com/gems/gem-27
[44] https://www.adacore.com/gems/gem-28

which forces the components to take only 3 bits, crossing byte boundaries as needed. A final example is:

Listing 161: enumeration_representation.ads

```
package Enumeration_Representation is

   type Status is (Off, On, Unknown);
   for Status use (Off     => 2#001#,
                   On      => 2#010#,
                   Unknown => 2#100#);

end Enumeration_Representation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Changing_Data_
 ↪Representation.Enum_Rep
MD5: 3c3e9f4ae11e9bb2482588d27ba43c30
```

which allows specified values for an enumeration type, instead of the efficient default values of 0, 1, 2.

In all these cases, we might use these representation clauses to match external specifications, which can be very useful. The disadvantage of such layouts is that they are inefficient, and accessing individual components, or, in the case of the enumeration type, looping through the values can increase space and time requirements for the program code.

One approach that is often effective is to read or write the data in question in this specified form, but internally in the program represent the data in the normal default layout, allowing efficient access, and do all internal computations with this more efficient form.

To follow this approach, you will need to convert between the efficient format and the specified format. Ada provides a very convenient method for doing this, as described in RM 13.6 "Change of Representation"[45].

The idea is to use type derivation, where one type has the specified format and the other has the normal default format. For instance for the array case above, we would write:

Listing 162: array_representation.ads

```
package Array_Representation is

   type Val is (A, B, C, D, E, F, G, H);
   type Arr is array (1 .. 16) of Val;

   type External_Arr is new Arr
     with Component_Size => 3;

end Array_Representation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Changing_Data_
 ↪Representation.Array_Rep
MD5: d4e90f6ef8ff81771980771356eab235
```

Now we read and write the data using the `External_Arr` type. When we want to convert to the efficient form, `Arr`, we simply use a type conversion.

[45] http://www.ada-auth.org/standards/22rm/html/RM-13-6.html

Listing 163: using_array_for_io.adb

```
with Array_Representation;
use  Array_Representation;

procedure Using_Array_For_IO is
   Input_Data  : External_Arr;
   Work_Data   : Arr;
   Output_Data : External_Arr;
begin
   --  (read data into Input_Data)

   --  Now convert to internal form
   Work_Data := Arr (Input_Data);

   --  (computations using efficient
   --   Work_Data form)

   --  Convert back to external form
   Output_Data := External_Arr (Work_Data);

end Using_Array_For_IO;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Changing_Data_
 ↪Representation.Array_Rep
MD5: 88efe4b8a7f07e0c32f11131d6eafbc1
```

Build output

```
using_array_for_io.adb:5:04: warning: variable "Input_Data" is read but never␣
 ↪assigned [-gnatwv]
```

Using this approach, the quite complex task of copying all the data of the array from one form to another, with all the necessary masking and shift operations, is completely automatic.

Similar code can be used in the record and enumeration type cases. It is even possible to specify two different representations for the two types, and convert from one form to the other, as in:

Listing 164: enumeration_representation.ads

```
package Enumeration_Representation is

   type Status_In is (Off, On, Unknown);
   type Status_Out is new Status_In;

   for Status_In use (Off     => 2#001#,
                      On      => 2#010#,
                      Unknown => 2#100#);
   for Status_Out use (Off     => 103,
                       On      => 1045,
                       Unknown => 7700);

end Enumeration_Representation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Changing_Data_
 ↪Representation.Enum_Rep
```

(continues on next page)

(continued from previous page)

```
MD5: f78c3718280f9265ff54270c5834b458
```

There are two restrictions that must be kept in mind when using this feature. First, you have to use a derived type. You can't put representation clauses on subtypes, which means that the conversion must always be explicit. Second, there is a rule RM 13.1[46] (10) that restricts the placement of interesting representation clauses:

> 10 For an untagged derived type, no type-related representation items are allowed if the parent type is a by-reference type, or has any user-defined primitive subprograms.

All the representation clauses that are interesting from the point of view of change of representation are "type related", so for example, the following sequence would be illegal:

Listing 165: array_representation.ads

```
1  package Array_Representation is
2
3     type Val is (A, B, C, D, E, F, G, H);
4     type Arr is array (1 .. 16) of Val;
5
6     procedure Rearrange (Arg : in out Arr);
7
8     type External_Arr is new Arr
9       with Component_Size => 3;
10
11 end Array_Representation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Changing_Data_
 ↪Representation.Array_Rep_2
MD5: 70201932d40e3fb356bc1d8ab188f2df
```

Build output

```
array_representation.ads:9:11: error: representation item not permitted before Ada␣
 ↪2022
array_representation.ads:9:11: error: parent type "Arr" has primitive operations
gprbuild: *** compilation phase failed
```

Why these restrictions? Well, the answer is a little complex, and has to do with efficiency considerations, which we will address below.

Restrictions

In the previous subsection, we discussed the use of derived types and representation clauses to achieve automatic change of representation. More accurately, this feature is not completely automatic, since it requires you to write an explicit conversion. In fact there is a principle behind the design here which says that a change of representation should never occur implicitly behind the back of the programmer without such an explicit request by means of a type conversion.

The reason for that is that the change of representation operation can be very expensive, since in general it can require component by component copying, changing the representation on each component.

[46] http://www.ada-auth.org/standards/22rm/html/RM-13-1.html

Let's have a look at the `-gnatG` expanded code to see what is hidden under the covers here. For example, the conversion `Arr (Input_Data)` from the previous example generates the following expanded code:

```
B26b : declare
   [subtype p__TarrD1 is integer range 1 .. 16]
   R25b : p__TarrD1 := 1;
begin
   for L24b in 1 .. 16 loop
      [subtype p__arr___XP3 is
        system__unsigned_types__long_long_unsigned range 0 ..
        16#FFFF_FFFF_FFFF#]
      work_data := p__arr___XP3!((work_data and not shift_left!(
        16#7#, 3 * (integer(L24b - 1)))) or shift_left!(p__arr___XP3!
        (input_data (R25b)), 3 * (integer(L24b - 1))));
      R25b := p__TarrD1'succ(R25b);
   end loop;
end B26b;
```

That's pretty horrible! In fact, we could have simplified it for this section, but we have left it in its original form, so that you can see why it is nice to let the compiler generate all this stuff so you don't have to worry about it yourself.

Given that the conversion can be pretty inefficient, you don't want to convert backwards and forwards more than you have to, and the whole approach is only worthwhile if we'll be doing extensive computations involving the value.

The expense of the conversion explains two aspects of this feature that are not obvious. First, why do we require derived types instead of just allowing subtypes to have different representations, avoiding the need for an explicit conversion?

The answer is precisely that the conversions are expensive, and you don't want them happening behind your back. So if you write the explicit conversion, you get all the gobbledygook listed above, but you can be sure that this never happens unless you explicitly ask for it.

This also explains the restriction we mentioned in previous subsection from RM 13.1[47] (10):

> 10 For an untagged derived type, no type-related representation items are allowed if the parent type is a by-reference type, or has any user-defined primitive subprograms.

It turns out this restriction is all about avoiding implicit changes of representation. Let's have a look at how type derivation works when there are primitive subprograms defined at the point of derivation. Consider this example:

Listing 166: my_ints.ads

```
1  package My_Ints is
2
3     type My_Int_1 is range 1 .. 10;
4
5     function Odd (Arg : My_Int_1)
6                   return Boolean;
7
8     type My_Int_2 is new My_Int_1;
9
10 end My_Ints;
```

[47] http://www.ada-auth.org/standards/22rm/html/RM-13-1.html

Listing 167: my_ints.adb

```
package body My_Ints is

   function Odd (Arg : My_Int_1)
                 return Boolean is
     (True);
   --  Dummy implementation!

end My_Ints;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Changing_Data_
 ↪Representation.My_Int
MD5: a29401698307998288f02b349d04d1d2
```

Now when we do the type derivation, we inherit the function Odd for My_Int_2. But where does this function come from? We haven't written it explicitly, so the compiler somehow materializes this new implicit function. How does it do that?

We might think that a complete new function is created including a body in which My_Int_2 replaces My_Int_1, but that would be impractical and expensive. The actual mechanism avoids the need to do this by use of implicit type conversions. Suppose after the above declarations, we write:

Listing 168: using_my_int.adb

```
with My_Ints; use My_Ints;

procedure Using_My_Int is
   Var : My_Int_2;
begin

   if Odd (Var) then
      --   ^ Calling Odd function
      --     for My_Int_2 type.
      null;
   end if;

end Using_My_Int;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Changing_Data_
 ↪Representation.My_Int
MD5: f68272d55e68687b7102885313c7831b
```

Build output

```
using_my_int.adb:4:04: warning: variable "Var" is read but never assigned [-gnatwv]
```

The compiler translates this as:

Listing 169: using_my_int.adb

```
with My_Ints; use My_Ints;

procedure Using_My_Int is
   Var : My_Int_2;
begin
```

(continues on next page)

(continued from previous page)

```
6
7     if Odd (My_Int_1 (Var)) then
8        --    ^ Converting My_Int_2 to
9        --      My_Int_1 type before
10       --      calling Odd function.
11       null;
12    end if;
13
14 end Using_My_Int;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Changing_Data_
 ↪Representation.My_Int
MD5: b3d0053c61412a2b985cd580b645e048
```

Build output

```
using_my_int.adb:4:04: warning: variable "Var" is read but never assigned [-gnatwv]
```

This implicit conversion is a nice trick, it means that we can get the effect of inheriting a new operation without actually having to create it. Furthermore, in a case like this, the type conversion generates no code, since `My_Int_1` and `My_Int_2` have the same representation.

But the whole point is that they might not have the same representation if one of them had a representation clause that made the representations different, and in this case the implicit conversion inserted by the compiler could be expensive, perhaps generating the junk we quoted above for the `Arr` case. Since we never want that to happen implicitly, there is a rule to prevent it.

The business of forbidding by-reference types (which includes all tagged types) is also driven by this consideration. If the representations are the same, it is fine to pass by reference, even in the presence of the conversion, but if there was a change of representation, it would force a copy, which would violate the by-reference requirement.

So to summarize this section, on the one hand Ada gives you a very convenient way to trigger these complex conversions between different representations. On the other hand, Ada guarantees that you never get these potentially expensive conversions happening unless you explicitly ask for them.

25.2.5 Valid Attribute

When receiving data from external sources, we're subjected to problems such as transmission errors. If not handled properly, erroneous data can lead to major issues in an application.

One of those issues originates from the fact that transmission errors might lead to invalid information stored in memory. When proper checks are active, using invalid information is detected at runtime and an exception is raised at this point, which might then be handled by the application.

Instead of relying on exception handling, however, we could instead ensure that the information we're about to use is valid. We can do this by using the `Valid` attribute. For example, if we have a variable `Var`, we can verify that the value stored in `Var` is valid by writing `Var'Valid`, which returns a **`Boolean`** value. Therefore, if the value of `Var` isn't valid, `Var'Valid` returns **`False`**, so we can have code that handles this situation before we actually make use of `Var`. In other words, instead of handling a potential exception in other parts of the application, we can proactively verify that input information is correct and avoid that an exception is raised.

In the next example, we show an application that

- generates a file containing mock-up data, and then
- reads information from this file as state values.

The mock-up data includes valid and invalid states.

Listing 170: create_test_file.ads

```
procedure Create_Test_File (File_Name : String);
```

Listing 171: create_test_file.adb

```

↪States
MD5: f7af2946ebe663932494448a0d3d3020
```

Runtime output

```
OFF
ON
WAITING
Invalid value detected!
ON
Invalid value detected!
```

Let's start our discussion on this example with the `States` package, which contains the declaration of the `State` type. This type is a simple enumeration containing three states: `Off`, `On` and `Waiting`. We're assigning specific integer values for this type by declaring an

enumeration representation clause. Note that we're using the `Size` aspect to request that objects of this type have the same size as the **`Integer`** type. This becomes important later on when parsing data from the file.

In the `Create_Test_File` procedure, we create a file containing integer values, which is parsed later by the `Read_Display_States` procedure. The `Create_Test_File` procedure doesn't contain any reference to the `State` type, so we're not constrained to just writing information that is valid for this type. On the contrary, this procedure makes use of the **`Integer`** type, so we can write any integer value to the file. We use this strategy to write both valid and invalid values of `State` to the file. This allows us to simulate an environment where transmission errors occur.

We call the `Read_Display_States` procedure to read information from the file and display each state stored in the file. In the main loop of this procedure, we call Read to read a state from the file and store it in the S variable. We then call the nested `Display_State` procedure to display the actual state stored in S. The most important line of code in the `Display_State` procedure is the one that uses the `Valid` attribute:

```
if S'Valid then
```

In this line, we're verifying that the S variable contains a valid state before displaying the actual information from S. If the value stored in S isn't valid, we can handle the issue accordingly. In this case, we're simply displaying a message indicating that an invalid value was detected. If we didn't have this check, the `Constraint_Error` exception would be raised when trying to use invalid data stored in S — this would happen, for example, after reading the integer value 3 from the input file.

In summary, using the `Valid` attribute is a good strategy we can employ when we know that information stored in memory might be corrupted.

In the Ada Reference Manual

- 13.9.2 The Valid Attribute[48]

25.2.6 Unchecked Union

We've introduced variant records back in the *Introduction to Ada course* (page 104). In simple terms, a variant record is a record with discriminants that allows for changing its structure. Basically, it's a record containing a **`case`**.

The `State_Or_Integer` declaration in the `States` package below is an example of a variant record:

Listing 175: states.ads

```
1  package States is
2
3     type State is (Off, On, Waiting)
4       with Size => Integer'Size;
5
6     for State use (Off     => 1,
7                    On      => 2,
8                    Waiting => 4);
9
10    type State_Or_Integer (Use_Enum : Boolean) is
11    record
12       case Use_Enum is
```

(continues on next page)

[48] http://www.ada-auth.org/standards/22rm/html/RM-13-9-2.html

(continued from previous page)

```
         when False => I : Integer;
         when True  => S : State;
      end case;
   end record;

   procedure Display_State_Value
     (V : State_Or_Integer);

end States;
```

Listing 176: states.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body States is

   procedure Display_State_Value
     (V : State_Or_Integer)
   is
   begin
      Put_Line ("State: " & V.S'Image);
      Put_Line ("Value: " & V.I'Image);
   end Display_State_Value;

end States;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Unchecked_Union.State_
 ↪Or_Integer
MD5: fa72f52a4396a2e66931ff6932c567fc
```

As mentioned in the previous course, if you try to access a component that is not valid for your record, a `Constraint_Error` exception is raised. For example, in the implementation of the `Display_State_Value` procedure, we're trying to retrieve the value of the integer component (`I`) of the `V` record. When calling this procedure, the `Constraint_Error` exception is raised as expected because `Use_Enum` is set to **`True`**, so that the `I` component is invalid — only the `S` component is valid in this case.

Listing 177: show_variant_rec_error.adb

```
with States; use States;

procedure Show_Variant_Rec_Error is
   V : State_Or_Integer (Use_Enum => True);
begin
   V.S := On;
   Display_State_Value (V);
end Show_Variant_Rec_Error;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Unchecked_Union.State_
 ↪Or_Integer
MD5: b8cf215dd55bfdec6950df35c7bc19b9
```

Runtime output

```
State: ON

raised CONSTRAINT_ERROR : states.adb:10 discriminant check failed
```

In addition to not being able to read the value of a component that isn't valid, assigning a value to a component that isn't valid also raises an exception at runtime. In this example, we cannot assign to `V.I`:

Listing 178: show_variant_rec_error.adb

```
with States; use States;

procedure Show_Variant_Rec_Error is
   V : State_Or_Integer (Use_Enum => True);
begin
   V.I := 4;
   --  Error: V.I cannot be accessed because
   --         Use_Enum is set to True.
end Show_Variant_Rec_Error;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Unchecked_Union.State_
 ↪Or_Integer
MD5: 985a84faccc3d590ac767e914bea0c1d
```

Build output

```
show_variant_rec_error.adb:4:04: warning: variable "V" is never read and never␣
 ↪assigned [-gnatwv]
show_variant_rec_error.adb:6:05: warning: component not present in subtype of
 ↪"State_Or_Integer" defined at line 4 [enabled by default]
show_variant_rec_error.adb:6:05: warning: Constraint_Error will be raised at run␣
 ↪time [enabled by default]
```

Runtime output

```

raised CONSTRAINT_ERROR : show_variant_rec_error.adb:6 discriminant check failed
```

We may circumvent this limitation by using the `Unchecked_Union` aspect. For example, we can derive a new type from `State_Or_Integer` and use this aspect in its declaration. We do this in the declaration of the `Unchecked_State_Or_Integer` type below.

Listing 179: states.ads

```
package States is

   type State is (Off, On, Waiting)
     with Size => Integer'Size;

   for State use (Off     => 1,
                  On      => 2,
                  Waiting => 4);

   type State_Or_Integer (Use_Enum : Boolean) is
   record
      case Use_Enum is
         when False => I : Integer;
         when True  => S : State;
      end case;
   end record;

   type Unchecked_State_Or_Integer
     (Use_Enum : Boolean) is new
       State_Or_Integer (Use_Enum)
```

(continues on next page)

(continued from previous page)

```
         with Unchecked_Union;

   procedure Display_State_Value
     (V : Unchecked_State_Or_Integer);

end States;
```

Listing 180: states.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body States is

   procedure Display_State_Value
     (V : Unchecked_State_Or_Integer)
   is
   begin
      Put_Line ("State: " & V.S'Image);
      Put_Line ("Value: " & V.I'Image);
   end Display_State_Value;

end States;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Unchecked_Union.
 ↪Unchecked_State_Or_Integer
MD5: e97271a24aab23d2db450308401667ac
```

Because we now use the `Unchecked_State_Or_Integer` type for the input parameter of the `Display_State_Value` procedure, no exception is raised at runtime, as both components are now accessible. For example:

Listing 181: show_unchecked_union.adb

```
with States; use States;

procedure Show_Unchecked_Union is
   V : State_Or_Integer (Use_Enum => True);
begin
   V.S := On;
   Display_State_Value
     (Unchecked_State_Or_Integer (V));
end Show_Unchecked_Union;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Unchecked_Union.
 ↪Unchecked_State_Or_Integer
MD5: 331cc1ab6709ab7e0062d64c55a75a6c
```

Runtime output

```
State: ON
Value:  2
```

Note that, in the call to the `Display_State_Value` procedure, we first need to convert the `V` argument from the `State_Or_Integer` to the `Unchecked_State_Or_Integer` type.

Also, we can assign to any of the components of a record that has the `Unchecked_Union` aspect. In our example, we can now assign to both the `S` and the `I` components of the `V`

record:

Listing 182: show_unchecked_union.adb

```
with States; use States;

procedure Show_Unchecked_Union is
   V : Unchecked_State_Or_Integer
         (Use_Enum => True);
begin
   V := (Use_Enum => True, S => On);
   Display_State_Value (V);

   V := (Use_Enum => False, I => 4);
   Display_State_Value (V);
end Show_Unchecked_Union;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Unchecked_Union.
 ↪Unchecked_State_Or_Integer
MD5: bb472e91c5e7b7e63d6246dbcf5226a0
```

Runtime output

```
State: ON
Value:  2
State: WAITING
Value:  4
```

In the example above, we're use an aggregate in the assignments to V. By doing so, we avoid that Use_Enum is set to the *wrong* component. For example:

Listing 183: show_unchecked_union.adb

```
with States; use States;

procedure Show_Unchecked_Union is
   V : Unchecked_State_Or_Integer
         (Use_Enum => True);
begin
   V.S := On;
   Display_State_Value (V);

   V.I := 4;
   --  Error: cannot directly assign to V.I,
   --         as Use_Enum is set to True.

   Display_State_Value (V);
end Show_Unchecked_Union;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Unchecked_Union.
 ↪Unchecked_State_Or_Integer
MD5: 74ac11a3effdafd3959fface295a86da
```

Build output

```
show_unchecked_union.adb:10:05: warning: component not present in subtype of
 ↪"Unchecked_State_Or_Integer" defined at line 4 [enabled by default]
show_unchecked_union.adb:10:05: warning: Constraint_Error will be raised at run␣
 ↪time [enabled by default]
```

Runtime output

```
State: ON
Value:  2

raised CONSTRAINT_ERROR : show_unchecked_union.adb:10 discriminant check failed
```

Here, even though the record has the `Unchecked_Union` attribute, we cannot directly assign to the `I` component because `Use_Enum` is set to **`True`**, so only the `S` is accessible. We can, however, read its value, as we do in the `Display_State_Value` procedure.

Be aware that, due to the fact the union is not checked, we might write invalid data to the record. In the example below, we initialize the `I` component with 3, which is a valid integer value, but results in an invalid value for the `S` component, as the value 3 cannot be mapped to the representation of the `State` type.

Listing 184: show_unchecked_union.adb

```
1  with States; use States;
2
3  procedure Show_Unchecked_Union is
4     V : Unchecked_State_Or_Integer
5           (Use_Enum => True);
6  begin
7     V := (Use_Enum => False, I => 3);
8     Display_State_Value (V);
9  end Show_Unchecked_Union;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Unchecked_Union.
 ↪Unchecked_State_Or_Integer
MD5: f63e64df137cfc3c29e41f784306f0e4
```

Runtime output

```

raised CONSTRAINT_ERROR : states.adb:9 invalid data
```

To mitigate this problem, we could use the `Valid` attribute — discussed in the previous section — for the `S` component before trying to use its value in the implementation of the `Display_State_Value` procedure:

Listing 185: states.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body States is
4
5     procedure Display_State_Value
6       (V : Unchecked_State_Or_Integer)
7     is
8     begin
9        if V.S'Valid then
10          Put_Line ("State: " & V.S'Image);
11       else
12          Put_Line ("State: <invalid>");
13       end if;
14       Put_Line ("Value: " & V.I'Image);
15    end Display_State_Value;
16
17 end States;
```

Listing 186: show_unchecked_union.adb

```
with States; use States;

procedure Show_Unchecked_Union is
   V : Unchecked_State_Or_Integer
         (Use_Enum => True);
begin
   V := (Use_Enum => False, I => 3);
   Display_State_Value (V);
end Show_Unchecked_Union;
```

However, in general, you should avoid using the `Unchecked_Union` aspect due to the potential issues you might introduce into your application. In the majority of the cases, you don't need it at all — except for special cases such as when interfacing with C code that makes use of union types or solving very specific problems when doing low-level programming.

In the Ada Reference Manual

- B.3.3 Unchecked Union Types[49]

25.2.7 Shared variable control

Ada has built-in support for handling both volatile and atomic data. Let's start by discussing volatile objects.

In the Ada Reference Manual

- C.6 Shared Variable Control[50]

Volatile

A volatile[51] object can be described as an object in memory whose value may change between two consecutive memory accesses of a process A — even if process A itself hasn't changed the value. This situation may arise when an object in memory is being shared by multiple threads. For example, a thread *B* may modify the value of that object between two read accesses of a thread *A*. Another typical example is the one of memory-mapped I/O[52], where the hardware might be constantly changing the value of an object in memory.

Because the value of a volatile object may be constantly changing, a compiler cannot generate code to store the value of that object in a register and then use the value from the register in subsequent operations. Storing into a register is avoided because, if the value is stored there, it would be outdated if another process had changed the volatile object in the meantime. Instead, the compiler generates code in such a way that the process must read the value of the volatile object from memory for each access.

Let's look at a simple example:

[49] http://www.ada-auth.org/standards/22rm/html/RM-B-3-3.html
[50] http://www.ada-auth.org/standards/22rm/html/RM-C-6.html
[51] https://en.wikipedia.org/wiki/Volatile_(computer_programming)
[52] https://en.wikipedia.org/wiki/Memory-mapped_I/O

Listing 187: show_volatile_object.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Volatile_Object is
   Val : Long_Float with Volatile;
begin
   Val := 0.0;
   for I in 0 .. 999 loop
      Val := Val + 2.0 * Long_Float (I);
   end loop;

   Put_Line ("Val: " & Long_Float'Image (Val));
end Show_Volatile_Object;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Shared_Variable_
 ↪Control.Volatile_Object_Ada
MD5: aa1e276e64e69813bfc3e3ef39f3dd47
```

Runtime output

```
Val:  9.99000000000000E+05
```

In this example, Val has the Volatile aspect, which makes the object volatile. We can also use the Volatile aspect in type declarations. For example:

Listing 188: shared_var_types.ads

```
package Shared_Var_Types is

   type Volatile_Long_Float is new
     Long_Float with Volatile;

end Shared_Var_Types;
```

Listing 189: show_volatile_type.adb

```
with Ada.Text_IO;      use Ada.Text_IO;
with Shared_Var_Types; use Shared_Var_Types;

procedure Show_Volatile_Type is
   Val : Volatile_Long_Float;
begin
   Val := 0.0;
   for I in 0 .. 999 loop
      Val := Val + 2.0 * Volatile_Long_Float (I);
   end loop;

   Put_Line ("Val: "
             & Volatile_Long_Float'Image (Val));
end Show_Volatile_Type;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Shared_Variable_
 ↪Control.Volatile_Type
MD5: 0d31156d47b2edcfb94debd016c8bb87
```

Runtime output

```
Val:  9.99000000000000E+05
```

Here, we're declaring a new type `Volatile_Long_Float` in the `Shared_Var_Types` package. This type is based on the **`Long_Float`** type and uses the `Volatile` aspect. Any object of this type is automatically volatile.

In addition to that, we can declare components of an array to be volatile. In this case, we can use the `Volatile_Components` aspect in the array declaration. For example:

Listing 190: show_volatile_array_components.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Volatile_Array_Components is
   Arr : array (1 .. 2) of Long_Float
           with Volatile_Components;
begin
   Arr := (others => 0.0);

   for I in 0 .. 999 loop
      Arr (1) := Arr (1) +  2.0 * Long_Float (I);
      Arr (2) := Arr (2) + 10.0 * Long_Float (I);
   end loop;

   Put_Line ("Arr (1): "
             & Long_Float'Image (Arr (1)));
   Put_Line ("Arr (2): "
             & Long_Float'Image (Arr (2)));
end Show_Volatile_Array_Components;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Shared_Variable_
 ↪Control.Volatile_Array_Components
MD5: 05b3ee20f08c5a85f5872727a61c148d
```

Runtime output

```
Arr (1):  9.99000000000000E+05
Arr (2):  4.99500000000000E+06
```

Note that it's possible to use the `Volatile` aspect for the array declaration as well:

Listing 191: shared_var_types.ads

```
package Shared_Var_Types is

private
   Arr : array (1 .. 2) of Long_Float
           with Volatile;

end Shared_Var_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Shared_Variable_
 ↪Control.Volatile_Array
MD5: c9b7b9f94f1fac295753c7e7b9426fb2
```

Note that, if the `Volatile` aspect is specified for an object, then the `Volatile_Components` aspect is also specified automatically — if it makes sense in the context, of course. In the

example above, even though `Volatile_Components` isn't specified in the declaration of the `Arr` array , it's automatically set as well.

Independent

When you write code to access a single object in memory, you might actually be accessing multiple objects at once. For example, when you declare types that make use of representation clauses — as we've seen in previous sections —, you might be accessing multiple objects that are grouped together in a single storage unit. For example, if you have components A and B stored in the same storage unit, you cannot update A without actually writing (the same value) to B. Those objects aren't independently addressable because, in order to access one of them, we have to actually address multiple objects at once.

When an object is independently addressable, we call it an independent object. In this case, we make sure that, when accessing that object, we won't be simultaneously accessing another object. As a consequence, this feature limits the way objects can be represented in memory, as we'll see next.

To indicate that an object is independent, we use the `Independent` aspect:

Listing 192: shared_var_types.ads

```
package Shared_Var_Types is

   I : Integer with Independent;

end Shared_Var_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Shared_Variable_
 ↪Control.Independent_Object
MD5: d90fef37584ca8802b8a3e3858c0095b
```

Similarly, we can use this aspect when declaring types:

Listing 193: shared_var_types.ads

```
package Shared_Var_Types is

   type Independent_Boolean is new Boolean
     with Independent;

   type Flags is record
      F1 : Independent_Boolean;
      F2 : Independent_Boolean;
   end record;

end Shared_Var_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Shared_Variable_
 ↪Control.Independent_Type
MD5: 7bcbee5b73067149b14c4b1b061f803c
```

In this example, we're declaring the `Independent_Boolean` type and using it in the declaration of the `Flag` record type. Let's now derive the `Flags` type and use a representation clause for the derived type:

Listing 194: shared_var_types-representation.ads

```
package Shared_Var_Types.Representation is

   type Rep_Flags is new Flags;

   for Rep_Flags use record
      F1 at 0 range 0 .. 0;
      F2 at 0 range 1 .. 1;
      --            ^  ERROR: start position of
      --                      F2 is wrong!
      --    ^          ERROR: F1 and F2 share the
      --                      same storage unit!
   end record;

end Shared_Var_Types.Representation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Shared_Variable_
 ↪Control.Independent_Type
MD5: bb9d5badf33401660e7e20a7cd612dab
```

Build output

```
shared_var_types-representation.ads:6:26: error: size for independent "F1" must be␣
 ↪multiple of Storage_Unit
shared_var_types-representation.ads:7:21: error: position for independent "F2"␣
 ↪must be multiple of Storage_Unit
shared_var_types-representation.ads:7:26: error: size for independent "F2" must be␣
 ↪multiple of Storage_Unit
gprbuild: *** compilation phase failed
```

As you can see when trying to compile this example, the representation clause that we used for Rep_Flags isn't following these limitations:

1. The size of each independent component must be a multiple of a storage unit.
2. The start position of each independent component must be a multiple of a storage unit.

For example, for architectures that have a storage unit of one byte — such as standard desktop computers —, this means that the size and the position of independent components must be a multiple of a byte. Let's correct the issues in the code above by:

- setting the size of each independent component to correspond to `Storage_Unit` — using a range between 0 and `Storage_Unit - 1` —, and
- setting the start position to zero.

This is the corrected version:

Listing 195: shared_var_types-representation.ads

```
with System;

package Shared_Var_Types.Representation is

   type Rep_Flags is new Flags;

   for Rep_Flags use record
      F1 at 0 range 0 .. System.Storage_Unit - 1;
      F2 at 1 range 0 .. System.Storage_Unit - 1;
```

(continues on next page)

(continued from previous page)

```
   end record;

end Shared_Var_Types.Representation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Shared_Variable_
 ↪Control.Independent_Type
MD5: ed57e57cd746698909a4f7ce40a29dfc
```

Note that the representation that we're now using for Rep_Flags is most likely the representation that the compiler would have chosen for this data type. We could, however, have added an empty storage unit between F1 and F2 — by simply writing F2 `at 2 ...`:

Listing 196: shared_var_types-representation.ads

```
with System;

package Shared_Var_Types.Representation is

   type Rep_Flags is new Flags;

   for Rep_Flags use record
      F1 at 0 range 0 .. System.Storage_Unit - 1;
      F2 at 2 range 0 .. System.Storage_Unit - 1;
   end record;

end Shared_Var_Types.Representation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Shared_Variable_
 ↪Control.Independent_Type
MD5: 71fedf8aac7c19bca1ba3b487efa9b17
```

As long as we follow the rules for independent objects, we're still allowed to use representation clauses that don't correspond to the one that the compiler might select.

For arrays, we can use the `Independent_Components` aspect:

Listing 197: shared_var_types.ads

```
package Shared_Var_Types is

   Flags : array (1 .. 8) of Boolean
             with Independent_Components;

end Shared_Var_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Shared_Variable_
 ↪Control.Independent_Components
MD5: b331d0a13adf45624b664839fe4ba42c
```

We've just seen in a previous example that some representation clauses might not work with objects and types that have the `Independent` aspect. The same restrictions apply when we use the `Independent_Components` aspect. For example, this aspect prevents that array components are packed when the `Pack` aspect is used. Let's discuss the following erroneous code example:

Listing 198: shared_var_types.ads

```
package Shared_Var_Types is

   type Flags is
     array (Positive range <>) of Boolean
       with Independent_Components, Pack;

   F : Flags (1 .. 8) with Size => 8;

end Shared_Var_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Shared_Variable_
 ↪Control.Packed_Independent_Components
MD5: dbaff4f2559ef8a449dad251f42cddc0
```

Build output

```
shared_var_types.ads:5:37: warning: cannot pack independent components (RM 13.2(7))
shared_var_types.ads:7:36: error: size for "F" too small, minimum allowed is 64
gprbuild: *** compilation phase failed
```

As expected, this code doesn't compile. Here, we can have either independent components, or packed components. We cannot have both at the same time because packed components aren't independently addressable. The compiler warns us that the Pack aspect won't have any effect on independent components. When we use the Size aspect in the declaration of F, we confirm this limitation. If we remove the Size aspect, however, the code is compiled successfully because the compiler ignores the Pack aspect and allocates a larger size for F:

Listing 199: shared_var_types.ads

```
package Shared_Var_Types is

   type Flags is
     array (Positive range <>) of Boolean
       with Independent_Components, Pack;

end Shared_Var_Types;
```

Listing 200: show_flags_size.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with System;

with Shared_Var_Types; use Shared_Var_Types;

procedure Show_Flags_Size is
   F : Flags (1 .. 8);
begin
   Put_Line ("Flags'Size:      "
             & F'Size'Image & " bits");
   Put_Line ("Flags (1)'Size:  "
             & F (1)'Size'Image & " bits");
   Put_Line ("# storage units: "
             & Integer'Image
                 (F'Size /
                  System.Storage_Unit));
end Show_Flags_Size;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Shared_Variable_
 ↪Control.Packed_Independent_Components
MD5: b96f921b08b1d8207749517f833fc121
```

Build output

```
show_flags_size.adb:7:04: warning: variable "F" is read but never assigned [-
 ↪gnatwv]
shared_var_types.ads:5:37: warning: cannot pack independent components (RM 13.2(7))
```

Runtime output

```
Flags'Size:       64 bits
Flags (1)'Size:   8 bits
# storage units:  8
```

As you can see in the output of the application, even though we specify the Pack aspect for the Flags type, the compiler allocates eight storage units, one per each component of the F array.

Atomic

An atomic object is an object that only accepts atomic reads and updates. The Ada standard specifies that "for an atomic object (including an atomic component), all reads and updates of the object as a whole are indivisible." In this case, the compiler must generate Assembly code in such a way that reads and updates of an atomic object must be done in a single instruction, so that no other instruction could execute on that same object before the read or update completes.

In other contexts

Generally, we can say that operations are said to be atomic when they can be completed without interruptions. This is an important requirement when we're performing operations on objects in memory that are shared between multiple processes.

This definition of atomicity above is used, for example, when implementing databases. However, for this section, we're using the term "atomic" differently. Here, it really means that reads and updates must be performed with a single Assembly instruction.

For example, if we have a 32-bit object composed of four 8-bit bytes, the compiler cannot generate code to read or update the object using four 8-bit store / load instructions, or even two 16-bit store / load instructions. In this case, in order to maintain atomicity, the compiler must generate code using one 32-bit store / load instruction.

Because of this strict definition, we might have objects for which the Atomic aspect cannot be specified. Lots of machines support integer types that are larger than the native word-sized integer. For example, a 16-bit machine probably supports both 16-bit and 32-bit integers, but only 16-bit integer objects can be marked as atomic — or, more generally, only objects that fit into at most 16 bits.

Atomicity may be important, for example, when dealing with shared hardware registers. In fact, for certain architectures, the hardware may require that memory-mapped registers are handled atomically. In Ada, we can use the Atomic aspect to indicate that an object is atomic. This is how we can use the aspect to declare a shared hardware register:

Listing 201: shared_var_types.ads

```
with System;

package Shared_Var_Types is

private
   R : Integer
         with Atomic,
              Address =>
                System'To_Address (16#FFFF00A0#);

end Shared_Var_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Shared_Variable_
 ↪Control.Atomic_Object
MD5: 5c2d8e0a9615084c2a15f896c61adaa6
```

Note that the **Address** aspect allows for assigning a variable to a specific location in the memory. In this example, we're using this aspect to specify the address of the memory-mapped register.

Later on, we talk again about the *Address aspect* (page 403) and the GNAT-specific *System'To_Address attribute* (page 404).

In addition to atomic objects, we can declare atomic types — similar to what we've seen before for volatile objects. For example:

Listing 202: shared_var_types.ads

```
with System;

package Shared_Var_Types is

   type Atomic_Integer is new Integer
     with Atomic;

private
   R : Atomic_Integer
         with Address =>
                System'To_Address (16#FFFF00A0#);

end Shared_Var_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Shared_Variable_
 ↪Control.Atomic_Types
MD5: 009632ba0155d70def8281ba590f3d12
```

In this example, we're declaring the `Atomic_Integer` type, which is an atomic type. Objects of this type — such as R in this example — are automatically atomic.

We can also declare atomic array components:

Listing 203: shared_var_types.ads

```
package Shared_Var_Types is

private
```

(continues on next page)

(continued from previous page)

```
   Arr : array (1 .. 2) of Integer
           with Atomic_Components;

end Shared_Var_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Shared_Variable_
 ↪Control.Atomic_Array_Components
MD5: 7501bdf618621a822d451da8d731ef75
```

This example shows the declaration of the `Arr` array, which has atomic components — the atomicity of its components is indicated by the `Atomic_Components` aspect.

Note that if an object is atomic, it is also volatile and independent. In other words, these type declarations are equivalent:

Listing 204: shared_var_types.ads

```
package Shared_Var_Types is

   type Atomic_Integer_1 is new Integer
     with Atomic;

   type Atomic_Integer_2 is new Integer
     with Atomic,
          Volatile,
          Independent;

end Shared_Var_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Shared_Variable_
 ↪Control.Atomic_Volatile_Independent
MD5: 3034c7a07698491f961d9b4fb74f03d8
```

A simular rule applies to components of an array. When we use the `Atomic_Components`, the following aspects are implied: `Volatile`, `Volatile_Components` and `Independent_Components`. For example, these array declarations are equivalent:

Listing 205: shared_var_types.ads

```
package Shared_Var_Types is

   Arr_1 : array (1 .. 2) of Integer
             with Atomic_Components;

   Arr_2 : array (1 .. 2) of Integer
             with Atomic_Components,
                  Volatile,
                  Volatile_Components,
                  Independent_Components;

end Shared_Var_Types;
```

25.2.8 Addresses

In other languages, such as C, the concept of pointers and addresses plays a prominent role. (In fact, in C, many optimizations rely on the usage of pointer arithmetic.) The concept of addresses does exist in Ada, but it's mainly reserved for very specific applications, mostly related to low-level programming. In general, other approaches — such as using access types — are more than sufficient. (We discuss *access types* (page 735) in another chapter. Also, later on in that chapter, we discuss the *relation between access types and addresses* (page 849).) In this section, we discuss some details about using addresses in Ada.

We make use of the **Address** type, which is defined in the System package, to handle addresses. In contrast to other programming languages (such as C or C++), an address in Ada isn't an integer value: its definition depends on the compiler implementation, and it's actually driven directly by the hardware. For now, let's consider it to usually be a private type — this can be seen as an attempt to achieve application code portability, given the variations in hardware that result in different definitions of what an address actually is.

The **Address** type has support for *address comparison* (page 405) and *address arithmetic* (page 407) (also known as *pointer arithmetic* in C). We discuss these topics later in this section. First, let's talk about the **Address** attribute and the **Address** aspect.

In the Ada Reference Manual

- 13.7 The Package System[53]

Address attribute

The **Address** attribute allows us to get the address of an object. For example:

Listing 206: use_address.adb

```
with System; use System;

procedure Use_Address is
   I : aliased Integer := 5;
   A : Address;
begin
   A := I'Address;
end Use_Address;
```

[53] http://www.ada-auth.org/standards/22rm/html/RM-13-7.html

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Addresses.Address_
 ↪Attribute
MD5: 1ee71b7cd3ed278647eb72f383da877f
```

Here, we're assigning the address of the I object to the A address.

In the GNAT toolchain

GNAT offers a very useful extension to the System package to retrieve a string for an address: System.Address_Image. This is the function profile:

```
function System.Address_Image
  (A : System.Address) return String;
```

We can use this function to display the address in an user message, for example:

Listing 207: show_address_attribute.adb

```
1 with Ada.Text_IO; use Ada.Text_IO;
2 with System.Address_Image;
3
4 procedure Show_Address_Attribute is
5    I  : aliased Integer := 5;
6 begin
7    Put_Line ("Address : "
8              & System.Address_Image (I'Address));
9 end Show_Address_Attribute;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Addresses.Show_
 ↪Address_Attribute
MD5: 72efddedc57701665594de5ee1939d3d
```

Runtime output

```
Address : 00007FFC1194DB04
```

In the Ada Reference Manual

- 13.3 Operational and Representation Attributes[54]
- 13.7 The Package System[55]

---

[54] http://www.ada-auth.org/standards/22rm/html/RM-13-3.html
[55] http://www.ada-auth.org/standards/22rm/html/RM-13-7.html

Address aspect

Usually, we let the compiler select the address of an object in memory, or let it use a register to store that object. However, we can specify the address of an object with the **Address** aspect. In this case, the compiler won't select an address automatically, but use the address that we're specifying. For example:

Listing 208: show_address.adb

```
with System; use System;
with System.Address_Image;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Address is

   I_Main   : aliased Integer;
   I_Mapped : Integer
                with Address => I_Main'Address;
begin
   Put_Line ("I_Main'Address   : "
             & System.Address_Image
                 (I_Main'Address));
   Put_Line ("I_Mapped'Address : "
             & System.Address_Image
                 (I_Mapped'Address));
end Show_Address;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Addresses.Address_
↪Aspect
MD5: 6339c743b1ca2b1adf58c977540b43d5
```

Runtime output

```
I_Main'Address   : 00007FFD95171854
I_Mapped'Address : 00007FFD95171854
```

This approach allows us to create an overlay. For example:

Listing 209: simple_overlay.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Simple_Overlay is
   type State is (Off, State_1, State_2)
     with Size => Integer'Size;

   for State use (Off     => 0,
                  State_1 => 32,
                  State_2 => 64);

   S : State;
   I : Integer
     with Address => S'Address, Import, Volatile;
begin
   S := State_2;
   Put_Line ("I = " & Integer'Image (I));
end Simple_Overlay;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Addresses.Simple_
 ↪Overlay
MD5: a65057882518824d3ea173d193a7ae67
```

Runtime output

```
I =  64
```

Here, I is an overlay of S, as it uses S'Address. With this approach, we can either use the enumeration directly (by using the S object of State type) or its integer representation (by using the I variable).

In the GNAT toolchain

We could call the GNAT-specific System'To_Address attribute when using the **Address** aspect, as we did while talking about the *Atomic* (page 398) aspect:

Listing 210: shared_var_types.ads

```
1  with System;
2
3  package Shared_Var_Types is
4
5  private
6     R : Integer
7           with Atomic,
8                Address =>
9                  System'To_Address (16#FFFF00A0#);
10
11 end Shared_Var_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Addresses.Show_Access_
 ↪Address
MD5: 5c2d8e0a9615084c2a15f896c61adaa6
```

In this case, R will refer to the address in memory that we're specifying (16#FFFF00A0# in this case).

As explained in the GNAT Reference Manual[56], the System'To_Address attribute denotes a function identical to To_Address (from the System.Storage_Elements package) except that it is a static attribute. (We talk about the *To_Address function* (page 406) function later on.)

In the Ada Reference Manual

Address comparison

We can compare addresses using the common comparison operators. For example:

Listing 211: show_address.adb

```
with System; use System;
with System.Address_Image;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Address is

   I, J : Integer;
begin
   Put_Line ("I'Address   : "
             & System.Address_Image
                (I'Address));
   Put_Line ("J'Address   : "
             & System.Address_Image
                (J'Address));

   if I'Address = J'Address then
      Put_Line ("I'Address = J'Address");
   elsif I'Address < J'Address then
      Put_Line ("I'Address < J'Address");
   else
      Put_Line ("I'Address > J'Address");
   end if;
end Show_Address;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Addresses.Address_
↪Aspect
MD5: 24ddb7d05159f26ef3b2ff6bcc2691e8
```

Runtime output

```
I'Address   : 00007FFC9FF008AC
J'Address   : 00007FFC9FF008A8
I'Address > J'Address
```

In this example, we compare the address of the `I` object with the address of the `J` object using the `=`, `<` and `>` operators.

In the Ada Reference Manual

- 13.7 The Package System[60]

---

[60] http://www.ada-auth.org/standards/22rm/html/RM-13-7.html

Address to integer conversion

The System.Storage_Elements package offers an integer representation of an address via the Integer_Address type, which is an integer type unrelated to common integer types such as **Integer** and **Long_Integer**. (The actual definition of Integer_Address is compiler-dependent, and it can be a signed or modular integer subtype.)

We can convert between the **Address** and Integer_Address types by using the To_Address and To_Integer functions. Let's see an example:

Listing 212: show_address.adb

```
with System;      use System;

with System.Storage_Elements;
use  System.Storage_Elements;

with System.Address_Image;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Address is
   I      : Integer;
   A1, A2 : Address;
   IA     : Integer_Address;
begin
   A1 := I'Address;
   IA := To_Integer (A1);
   A2 := To_Address (IA);

   Put_Line ("A1 : "
             & System.Address_Image (A1));
   Put_Line ("IA : "
             & Integer_Address'Image (IA));
   Put_Line ("A2 : "
             & System.Address_Image (A2));
end Show_Address;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Addresses.Pointer_
↪Arith_Ada
MD5: 69e053886fb8e8571d6c94247dc9f30f
```

Runtime output

```
A1 : 00007FFE6C199BFC
IA :  140730712038396
A2 : 00007FFE6C199BFC
```

Here, we retrieve the address of the I object and store it in the A1 address. Then, we convert A1 to an integer address by calling To_Integer (and store it in IA). Finally, we convert this integer address back to an actual address by calling To_Address.

In the Ada Reference Manual

- 13.7.1 The Package System.Storage_Elements[61]

[61] http://www.ada-auth.org/standards/22rm/html/RM-13-7-1.html

Address arithmetic

Although Ada supports address arithmetic, which we discuss in this section, it should be reserved for very specific applications such as low-level programming. However, even in situations that require close access to the underlying hardware, using address arithmetic might not be the approach you should consider — make sure to evaluate other options first!

Ada supports address arithmetic via the `System.Storage_Elements` package, which includes operators such as `+` and `-` for addresses. Let's see a code example where we iterate over an array by incrementing an address that *points* to each component in memory:

Listing 213: show_address.adb

```
with System;      use System;

with System.Storage_Elements;
use  System.Storage_Elements;

with System.Address_Image;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Address is

   Arr : array (1 .. 10) of Integer;
   A   : Address := Arr'Address;
   --              ^^^^^^^^^^^
   --   Initializing address object with
   --   address of the first component of Arr.
   --
   --   We could write this as well:
   --   ___ := Arr (1)'Address

begin
   for I in Arr'Range loop
      declare
         Curr : Integer
                  with Address => A;
      begin
         Curr := I;
         Put_Line ("Curr'Address : "
                   & System.Address_Image
                       (Curr'Address));
      end;

      --
      --  Address arithmetic
      --
      A := A + Storage_Offset (Integer'Size)
                 / Storage_Unit;
      --     ^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^
      --       Moving to next component
   end loop;

   for I in Arr'Range loop
     Put_Line ("Arr ("
               & Integer'Image (I)
               & ") :"
               & Integer'Image (Arr (I)));
   end loop;
end Show_Address;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Addresses.Pointer_
 ↪Arith_Ada
MD5: 2c1cdd6874036fb9a527baae63a312d9
```

Runtime output

```
Curr'Address : 00007FFC306CD8F0
Curr'Address : 00007FFC306CD8F4
Curr'Address : 00007FFC306CD8F8
Curr'Address : 00007FFC306CD8FC
Curr'Address : 00007FFC306CD900
Curr'Address : 00007FFC306CD904
Curr'Address : 00007FFC306CD908
Curr'Address : 00007FFC306CD90C
Curr'Address : 00007FFC306CD910
Curr'Address : 00007FFC306CD914
Arr ( 1) : 1
Arr ( 2) : 2
Arr ( 3) : 3
Arr ( 4) : 4
Arr ( 5) : 5
Arr ( 6) : 6
Arr ( 7) : 7
Arr ( 8) : 8
Arr ( 9) : 9
Arr ( 10) : 10
```

In this example, we initialize the address A by retrieving the address of the first component of the array `Arr`. (Note that we could have written `Arr(1)'Address` instead of `Arr'Address`. In any case, the language guarantees that `Arr'Address` gives us the address of the first component, i.e. `Arr'Address = Arr(1)'Address`.)

Then, in the loop, we declare an overlay `Curr` using the current value of the A address. We can then operate on this overlay — here, we assign `I` to `Curr`. Finally, in the loop, we increment address A and make it *point* to the next component in the `Arr` array — to do so, we calculate the size of an **`Integer`** component in storage units. (For details on storage units, see the section on *storage size attribute* (page 353).)

In other languages

The code example above corresponds (more or less) to the following C code:

Listing 214: main.c

```c
#include <stdio.h>

int main(int argc, const char * argv[])
{
    int i;
    int arr[10];

    int *a = arr;
    /* int *a = &arr[0]; */

    for (i = 0; i < 10; i++)
    {
        *a++ = i;
        printf("curr address: %p\n", a);
    }

    for (i = 0; i < 10; i++)
```

(continues on next page)

(continued from previous page)

```
    {
        printf("arr[%d]: %d\n", i, arr[i]);
    }

    return 0;
}
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Addresses.Pointer_
↪Arith_C
MD5: 7aa709a4d7ed6ce2346dbabc853e28c0
```

Runtime output

```
curr address: 0x7fff85be73f4
curr address: 0x7fff85be73f8
curr address: 0x7fff85be73fc
curr address: 0x7fff85be7400
curr address: 0x7fff85be7404
curr address: 0x7fff85be7408
curr address: 0x7fff85be740c
curr address: 0x7fff85be7410
curr address: 0x7fff85be7414
curr address: 0x7fff85be7418
arr[0]: 0
arr[1]: 1
arr[2]: 2
arr[3]: 3
arr[4]: 4
arr[5]: 5
arr[6]: 6
arr[7]: 7
arr[8]: 8
arr[9]: 9
```

While pointer arithmetic is very common in C, using address arithmetic in Ada is far from common, and it should be only used when it's really necessary to do so.

In the Ada Reference Manual

- 13.3 Operational and Representation Attributes[62]
- 13.7.1 The Package System.Storage_Elements[63]

---

[62] http://www.ada-auth.org/standards/22rm/html/RM-13-3.html
[63] http://www.ada-auth.org/standards/22rm/html/RM-13-7-1.html

25.2.9 Discarding names

As we know, we can use the Image attribute of a type to get a string associated with this type. This is useful for example when we want to display a user message for an enumeration type:

Listing 215: show_enumeration_image.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Enumeration_Image is

   type Months is
     (January, February, March, April,
      May, June, July, August, September,
      October, November, December);

   M : constant Months := January;
begin
   Put_Line ("Month: "
             & Months'Image (M));
end Show_Enumeration_Image;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Discarding_Names.
↪Enumeration_Image
MD5: 3863c5e06641d96b59edb9e76daa7560
```

Runtime output

```
Month: JANUARY
```

This is similar to having this code:

Listing 216: show_enumeration_image.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Enumeration_Image is

   type Months is
     (January, February, March, April,
      May, June, July, August, September,
      October, November, December);

   M : constant Months := January;

   function Months_Image (M : Months)
                          return String is
   begin
      case M is
         when January   => return "JANUARY";
         when February  => return "FEBRUARY";
         when March     => return "MARCH";
         when April     => return "APRIL";
         when May       => return "MAY";
         when June      => return "JUNE";
         when July      => return "JULY";
         when August    => return "AUGUST";
         when September => return "SEPTEMBER";
         when October   => return "OCTOBER";
```

(continues on next page)

(continued from previous page)

```
         when November  => return "NOVEMBER";
         when December  => return "DECEMBER";
      end case;
   end Months_Image;

begin
   Put_Line ("Month: "
             & Months_Image (M));
end Show_Enumeration_Image;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Discarding_Names.
 ↪Enumeration_Image
MD5: 2db86044d2045bd9d4c3998cca36d51c
```

Runtime output

```
Month: JANUARY
```

Here, the `Months_Image` function associates a string with each month of the `Months` enumeration. As expected, the compiler needs to store the strings used in the `Months_Image` function when compiling this code. Similarly, the compiler needs to store strings for the `Months` enumeration for the `Image` attribute.

Sometimes, we don't need to call the `Image` attribute for a type. In this case, we could save some storage by eliminating the strings associated with the type. Here, we can use the `Discard_Names` aspect to request the compiler to reduce — as much as possible — the amount of storage used for storing names for this type. Let's see an example:

Listing 217: show_discard_names.adb

```
procedure Show_Discard_Names is
   pragma Warnings (Off, "is not referenced");

   type Months is
     (January, February, March, April,
      May, June, July, August, September,
      October, November, December)
     with Discard_Names;

   M : constant Months := January;
begin
   null;
end Show_Discard_Names;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Type_Representation.Discarding_Names.
 ↪Discard_Names
MD5: 7891caac459a4be2096d443ca3190036
```

In this example, the compiler attempts to not store strings associated with the `Months` type duration compilation.

Note that the `Discard_Names` aspect is available for enumerations, exceptions, and tagged types.

In the GNAT toolchain

If we add this statement to the `Show_Discard_Names` procedure above:

```
Put_Line ("Month: "
          & Months'Image (M));
```

we see that the application displays "0" instead of "JANUARY". This is because GNAT doesn't store the strings associated with the `Months` type when we use the `Discard_Names` aspect for the `Months` type. (Therefore, the `Months'Image` attribute doesn't have that information.) Instead, the compiler uses the integer value of the enumeration, so that `Months'Image` returns the corresponding string for this integer value.

In the Ada Reference Manual

- Aspect Discard_Names[64]

25.3 Records

25.3.1 Default Initialization

As mentioned in the *Introduction to Ada* (page 65) course, record components can have default initial values. Also, we've seen that other kinds of types can have *default values* (page 334).

In the Ada Reference Manual, we refer to these default initial values as "default expressions of record components." The term *default expression* indicates that we can use any kind of expression for the default initialization of record components — which includes subprogram calls for example:

Listing 218: show_default_initialization.ads

```
1  package Show_Default_Initialization is
2
3     function Init return Integer is
4       (42);
5
6     type Rec is record
7        A : Integer := Init;
8     end record;
9
10 end Show_Default_Initialization;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Default_Initialization.Simple_
 ↪Example
MD5: 6d06be7f087513b669ba5481d6ee5004
```

In this example, the `A` component is initialized by default by a call to the `Init` procedure.

In the Ada Reference Manual

- 3.8 Record Types[65]

[64] http://www.ada-auth.org/standards/22rm/html/RM-C-5.html
[65] http://www.ada-auth.org/standards/22rm/html/RM-3-8.html

Dependencies

Default expressions cannot depend on other components. For example, if we have two components A and B, we cannot initialize B based on the value that A has:

Listing 219: show_default_initialization_dependency.ads

```
package Show_Default_Initialization_Dependency is

   function Init return Integer is
     (42);

   type Rec is record
      A : Integer := Init;
      B : Integer := Rec.A;  --  Illegal!
   end record;

end Show_Default_Initialization_Dependency;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Default_Initialization.No_
 ↪Dependency
MD5: ca23cbd7e4a54d0b9c6974aed0ee77c8
```

Build output

```
show_default_initialization_dependency.ads:8:25: error: component "Rec.A" cannot␣
 ↪be used before end of record declaration
gprbuild: *** compilation phase failed
```

In this example, we cannot initialize the B component based on the value of the A component. (In fact, the syntax Rec.A as a way to refer to the A component is only allowed in predicates, not in the record component declaration.)

Initialization Order

The default initialization of record components is performed in arbitrary order. In fact, the order is decided by the compiler, so we don't have control over it.

Let's see an example:

Listing 220: simple_recs.ads

```
package Simple_Recs is

   function Init (S : String;
                  I : Integer)
                  return Integer;

   type Rec is record
      A : Integer := Init ("A", 1);
      B : Integer := Init ("B", 2);
   end record;

end Simple_Recs;
```

Listing 221: simple_recs.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Simple_Recs is

   function Init (S : String;
                  I : Integer)
                  return Integer is
   begin
      Put_Line (S & ": " & I'Image);
      return I;
   end Init;

end Simple_Recs;
```

Listing 222: show_initialization_order.adb

```
with Simple_Recs; use Simple_Recs;

procedure Show_Initialization_Order is
   R : Rec;
begin
   null;
end Show_Initialization_Order;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Default_Initialization.
 ↪Initialization_Order
MD5: e3ab92ea9b2a99815cea8c2ea11cbbfb
```

Runtime output

```
A:  1
B:  2
```

When running this code example, you might see this:

```
A: 1
B: 2
```

However, the compiler is allowed to rearrange the operations, so this output is possible as well:

```
B: 2
A: 1
```

Therefore, we must write the default expression of each individual record components in such a way that the resulting initialization value is always correct, independently of the order that those expressions are evaluated.

Evaluation

According to the Annotated Ada Reference Manual, the "default expression of a record component is only evaluated upon the creation of a default-initialized object of the record type." This means that the default expression is by itself not evaluated when we declare the record type, but when we create an object of this type. It follows from this rule that the default is only evaluated when necessary, i.e,, when an explicit initial value is not specified in the object declaration.

Let's see an example:

Listing 223: show_initialization_order.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Simple_Recs; use Simple_Recs;

procedure Show_Initialization_Order is
begin
   Put_Line ("Some processing first...");
   Put_Line
     ("Now, let's declare an object "
      & "of the record type Rec...");

   declare
      R : Rec;
   begin
      Put_Line
        ("An object of Rec type has "
         & "just been created.");
   end;

end Show_Initialization_Order;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Default_Initialization.
 ↪Initialization_Order
MD5: 126e3edfe4cb8033f40b939ff9922958
```

Runtime output

```
Some processing first...
Now, let's declare an object of the record type Rec...
A:  1
B:  2
An object of Rec type has just been created.
```

Here, we only see the information displayed by the `Init` function — which is called to initialize the A and B components of the R record — during the object creation. In other words, the default expressions `Init ("A", 1)` and `Init ("B", 2)` are *not* evaluated when we declare the R type, but when we create an object of this type.

In the Ada Reference Manual

- 3.8 Record Types[66]

[66] http://www.ada-auth.org/standards/22aarm/html/AA-3-8.html

Defaults and object declaration

Note: This subsection was originally written by Robert A. Duff and published as Gem #12: Limited Types in Ada 2005[67].

Consider the following type declaration:

Listing 224: type_defaults.ads

```
package Type_Defaults is
   type Color_Enum is (Red, Blue, Green);

   type T is private;
private
   type T is
      record
         Color     : Color_Enum := Red;
         Is_Gnarly : Boolean := False;
         Count     : Natural;
      end record;

   procedure Do_Something;
end Type_Defaults;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Default_Initialization.Default_
 ↪Init
MD5: 218154278081f89595534bc02e34539b
```

If we want to say, "make `Count` equal `100`, but initialize `Color` and `Is_Gnarly` to their defaults", we can do this:

Listing 225: type_defaults.adb

```
package body Type_Defaults is

   Object_100 : constant T :=
                  (Color     => <>,
                   Is_Gnarly => <>,
                   Count     => 100);

   procedure Do_Something is null;

end Type_Defaults;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Default_Initialization.Default_
 ↪Init
MD5: e64f8881ee74b90dd6058ca8961aae31
```

Historically

Prior to Ada 2005, the following style was common:

[67] https://www.adacore.com/gems/ada-gem-12

Listing 226: type_defaults.adb

```
package body Type_Defaults is

   Object_100 : constant T :=
                  (Color     => Red,
                   Is_Gnarly => False,
                   Count     => 100);

   procedure Do_Something is null;

end Type_Defaults;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Default_Initialization.Default_
 ↪Init
MD5: c1ddfae75d7f0c691356027903a6d144
```

Here, we only wanted `Object_100` to be a default-initialized T, with **`Count`** equal to `100`. It's a little bit annoying that we had to write the default values Red and **`False`** twice. What if we change our mind about Red, and forget to change it in all the relevant places? Since Ada 2005, the <> notation comes to the rescue, as we've just seen.

On the other hand, if we want to say, "make **`Count`** equal `100`, but initialize all other components, including the ones we might add next week, to their defaults", we can do this:

Listing 227: type_defaults.adb

```
package body Type_Defaults is

   Object_100 : constant T := (Count  => 100,
                               others => <>);

   procedure Do_Something is null;

end Type_Defaults;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Default_Initialization.Default_
 ↪Init
MD5: 93f5d71ae80ff0ebad54f2569539f536
```

Note that if we add a component `Glorp : Integer;` to type T, then the **`others`** case leaves `Glorp` undefined just as this code would do:

Listing 228: type_defaults.adb

```
package body Type_Defaults is

   procedure Do_Something is
      Object_100 : T;
   begin
      Object_100.Count := 100;
   end Do_Something;

end Type_Defaults;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Default_Initialization.Default_
 ↪Init
MD5: 6d328318e2695516794df33466fa5283
```

Therefore, you should be careful and think twice before using **others**.

Advanced Usages

In addition to expressions such as subprogram calls, we can use *per-object expressions* (page 432) for the default value of a record component. (We discuss this topic later on in more details.)

For example:

Listing 229: rec_per_object_expressions.ads

```
1  package Rec_Per_Object_Expressions is
2
3     type T (D : Positive) is private;
4
5  private
6
7     type T (D : Positive) is record
8        V : Natural := D - 1;
9        --             ^^^^^
10       --    Per-object expression
11    end record;
12
13 end Rec_Per_Object_Expressions;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Default_Initialization.Per_Object_
 ↪Expressions
MD5: 92591ea482db2b009b8eeafe633ca6cd
```

In this example, component V is initialized by default with the per-object expression `D - 1`, where D refers to the discriminant D.

25.3.2 Mutually dependent types

In this section, we discuss how to use *incomplete types* (page 305) to declare mutually dependent types. Let's start with this example:

Listing 230: mutually_dependent.ads

```
1  package Mutually_Dependent is
2
3     type T1 is record
4        B : T2;
5     end record;
6
7     type T2 is record
8        A : T1;
9     end record;
10
11 end Mutually_Dependent;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Mutually_Dependent_Types.Mutually_
 ↪Dependent
MD5: ffa8d6ab83a1172dcbae0978952dacb2
```

Build output

```
mutually_dependent.ads:4:11: error: "T2" is undefined
gprbuild: *** compilation phase failed
```

When you try to compile this example, you get a compilation error. The first problem with this code is that, in the declaration of the T1 record, the compiler doesn't know anything about T2. We could solve this by declaring an incomplete type (`type T2;`) before the declaration of T1. This, however, doesn't solve all the problems in the code: the compiler still doesn't know the size of T2, so we cannot create a component of this type. We could, instead, declare an access type and use it here. By doing this, even though the compiler doesn't know the size of T2, it knows the size of an access type designating T2, so the record component can be of such an access type.

To summarize, in order to solve the compilation error above, we need to:

- use at least one incomplete type;
- declare at least one component as an access to an object.

For example, we could declare an incomplete type T2 and then declare the component B of the T1 record as an access to T2. This is the corrected version:

Listing 231: mutually_dependent.ads

```
1  package Mutually_Dependent is
2
3     type T2;
4     type T2_Access is access T2;
5
6     type T1 is record
7        B : T2_Access;
8     end record;
9
10    type T2 is record
11       A : T1;
12    end record;
13
14 end Mutually_Dependent;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Mutually_Dependent_Types.Mutually_
 ↪Dependent
MD5: 1ae10638624a97fa18b9d8f96bfa74ed
```

We could strive for consistency and declare two incomplete types and two accesses, but this isn't strictly necessary in this case. Here's the adapted code:

Listing 232: mutually_dependent.ads

```
1  package Mutually_Dependent is
2
3     type T1;
4     type T1_Access is access T1;
5
6     type T2;
7     type T2_Access is access T2;
```

(continues on next page)

(continued from previous page)

```
8
9     type T1 is record
10       B : T2_Access;
11    end record;
12
13    type T2 is record
14       A : T1_Access;
15    end record;
16
17 end Mutually_Dependent;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Mutually_Dependent_Types.Mutually_
↪Dependent
MD5: 9a9899cd0dd2525bd27d67d6629a0071
```

Later on, we'll see that these code examples can be written using *anonymous access types* (page 877).

In the Ada Reference Manual

- 3.10.1 Incomplete Type Declarations[68]

25.3.3 Null records

A null record is a record that doesn't have any components. Consequently, it cannot store any information. When declaring a null record, we simply write **null** instead of declaring actual components, as we usually do for records. For example:

Listing 233: null_recs.ads

```
1  package Null_Recs is
2
3     type Null_Record is record
4        null;
5     end record;
6
7  end Null_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Null_Records.Null_Record
MD5: 3c82da822710342354134fa71a03452a
```

Note that the syntax can be simplified to **is null record**, which is much more common than the previous form:

Listing 234: null_recs.ads

```
1  package Null_Recs is
2
3     type Null_Record is null record;
4
5  end Null_Recs;
```

[68] http://www.ada-auth.org/standards/22rm/html/RM-3-10-1.html

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Null_Records.Null_Record
MD5: 1da1746ce5b0a237276272d2b620e282
```

Although a null record doesn't have components, we can still specify subprograms for it. For example, we could specify an addition operation for it:

Listing 235: null_recs.ads

```
1  package Null_Recs is
2
3     type Null_Record is null record;
4
5     function "+" (A, B : Null_Record)
6                   return Null_Record;
7
8  end Null_Recs;
```

Listing 236: null_recs.adb

```
1  package body Null_Recs is
2
3     function "+" (A, B : Null_Record)
4                   return Null_Record
5     is
6        pragma Unreferenced (A, B);
7     begin
8        return (null record);
9     end "+";
10
11 end Null_Recs;
```

Listing 237: show_null_rec.adb

```
1  with Null_Recs; use Null_Recs;
2
3  procedure Show_Null_Rec is
4     A, B : Null_Record;
5  begin
6     B := A + A;
7     A := A + B;
8  end Show_Null_Rec;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Null_Records.Null_Record
MD5: 3a1c2fbae75541dfb0b2ff4c14d22039
```

In the Ada Reference Manual

- 4.3.1 Record Aggregates[69]

[69] http://www.ada-auth.org/standards/22rm/html/RM-4-3-1.html

Simple Prototyping

A null record doesn't provide much functionality on itself, as we're not storing any information in it. However, it's far from being useless. For example, we can make use of null records to design an API, which we can then use in an application without having to implement the actual functionality of the API. This allows us to design a prototype without having to think about all the implementation details of the API in the first stage.

Consider this example:

Listing 238: devices.ads

```
package Devices is

   type Device is private;

   function Create
     (Active : Boolean)
      return Device;

   procedure Reset
     (D : out Device) is null;

   procedure Process
     (D : in out Device) is null;

   procedure Activate
     (D : in out Device) is null;

   procedure Deactivate
     (D : in out Device) is null;

private

   type Device is null record;

   function Create (Active : Boolean)
                    return Device is
     (null record);

end Devices;
```

Listing 239: show_device.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Devices;     use Devices;

procedure Show_Device is
   A : Device;
begin
   Put_Line ("Creating device...");
   A := Create (Active => True);

   Put_Line ("Processing on device...");
   Process (A);

   Put_Line ("Deactivating device...");
   Deactivate (A);

   Put_Line ("Activating device...");
   Activate (A);

```

(continues on next page)

(continued from previous page)

```
19    Put_Line ("Resetting device...");
20    Reset (A);
21 end Show_Device;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Null_Records.Device
MD5: 7d2fce20ac33607f7081381b307a564a
```

Runtime output

```
Creating device...
Processing on device...
Deactivating device...
Activating device...
Resetting device...
```

In the `Devices` package, we're declaring the `Device` type and its primitive subprograms: `Create`, `Reset`, `Process`, `Activate` and `Deactivate`. This is the API that we use in our prototype. Note that, although the `Device` type is declared as a private type, it's still defined as a null record in the full view.

In this example, the `Create` function, implemented as an expression function in the private part, simply returns a null record. As expected, this null record returned by `Create` matches the definition of the `Device` type.

All procedures associated with the `Device` type are implemented as null procedures, which means they don't actually have an implementation nor have any effect. We'll discuss this topic *later on in the course* (page 653).

In the `Show_Device` procedure — which is an application that implements our prototype —, we declare an object of `Device` type and call all subprograms associated with that type.

Extending the prototype

Because we're either using expression functions or null procedures in the specification of the `Devices` package, we don't have a package body for it (as there's nothing to be implemented). We could, however, move those user messages from the `Show_Devices` procedure to a dummy implementation of the `Devices` package. This is the adapted code:

Listing 240: devices.ads

```
1  package Devices is
2
3     type Device is null record;
4
5     function Create (Active : Boolean)
6                      return Device;
7
8     procedure Reset (D : out Device);
9
10    procedure Process (D : in out Device);
11
12    procedure Activate (D : in out Device);
13
14    procedure Deactivate (D : in out Device);
15
16 end Devices;
```

Listing 241: devices.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Devices is

   function Create (Active : Boolean)
                    return Device
   is
      pragma Unreferenced (Active);
   begin
      Put_Line ("Creating device...");
      return (null record);
   end Create;

   procedure Reset (D : out Device)
   is
      pragma Unreferenced (D);
   begin
      Put_Line ("Processing on device...");
   end Reset;

   procedure Process (D : in out Device)
   is
      pragma Unreferenced (D);
   begin
      Put_Line ("Deactivating device...");
   end Process;

   procedure Activate (D : in out Device)
   is
      pragma Unreferenced (D);
   begin
      Put_Line ("Activating device...");
   end Activate;

   procedure Deactivate (D : in out Device)
   is
      pragma Unreferenced (D);
   begin
      Put_Line ("Resetting device...");
   end Deactivate;

end Devices;
```

Listing 242: show_device.adb

```
with Devices; use Devices;

procedure Show_Device is
   A : Device;
begin
   A := Create (Active => True);
   Process (A);
   Deactivate (A);
   Activate (A);
   Reset (A);
end Show_Device;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Null_Records.Device
MD5: 1a21b41f3847f6c132ccbc9696ab7689
```

Runtime output

```
Creating device...
Deactivating device...
Resetting device...
Activating device...
Processing on device...
```

As we changed the specification of the Devices package to not use null procedures, we now need a corresponding package body for it. In this package body, we implement the operations on the Device type, which actually just display a user message indicating which operation is being called.

Let's focus on this updated version of the Show_Device procedure. Now that we've removed all those calls to Put_Line from this procedure and just have the calls to operations associated with the Device type, it becomes more apparent that, even though Device is just a null record, we can design an application with a sequence of various commands operating on it. Also, when we just read the source-code of the Show_Device procedure, there's no clear indication that the Device type doesn't actually hold any information.

More complex applications

As we've just seen, we can use null records like any other type and create complex prototypes with them. We could, for instance, design an application that makes use of many null records, or even have types that depend on or derive from null records. Let's see a simple example:

Listing 243: many_devices.ads

```
1  package Many_Devices is
2
3     type Device is null record;
4
5     type Device_Config is null record;
6
7     function Create (Config : Device_Config)
8                      return Device is
9       (null record);
10
11    type Derived_Device is new Device;
12
13    procedure Process (D : Derived_Device) is null;
14
15 end Many_Devices;
```

Listing 244: show_derived_device.adb

```
1  with Many_Devices; use Many_Devices;
2
3  procedure Show_Derived_Device is
4     A : Device;
5     B : Derived_Device;
6     C : Device_Config;
7  begin
8     A := Create (Config => C);
9     B := Create (Config => C);
```

(continues on next page)

(continued from previous page)

```
10
11    Process (B);
12 end Show_Derived_Device;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Null_Records.Derived_Device
MD5: 757a3def24c8333a27b64943727d8d4e
```

In this example, the `Create` function has a null record parameter (of `Device_Config` type) and returns a null record (of `Device` type). Also, we derive the `Derived_Device` type from the `Device` type. Consequently, `Derived_Device` is also a null record (since it's derived from a null record). In the `Show_Derived_Device` procedure, we declare objects of those types (`A`, `B` and `C`) and call primitive subprograms to operate on them.

This example shows that, even though the types we've declared are *just* null records, they can still be used to represent dependencies in our application.

Implementing the API

Let's focus again on the previous example. After we have an initial prototype, we can start implementing some of the functionality needed for the `Device` type. For example, we can store information about the current activation state in the record:

Listing 245: devices.ads

```
1  package Devices is
2
3     type Device is private;
4
5     function Create (Active : Boolean)
6                      return Device;
7
8     procedure Reset (D : out Device);
9
10    procedure Process (D : in out Device);
11
12    procedure Activate (D : in out Device);
13
14    procedure Deactivate (D : in out Device);
15
16 private
17
18    type Device is record
19       Active : Boolean;
20    end record;
21
22 end Devices;
```

Listing 246: devices.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Devices is
4
5     function Create (Active : Boolean)
6                      return Device
7     is
8        pragma Unreferenced (Active);
```

(continues on next page)

(continued from previous page)

```
   begin
      Put_Line ("Creating device...");
      return (Active => Active);
   end Create;

   procedure Reset (D : out Device)
   is
      pragma Unreferenced (D);
   begin
      Put_Line ("Processing on device...");
   end Reset;

   procedure Process (D : in out Device)
   is
      pragma Unreferenced (D);
   begin
      Put_Line ("Deactivating device...");
   end Process;

   procedure Activate (D : in out Device)
   is
   begin
      Put_Line ("Activating device...");
      D.Active := True;
   end Activate;

   procedure Deactivate (D : in out Device)
   is
   begin
      Put_Line ("Resetting device...");
      D.Active := False;
   end Deactivate;

end Devices;
```

Listing 247: show_device.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Devices;     use Devices;

procedure Show_Device is
   A : Device;
begin
   A := Create (Active => True);
   Process (A);
   Deactivate (A);
   Activate (A);
   Reset (A);
end Show_Device;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Null_Records.Device
MD5: 348ce0c110b47a6b6fd1c9fe73ef0558
```

Build output

```
devices.adb:11:25: warning: pragma Unreferenced given for "Active" [enabled by␣
↪default]
```

Runtime output

```
Creating device...
Deactivating device...
Resetting device...
Activating device...
Processing on device...
```

Now, the Device record contains an Active component, which is used in the updated versions of Create, Activate and Deactivate.

Note that we haven't done any change to the implementation of the Show_Device procedure: it's still the same application as before. As we've been hinting in the beginning, using null records makes it easy for us to first create a prototype — as we did in the Show_Device procedure — and postpone the API implementation to a later phase of the project.

Tagged null records

A null record may be tagged, as we can see in this example:

Listing 248: null_recs.ads

```
1  package Null_Recs is
2
3     type Tagged_Null_Record is
4       tagged null record;
5
6     type Abstract_Tagged_Null_Record is
7       abstract tagged null record;
8
9  end Null_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Null_Records.Tagged_Null_Record
MD5: 918572d2c50911b84c80a9c601b75439
```

As we see in this example, a type can be **tagged**, or even **abstract tagged**. We discuss abstract types *later on in the course* (page 1907).

As expected, in addition to deriving from tagged types, we can also extend them. For example:

Listing 249: devices.ads

```
1  package Devices is
2
3     type Device is private;
4
5     function Create (Active : Boolean)
6                      return Device;
7
8     type Derived_Device is private;
9
10 private
11
12    type Device is tagged null record;
13
14    function Create (Active : Boolean)
15                     return Device is
16      (null record);
17
```

(continues on next page)

(continued from previous page)

```
18    type Derived_Device is new Device with record
19       Active : Boolean;
20    end record;
21
22    function Create (Active : Boolean)
23                     return Derived_Device is
24      (Active => Active);
25
26 end Devices;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Null_Records.Extended_Device
MD5: 15e06a5115cbcb131477b5224a6594db
```

In this example, we derive `Derived_Device` from the `Device` type and extend it with the `Active` component. (Because we have a type extension, we also need to override the `Create` function.)

Since we're now introducing elements from object-oriented programming, we could consider using interfaces instead of null records. We'll discuss this topic *later on in the course* (page 1907).

25.3.4 Per-Object Expressions

In record type declarations, we might want to define a component that makes use of a name that refers to a discriminant of the record type, or to the record type itself. An expression where we use such a name is called a per-object expression.

The term "per-object" comes from the fact that, in the component definition, we're referring to a piece of information that will be known just when creating an object of that type. For example, if the per-object expression refers to a discriminant of a type T, the actual value of that discriminant will only be specified when we declare an object of type T. Therefore, the component definition is specific for that individual object — but not necessarily for other objects of the same type, as we might use different values for the discriminant.

The constraint that contains a per-object expression is called a per-object constraint. The actual constraint of that component isn't completely known when we declare the record type, but only later on when an object of that type is created. (Note that the syntax of a constraint includes the parentheses or the keyword **range**.)

In addition to referring to discriminants, per-object expressions can also refer to the record type itself, as we'll see later.

Let's start with a simple record declaration:

Listing 250: rec_per_object_expressions.ads

```
1  package Rec_Per_Object_Expressions is
2
3     type Stack (S : Positive) is private;
4
5  private
6
7     type Integer_Array is
8       array (Positive range <>) of Integer;
9
10    type Stack (S : Positive) is record
11       Arr : Integer_Array (1 .. S);
12       --                   ^^^^^^
```

(continues on next page)

(continued from previous page)

```
      --
      --                          S
      --                          ^
      --    Per-object expression
      --
      --                  (1 .. S)
      --                  ^^^^^^^^
      --     Per-object constraint

      Top : Natural := 0;
   end record;

end Rec_Per_Object_Expressions;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Per_Object_Expressions.Per_Object_
 ↪Expression
MD5: e4012454ea886fd429d82159b8d344b7
```

In this example, we see the `Stack` record type with a discriminant `S`. In the declaration of the `Arr` component of the that type, `S` is a per-object expression, as it refers to the `S` discriminant. Also, `(1 .. S)` is a per-object constraint.

Let's look at another example using *anonymous access types* (page 853):

Listing 251: rec_per_object_expressions.ads

```
package Rec_Per_Object_Expressions is

   type T is private;

   type T_Processor (Selected_T : access T) is
     private;

private

   type T is null record;

   type T_Container (Selected_T : access T) is
     null record;

   type T_Processor (Selected_T : access T) is
   record
      E : T_Container (Selected_T);
      --
      --               Selected_T
      --               ^^^^^^^^^^
      --    Per-object expression
      --
      --              (Selected_T)
      --              ^^^^^^^^^^^^
      --     Per-object constraint
   end record;

end Rec_Per_Object_Expressions;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Per_Object_Expressions.Per_Object_
 ↪Expression_Access_Discriminant
MD5: 8b404688be1e103773c28a6977785836
```

Let's focus on the T_Processor type from this example. The Selected_T discriminant is being used in the definition of the E component. The per-object constraint is (Selected_T).

Finally, per-object expressions can also refer to the record type we're declaring. For example:

Listing 252: rec_per_object_expressions.ads

```
package Rec_Per_Object_Expressions is

   type T is limited private;

private

   type T_Processor (Selected_T : access T) is
     null record;

   type T is limited record
      E : T_Processor (T'Access);
      --
      --               T'Access
      --               ^^^^^^^^
      --  Per-object expression
      --
      --              (T'Access)
      --              ^^^^^^^^^^
      --   Per-object constraint
   end record;

end Rec_Per_Object_Expressions;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Per_Object_Expressions.Per_Object_
↪Expression_Access_Discriminant
MD5: a67b3034008fdf2a8c5fd1b6da769128
```

In this example, when we write T'Access within the declaration of the T record type, the actual value for the **Access** attribute will be known when an object of T type is created. In that sense, T'Access is a per-object expression — (T'Access) is the corresponding per-object constraint.

Note that T'Access is referring to the type within a type definition. This is generally treated as a reference to the object being created, the so-called *current instance*.

Relevant topics

- 3.8 Record Types[70]

[70] http://www.ada-auth.org/standards/22rm/html/RM-3-8.html

Default value

We can also use per-object expressions to calculate the default value of a record component:

Listing 253: rec_per_object_expressions.ads

```
package Rec_Per_Object_Expressions is

   type T (D : Positive) is private;

private

   type T (D : Positive) is record
      V : Natural := D - 1;
      --             ^^^^^
      --    Per-object expression

      S : Natural := D'Size;
      --             ^^^^^^
      --    Per-object expression
   end record;

end Rec_Per_Object_Expressions;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Per_Object_Expressions.Per_Object_
 ↪Expression_Default_Value
MD5: 70454b0b116094a02b897d8d1d0080fb
```

Here, we calculate the default value of V using the per-object expression D - 1, and the default of value of S using the per-object D'Size.

The default expression for a component of a discriminated record can be an arbitrary per-object expression. (This contrasts with *important restrictions* (page 433) that exist for per-object constraints, as we discuss later on.) Such expressions might include function calls or uses of any defined operator. For this reason, the following code example is accepted by the compiler:

Listing 254: rec_per_object_expressions.ads

```
package Rec_Per_Object_Expressions is

   type Stack (S : Positive) is private;

private

   type Integer_Array is
     array (Positive range <>) of Integer;

   type Stack (S : Positive) is record
      Arr : Integer_Array (1 .. S);

      Top : Natural := 0;

      Overflow_Warning : Positive
        := S * 9 / 10;
      --   ^^^^^^^^^^
      --   Per-object expression
      --   using computation for
      --   the default expression.
   end record
```

(continues on next page)

(continued from previous page)

```
    with
      Dynamic_Predicate =>
        Overflow_Warning in
          (S + 1) / 2 .. S - 1;
      --
      --   (S + 1) / 2
      --   ^^^^^^^^^^^
      --   Per-object expression
      --   using computation.
      --
      --                  S - 1
      --                  ^^^^^
      --   Per-object expression
      --   using computation.

end Rec_Per_Object_Expressions;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Per_Object_Expressions.Per_Object_
 ↪Expression_Computation
MD5: 6783568fd3e76a85ca7c1cc65ba023c5
```

In this example, we can identify multiple per-object expressions that use a computation: `S * 9 / 10`, `(S + 1) / 2`, and `S - 1`.

Restrictions

There are some important restrictions on per-object constraints:

Per-object range constraints such as `1 .. T'Size` are not allowed.

- For example, the following code example doesn't compile:

Listing 255: rec_per_object_expressions.ads

```
package Rec_Per_Object_Expressions is

   type Bit_Field is
     array (Positive range <>) of Boolean
       with Pack;

   type T is record
      Arr : Bit_Field (1 .. T'Size);
      --                  ^^^^^^
      --  ERROR: per-object range constraint
      --         using the Size attribute
      --         is illegal.
   end record;

end Rec_Per_Object_Expressions;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Per_Object_
 ↪Expressions.Per_Object_Expression_Range_Constraint
MD5: c2ac9588c1d1adac8c584a0e36a81342
```

Build output

```
rec_per_object_expressions.ads:8:30: error: in a constraint the␣
 ↪current instance can only be used with an access attribute
gprbuild: *** compilation phase failed
```

1. Within a per-object index constraint or discriminant constraint, each per-object expression must be the name of a discriminant directly, without any further computation.
   - Therefore, we're allowed to write `(1 .. S)` — as we've seen in a previous example —. However, writing `(1 .. S - 1)` would be illegal.
   - For example, the following adaptation to the previous code example doesn't compile:

Listing 256: rec_per_object_expressions.ads

```
1  package Rec_Per_Object_Expressions is
2
3     type Stack (S : Positive) is private;
4
5  private
6
7     type Integer_Array is
8       array (Natural range <>) of Integer;
9
10    type Stack (S : Positive) is record
11       Arr : Integer_Array (0 .. S - 1);
12       --                          ^^^^^
13       --  ERROR: computation in per-object
14       --         expression is illegal.
15
16       Top : Integer := -1;
17    end record;
18
19 end Rec_Per_Object_Expressions;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Records.Per_Object_
 ↪Expressions.Per_Object_Expression_Range_Computation
MD5: 1224bb63f7953743d84a258226c35c50
```

Build output

```
rec_per_object_expressions.ads:11:33: error: discriminant in␣
 ↪constraint must appear alone
gprbuild: *** compilation phase failed
```

   In this example, using the computation `S - 1` to specify the range of `Arr` isn't permitted. (Note that, *as we've seen before* (page 432), this restriction doesn't apply when the computation is used in a per-object expression that calculates the default value of a component.)

2. We can only use access attributes (`T'Access` and `T'Unchecked_Access`) in per-object constraints.

25.4 Aggregates

25.4.1 Container Aggregates

Note: This feature was introduced in Ada 2022.

A container aggregate is a list of elements — such as `[1, 2, 3]` — that we use to initialize or assign to a container. For example:

Listing 257: show_container_aggregate.adb

```
pragma Ada_2022;

with Ada.Containers.Vectors;

procedure Show_Container_Aggregate is

   package Float_Vec is new
     Ada.Containers.Vectors (Positive, Float);

   V : constant Float_Vec.Vector :=
         [1.0, 2.0, 3.0];

   pragma Unreferenced (V);
begin
   null;
end Show_Container_Aggregate;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Container_Aggregates.Simple_
 ↪Container_Aggregate
MD5: ef13386fef0b7be0b3ea999a7752d5f1
```

In this example, `[1.0, 2.0, 3.0]` is a container aggregate that we use to initialize a vector V.

We can specify container aggregates in three forms:

- as a null container aggregate, which indicates a container without any elements and is represented by the `[]` syntax;
- as a positional container aggregate, where the elements are simply listed in a sequence (such as `[1, 2]`);
- as a named container aggregate, where a key is indicated for each element of the list (such as `[1 => 10, 2 => 15]`).

Let's look at a complete example:

Listing 258: show_container_aggregate.adb

```
pragma Ada_2022;

with Ada.Containers.Vectors;

procedure Show_Container_Aggregate is

   package Float_Vec is new
     Ada.Containers.Vectors (Positive, Float);
```

(continues on next page)

(continued from previous page)

```
9
10    --  Null container aggregate
11    Null_V  : constant Float_Vec.Vector :=
12                [];
13
14    --  Positional container aggregate
15    Pos_V   : constant Float_Vec.Vector :=
16                [1.0, 2.0, 3.0];
17
18    --  Named container aggregate
19    Named_V : constant Float_Vec.Vector :=
20                [1 => 1.0,
21                 2 => 2.0,
22                 3 => 3.0];
23
24    pragma Unreferenced (Null_V, Pos_V, Named_V);
25 begin
26    null;
27 end Show_Container_Aggregate;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Container_Aggregates.Simple_
 ↪Container_Aggregate
MD5: 15ed6370377423044368a5d56402e940
```

In this example, we see the three forms of container aggregates. The difference between positional and named container aggregates is that:

- for positional container aggregates, the vector index is implied by its position;

while

- for named container aggregates, the index (or key) of each element is explicitly indicated.

Also, the named container aggregate in this example (Named_V) is using an index as the name (i.e. it's an indexed aggregate). Another option is to use non-indexed aggregates, where we use actual keys — as we do in maps. For example:

Listing 259: show_named_container_aggregate.adb

```
1  pragma Ada_2022;
2
3  with Ada.Containers.Vectors;
4  with Ada.Containers.Indefinite_Hashed_Maps;
5  with Ada.Strings.Hash;
6
7  procedure Show_Named_Container_Aggregate is
8
9     package Float_Vec is new
10      Ada.Containers.Vectors (Positive, Float);
11
12    package Float_Hashed_Maps is new
13      Ada.Containers.Indefinite_Hashed_Maps
14        (Key_Type        => String,
15         Element_Type    => Float,
16         Hash            => Ada.Strings.Hash,
17         Equivalent_Keys => "=");
18
19    --  Named container aggregate
20    --  using an index
```

(continues on next page)

(continued from previous page)

```
   Indexed_Named_V : constant Float_Vec.Vector :=
                       [1 => 1.0,
                        2 => 2.0,
                        3 => 3.0];

   --  Named container aggregate
   --  using a key
   Keyed_Named_V : constant
     Float_Hashed_Maps.Map :=
       ["Key_1" => 1.0,
        "Key_2" => 2.0,
        "Key_3" => 3.0];

   pragma Unreferenced (Indexed_Named_V,
                        Keyed_Named_V);
begin
   null;
end Show_Named_Container_Aggregate;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Container_Aggregates.Named_
 ↪Container_Aggregate
MD5: 2eabf312c243856dcb2d6884f71e19e2
```

In this example, Indexed_Named_V and Keyed_Named_V are both initialized with a named container aggregate. However:

- the container aggregate for Indexed_Named_V is an indexed aggregate, so we use an index for each element;

while

- the container aggregate for Keyed_Named_V has a key for each element.

Later on, we'll talk about the *Aggregate aspect* (page 1869), which allows for defining custom container aggregates for any record type.

In the Ada Reference Manual

- 4.3.5 Container Aggregates[71]

25.4.2 Record aggregates

We've already seen record aggregates in the *Introduction to Ada* (page 66) course, so this is just a brief overview on the topic.

As we already know, record aggregates can have positional and named component associations. For example, consider this package:

Listing 260: points.ads

```
package Points is

   type Point_3D is record
      X, Y, Z : Integer;
   end record;
```

(continues on next page)

[71] http://www.ada-auth.org/standards/22rm/html/RM-4-3-5.html

(continued from previous page)

```
6
7     procedure Display (P : Point_3D);
8
9  end Points;
```

Listing 261: points.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Points is
4
5     procedure Display (P : Point_3D) is
6     begin
7        Put_Line ("(X => "
8                  & Integer'Image (P.X)
9                  & ",");
10       Put_Line (" Y => "
11                 & Integer'Image (P.Y)
12                 & ",");
13       Put_Line (" Z => "
14                 & Integer'Image (P.Z)
15                 & ")");
16    end Display;
17
18 end Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Record_Aggregates.Pos_Named_
 ↪Rec_Aggregates
MD5: fd01961cf1da9b48d2a6150da30f7377
```

We can use positional or named record aggregates when assigning to an object P of Point_3D type:

Listing 262: show_record_aggregates.adb

```
1  with Points; use Points;
2
3  procedure Show_Record_Aggregates is
4     P : Point_3D;
5  begin
6     --  Positional component association
7     P := (0, 1, 2);
8
9     Display (P);
10
11    --  Named component association
12    P := (X => 3,
13          Y => 4,
14          Z => 5);
15
16    Display (P);
17 end Show_Record_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Record_Aggregates.Pos_Named_
 ↪Rec_Aggregates
MD5: fc4cff950e31a633ab4e2ae3d21ddc7b
```

Runtime output

```
(X =>  0,
 Y =>  1,
 Z =>  2)
(X =>  3,
 Y =>  4,
 Z =>  5)
```

Also, we can have a mixture of both:

Listing 263: show_record_aggregates.adb

```
with Points; use Points;

procedure Show_Record_Aggregates is
   P : Point_3D;
begin
   --  Positional and named component associations
   P := (3, 4,
         Z => 5);

   Display (P);
end Show_Record_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Record_Aggregates.Pos_Named_
 ↪Rec_Aggregates
MD5: 493a2a87b4b28dfb0882ad73acf84710
```

Runtime output

```
(X =>  3,
 Y =>  4,
 Z =>  5)
```

In this case, only the Z component has a named association, while the other components have a positional association.

Note that a positional association cannot follow a named association, so we cannot write `P := (3, Y => 4, 5);`, for example. Once we start using a named association for a component, we have to continue using it for the remaining components.

In addition, we can choose multiple components at once and assign the same value to them. For that, we use the `|` syntax:

Listing 264: show_record_aggregates.adb

```
with Points; use Points;

procedure Show_Record_Aggregates is
   P : Point_3D;
begin
   --  Multiple component selection
   P := (X | Y => 5,
         Z     => 6);

   Display (P);
end Show_Record_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Record_Aggregates.Pos_Named_
 ↪Rec_Aggregates
MD5: a4fde562fb60d290caf46d86b13e694b
```

Runtime output

```
(X =>  5,
 Y =>  5,
 Z =>  6)
```

Here, we assign 5 to both X and Y.

In the Ada Reference Manual

- 4.3.1 Record Aggregates[72]

<>

We can use the <> syntax to tell the compiler to use the default value for specific components. However, if there's no default value for specific components, that component isn't initialized to a known value. For example:

Listing 265: show_record_aggregates.adb

```
with Points; use Points;

procedure Show_Record_Aggregates is
   P : Point_3D;
begin
   P := (0, 1, 2);
   Display (P);

   --  Specifying X component.
   P := (X => 42,
         Y => <>,
         Z => <>);
   Display (P);

   --  Specifying Y and Z components.
   P := (X => <>,
         Y => 10,
         Z => 20);
   Display (P);
end Show_Record_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Record_Aggregates.Pos_Named_
 ↪Rec_Aggregates
MD5: 25145e7cba5a566c518ac4218e550899
```

Runtime output

```
(X =>  0,
 Y =>  1,
 Z =>  2)
(X =>  42,
```

(continues on next page)

[72] http://www.ada-auth.org/standards/22rm/html/RM-4-3-1.html

(continued from previous page)

```
 Y =>  1,
 Z =>  2)
(X =>  42,
 Y =>  10,
 Z =>  20)
```

Here, as the components of `Point_3D` don't have a default value, those components that have <> are not initialized:

- when we write `(X => 42, Y => <>, Z => <>)`, only X is initialized;
- when we write `(X => <>, Y => 10, Z => 20)` instead, only X is uninitialized.

For further reading...

As we've just seen, all components that get a <> are uninitialized because the components of `Point_3D` don't have a default value. As no initialization is taking place for those components of the aggregate, the actual value that is assigned to the record is undefined. In other words, the resulting behavior might dependent on the compiler's implementation.

When using GNAT, writing `(X => 42, Y => <>, Z => <>)` keeps the value of Y and Z intact, while `(X => <>, Y => 10, Z => 20)` keeps the value of X intact.

If the components of `Point_3D` had default values, those would have been used. For example, we may change the type declaration of `Point_3D` and use default values for each component:

Listing 266: points.ads

```
1  package Points is
2
3     type Point_3D is record
4        X : Integer := 10;
5        Y : Integer := 20;
6        Z : Integer := 30;
7     end record;
8
9     procedure Display (P : Point_3D);
10
11 end Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Record_Aggregates.Pos_Named_
 ↪Rec_Aggregates
MD5: 8a716db129e6f231c4003b77d8b61ea3
```

Then, writing <> makes use of those default values we've just specified:

Listing 267: show_record_aggregates.adb

```
1  with Points; use Points;
2
3  procedure Show_Record_Aggregates is
4     P : Point_3D := (0, 0, 0);
5  begin
6     --  Using default value for
7     --  all components
8     P := (X => <>,
9           Y => <>,
```

(continues on next page)

(continued from previous page)

```
         Z => <>);
   Display (P);
end Show_Record_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Record_Aggregates.Pos_Named_
↪Rec_Aggregates
MD5: e64c6fe4e4b3dbaa084d9b97b4fb971f
```

Runtime output

```
(X =>  10,
 Y =>  20,
 Z =>  30)
```

Now, as expected, the default values of each component (10, 20 and 30) are used when we write <>.

Similarly, we can specify a default value for the type of each component. For example, let's declare a `Point_Value` type with a default value — using the `Default_Value` aspect — and use it in the `Point_3D` record type:

Listing 268: points.ads

```
package Points is

   type Point_Value is new Float
     with Default_Value => 99.9;

   type Point_3D is record
      X : Point_Value;
      Y : Point_Value;
      Z : Point_Value;
   end record;

   procedure Display (P : Point_3D);

end Points;
```

Listing 269: points.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Points is

   procedure Display (P : Point_3D) is
   begin
      Put_Line ("(X => "
                & Point_Value'Image (P.X)
                & ",");
      Put_Line (" Y => "
                & Point_Value'Image (P.Y)
                & ",");
      Put_Line (" Z => "
                & Point_Value'Image (P.Z)
                & ")");
   end Display;

end Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Record_Aggregates.Rec_
 ↪Aggregate_Default_Value
MD5: 508d7f5e7d02da1677485f7d588847f6
```

Then, writing <> makes use of the default value of the `Point_Value` type:

Listing 270: show_record_aggregates.adb

```
with Points; use Points;

procedure Show_Record_Aggregates is
   P : Point_3D := (0.0, 0.0, 0.0);
begin
   --  Using default value of Point_Value
   --  for all components
   P := (X => <>,
         Y => <>,
         Z => <>);
   Display (P);
end Show_Record_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Record_Aggregates.Rec_
 ↪Aggregate_Default_Value
MD5: 895799077af4a295c250480c32954a2c
```

Runtime output

```
(X =>  9.99000E+01,
 Y =>  9.99000E+01,
 Z =>  9.99000E+01)
```

In this case, the default value of the `Point_Value` type (99.9) is used for all components when we write <>.

others

Also, we can use the **others** selector to assign a value to all components that aren't explicitly mentioned in the aggregate. For example:

Listing 271: show_record_aggregates.adb

```
with Points; use Points;

procedure Show_Record_Aggregates is
   P : Point_3D;
begin
   --  Specifying X component;
   --  using 42 for all
   --  other components.
   P := (X      => 42,
         others => 100);
   Display (P);

   --  Specifying all components
   P := (others => 256);
   Display (P);
end Show_Record_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Record_Aggregates.Pos_Named_
 ↪Rec_Aggregates
MD5: 3146363eb36ab4485c7755794fb78bbc
```

Runtime output

```
(X =>  42,
 Y =>  100,
 Z =>  100)
(X =>  256,
 Y =>  256,
 Z =>  256)
```

When we write `P := (X => 42, others => 100)`, we're assigning 42 to X and 100 to all other components (Y and Z in this case). Also, when we write `P := (others => 256)`, all components have the same value (256).

Note that writing a specific value in **others** — such as (**others** => 256) — only works when all components have the same type. In this example, all components of `Point_3D` have the same type: **Integer**. If we had components with different types in the components selected by **others**, say **Integer** and **Float**, then (**others** => 256) would trigger a compilation error. For example, consider this package:

Listing 272: custom_records.ads

```
package Custom_Records is

   type Integer_Float is record
     A, B : Integer := 0;
     Y, Z : Float   := 0.0;
   end record;

end Custom_Records;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Record_Aggregates.Rec_
 ↪Aggregates_Others
MD5: 875e470aa2cbc5fcfefae649ed5528f6
```

If we had written an aggregate such as (**others** => 256) for an object of type `Integer_Float`, the value (256) would be OK for components A and B, but not for components Y and Z:

Listing 273: show_record_aggregates_others.adb

```
with Custom_Records; use Custom_Records;

procedure Show_Record_Aggregates_Others is
   Dummy : Integer_Float;
begin
   --  ERROR: components selected by
   --         others must be of same
   --         type.
   Dummy := (others => 256);
end Show_Record_Aggregates_Others;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Record_Aggregates.Rec_
 ↪Aggregates_Others
MD5: d543ee07e24caf63384ab0d140054be2
```

Build output

```
show_record_aggregates_others.adb:9:14: error: components in "others" choice must␣
 ↪have same type
show_record_aggregates_others.adb:9:24: error: expected type "Standard.Float"
show_record_aggregates_others.adb:9:24: error: found type universal integer
gprbuild: *** compilation phase failed
```

We can fix this compilation error by making sure that **others** only refers to components of the same type:

Listing 274: show_record_aggregates_others.adb

```
with Custom_Records; use Custom_Records;

procedure Show_Record_Aggregates_Others is
   Dummy : Integer_Float;
begin
   --  OK: components selected by
   --      others have Integer type.
   Dummy := (Y | Z  => 256.0,
             others => 256);
end Show_Record_Aggregates_Others;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Record_Aggregates.Rec_
 ↪Aggregates_Others
MD5: d01977a49e08d2c6cb6b7788581ed56f
```

In any case, writing (**others** => <>) is always accepted by the compiler because it simply selects the default value of each component, so the type of those values is unambiguous:

Listing 275: show_record_aggregates_others.adb

```
with Custom_Records; use Custom_Records;

procedure Show_Record_Aggregates_Others is
   Dummy : Integer_Float;
begin
   Dummy := (others => <>);
end Show_Record_Aggregates_Others;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Record_Aggregates.Rec_
 ↪Aggregates_Others
MD5: db9b72ffc933436e76305887276eeafd
```

This code compiles because <> uses the appropriate default value of each component.

Record discriminants

When a record type has discriminants, they must appear as components of an aggregate of that type. For example, consider this package:

Listing 276: points.ads

```
package Points is

   type Point_Dimension is (Dim_1, Dim_2, Dim_3);

   type Point (D : Point_Dimension) is record
      case D is
      when Dim_1 =>
         X1         : Integer;
      when Dim_2 =>
         X2, Y2     : Integer;
      when Dim_3 =>
         X3, Y3, Z3 : Integer;
      end case;
   end record;

   procedure Display (P : Point);

end Points;
```

Listing 277: points.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Points is

   procedure Display (P : Point) is
   begin
      Put_Line (Point_Dimension'Image (P.D));

      case P.D is
      when Dim_1 =>
         Put_Line ("  (X => "
                   & Integer'Image (P.X1)
                   & ")");
      when Dim_2 =>
         Put_Line ("  (X => "
                   & Integer'Image (P.X2)
                   & ",");
         Put_Line ("   Y => "
                   & Integer'Image (P.Y2)
                  & ")");
      when Dim_3 =>
         Put_Line ("  (X => "
                   & Integer'Image (P.X3)
                   & ",");
         Put_Line ("   Y => "
                   & Integer'Image (P.Y3)
                   & ",");
         Put_Line ("   Z => "
                   & Integer'Image (P.Z3)
                   & ")");
      end case;
   end Display;

end Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Record_Aggregates.Rec_
 ↪Aggregate_Discriminant
MD5: bd71322a65ca50e1eefa0aedd407931a
```

To write aggregates of the `Point` type, we have to specify the `D` discriminant as a component of the aggregate. The discriminant must be included in the aggregate — and must be static — because the compiler must be able to examine the aggregate to determine if it is both complete and consistent. All components must be accounted for one way or another, as usual — but, in addition, references to those components whose existence depends on the discriminant's values must be consistent with the actual discriminant value used in the aggregate. For example, for type `Point`, an aggregate can only reference the `X3`, `Y3`, and `Z3` components when `Dim_3` is specified for the discriminant `D`; otherwise, those three components don't exist in that aggregate. Also, the discriminant `D` must be the first one if we use positional component association. For example:

Listing 278: show_rec_aggregate_discriminant.adb

```
with Points; use Points;

procedure Show_Rec_Aggregate_Discriminant is
   --  Positional component association
   P1 : constant Point := (Dim_1, 0);

   --  Named component association
   P2 : constant Point := (D  => Dim_2,
                           X2 => 3,
                           Y2 => 4);

   --  Positional / named component association
   P3 : constant Point := (Dim_3,
                           X3 => 3,
                           Y3 => 4,
                           Z3 => 5);
begin
   Display (P1);
   Display (P2);
   Display (P3);
end Show_Rec_Aggregate_Discriminant;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Record_Aggregates.Rec_
 ↪Aggregate_Discriminant
MD5: d487e0c68ea69c3e0f2adb8ac958e31d
```

Runtime output

```
DIM_1
  (X =>  0)
DIM_2
  (X =>  3,
   Y =>  4)
DIM_3
  (X =>  3,
   Y =>  4,
   Z =>  5)
```

As we see in this example, we can use any component association in the aggregate, as long as we make sure that the discriminants of the type appear as components — and are the first components in the case of positional component association.

25.4.3 Full coverage rules for Aggregates

Note: This section was originally written by Robert A. Duff and published as Gem #1: Limited Types in Ada 2005[73].

One interesting feature of Ada are the *full coverage rules* for aggregates. For example, suppose we have a record type:

Listing 279: persons.ads

```
with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

package Persons is
   type Years is new Natural;

   type Person is record
      Name : Unbounded_String;
      Age  : Years;
   end record;
end Persons;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Full_Coverage_Rules_Aggregates.
 ↪Full_Coverage_Rules
MD5: 7755bffa8b4473c425ae5075e9c478e9
```

We can create an object of the type using an aggregate:

Listing 280: show_aggregate_init.adb

```
with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

with Persons; use Persons;

procedure Show_Aggregate_Init is

   X : constant Person :=
         (Name =>
            To_Unbounded_String ("John Doe"),
          Age  => 25);
begin
   null;
end Show_Aggregate_Init;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Full_Coverage_Rules_Aggregates.
 ↪Full_Coverage_Rules
MD5: 681e665b76265eff4c4d870ec011ba37
```

The full coverage rules say that every component of Person must be accounted for in the aggregate. If we later modify type Person by adding a component:

[73] https://www.adacore.com/gems/gem-1

Listing 281: persons.ads

```
with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

package Persons is
   type Years is new Natural;

   type Person is record
      Name      : Unbounded_String;
      Age       : Natural;
      Shoe_Size : Positive;
   end record;
end Persons;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Full_Coverage_Rules_Aggregates.
 ↪Full_Coverage_Rules
MD5: 5fc5b93748d92932bfc9e0f15c0228b7
```

and we forget to modify X accordingly, the compiler will remind us. Case statements also have full coverage rules, which serve a similar purpose.

Of course, we can defeat the full coverage rules by using **others** (usually for *array aggregates* (page 450) and case statements, but occasionally useful for *record aggregates* (page 437)):

Listing 282: show_aggregate_init_others.adb

```
with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

with Persons; use Persons;

procedure Show_Aggregate_Init_Others is

   X : constant Person :=
         (Name   =>
            To_Unbounded_String ("John Doe"),
          others => 25);
begin
   null;
end Show_Aggregate_Init_Others;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Full_Coverage_Rules_Aggregates.
 ↪Full_Coverage_Rules
MD5: 6d26de8dd6820682cb9150dcbb40f106
```

According to the Ada RM, **others** here means precisely the same thing as `Age | Shoe_Size`. But that's wrong: what **others** really means is "all the other components, including the ones we might add next week or next year". That means you shouldn't use **others** unless you're pretty sure it should apply to all the cases that haven't been invented yet.

Later on, we'll discuss *full coverage rules for limited types* (page 951).

25.4.4 Array aggregates

We've already discussed array aggregates in the *Introduction to Ada* (page 71) course. Therefore, this section just presents some details about this topic.

In the Ada Reference Manual

- 4.3.3 Array Aggregates[74]

Positional and named array aggregates

Note: The array aggregate syntax using brackets (e.g.: `[1, 2, 3]`), which we mention in this section, was introduced in Ada 2022.

Similar to *record aggregates* (page 437), array aggregates can be positional or named. Consider this package:

Listing 283: points.ads

```
package Points is

   type Point_3D is array (1 .. 3) of Integer;

   procedure Display (P : Point_3D);

end Points;
```

Listing 284: points.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

package body Points is

   procedure Display (P : Point_3D) is
   begin
      Put_Line ("(X => "
                & Integer'Image (P (1))
                & ",");
      Put_Line (" Y => "
                & Integer'Image (P (2))
                & ",");
      Put_Line (" Z => "
                & Integer'Image (P (3))
                & ")");
   end Display;

end Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Array_
 ↪Aggregates
MD5: 7ed70d1c9685bc36900e1713619f3321
```

[74] http://www.ada-auth.org/standards/22rm/html/RM-4-3-3.html

We can write positional or named aggregates when assigning to an object P of `Point_3D` type:

Listing 285: show_array_aggregates.adb

```
pragma Ada_2022;

with Points; use Points;

procedure Show_Array_Aggregates is
   P : Point_3D;
begin
   --  Positional component association
   P := [0, 1, 2];

   Display (P);

   --  Named component association
   P := [1 => 3,
         2 => 4,
         3 => 5];

   Display (P);
end Show_Array_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Array_
 ↪Aggregates
MD5: 5913ef6f43ea873de4e3f0760265de4b
```

Runtime output

```
(X =>  0,
 Y =>  1,
 Z =>  2)
(X =>  3,
 Y =>  4,
 Z =>  5)
```

In this example, we assign a positional array aggregate (`[1, 2, 3]`) to P. Then, we assign a named array aggregate (`[1 => 3, 2 => 4, 3 => 5]`) to P. In this case, the *names* are the indices of the components we're assigning to.

We can also assign array aggregates to slices:

Listing 286: show_array_aggregates.adb

```
pragma Ada_2022;

with Points; use Points;

procedure Show_Array_Aggregates is
   P : Point_3D := [others => 0];
begin
   --  Positional component association
   P (2 .. 3) := [1, 2];

   Display (P);

   --  Named component association
   P (2 .. 3) := [1 => 3,
                  2 => 4];
```

(continues on next page)

(continued from previous page)

```
16
17    Display (P);
18 end Show_Array_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Array_
 ↪Aggregates
MD5: 8b36bd7638bd765f45693b78c5c7b872
```

Runtime output

```
(X =>  0,
 Y =>  1,
 Z =>  2)
(X =>  0,
 Y =>  3,
 Z =>  4)
```

Note that, when using a named array aggregate, the index (*name*) that we use in the aggregate doesn't have to match the slice. In this example, we're assigning the component from index 1 of the aggregate to the component of index 2 of the array P (and so on).

Historically

In the first versions of Ada, we could only write array aggregates using parentheses.

Listing 287: show_array_aggregates.adb

```
1  pragma Ada_2012;
2
3  with Points; use Points;
4
5  procedure Show_Array_Aggregates is
6     P : Point_3D;
7  begin
8     --  Positional component association
9     P := (0, 1, 2);
10
11    Display (P);
12
13    --  Named component association
14    P := (1 => 3,
15          2 => 4,
16          3 => 5);
17
18    Display (P);
19 end Show_Array_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.
 ↪Array_Aggregates
MD5: 3d9f1fda006f1d566ae2743240568879
```

Runtime output

```
(X =>  0,
 Y =>  1,
 Z =>  2)
```

(continues on next page)

(continued from previous page)

```
(X =>  3,
 Y =>  4,
 Z =>  5)
```

This syntax is considered obsolescent since Ada 2022: brackets (`[1, 2, 3]`) should be used instead.

Null array aggregate

Note: This feature was introduced in Ada 2022.

We can also write null array aggregates: `[]`. As the name implies, this kind of array aggregate doesn't have any components.

Consider this package:

Listing 288: integer_arrays.ads

```
package Integer_Arrays is

   type Integer_Array is
     array (Positive range <>) of Integer;

   procedure Display (A : Integer_Array);

end Integer_Arrays;
```

Listing 289: integer_arrays.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

package body Integer_Arrays is

   procedure Display (A : Integer_Array) is
   begin
      Put_Line ("Length = "
                & A'Length'Image);

      Put_Line ("(");
      for I in A'Range loop
         Put ("  "
              & I'Image
              & " => "
              & A (I)'Image);
         if I /= A'Last then
            Put_Line (",");
         else
            New_Line;
         end if;
      end loop;
      Put_Line (")");
   end Display;

end Integer_Arrays;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Array_
 ↪Aggregates_2
MD5: 412ebe9de1dfb9157f5379d31162554d
```

We can initialize an object `N` of `Integer_Array` type with a null array aggregate:

Listing 290: show_array_aggregates.adb

```
pragma Ada_2022;

with Integer_Arrays; use Integer_Arrays;

procedure Show_Array_Aggregates is
   N : constant Integer_Array := [];
begin
   Display (N);
end Show_Array_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Array_
 ↪Aggregates_2
MD5: 8cdb9a004ea16f716bf2e2ad5a65358e
```

Runtime output

```
Length =  0
(
)
```

In this example, when we call the `Display` procedure, we confirm that `N` doesn't have any components.

`|`, `<>`, `others`

We've seen the following syntactic elements when we were discussing *record aggregates* (page 437): `|`, `<>` and **`others`**. We can apply them to array aggregates as well:

Listing 291: show_array_aggregates.adb

```
pragma Ada_2022;

with Points; use Points;

procedure Show_Array_Aggregates is
   P : Point_3D;
begin
   --  All components have a value of zero.
   P := [others => 0];

   Display (P);

   --  Both first and second components have
   --  a value of three.
   P := [1 | 2 => 3,
         3     => 4];

   Display (P);

```

(continues on next page)

(continued from previous page)

```
   --  The default value is used for the first
   --  component, and all other components
   --  have a value of five.
   P := [1      => <>,
         others => 5];

   Display (P);
end Show_Array_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Array_
 ↪Aggregates
MD5: 053d4f162cc676b61d8e8a720321d40f
```

Runtime output

```
(X =>  0,
 Y =>  0,
 Z =>  0)
(X =>  3,
 Y =>  3,
 Z =>  4)
(X =>  1358105832,
 Y =>  5,
 Z =>  5)
```

In this example, we use the |, <> and **others** elements in a very similar way as we did with record aggregates. (See the comments in the code example for more details.)

Note that, as for record aggregates, the <> makes use of the default value (if it is available). We discuss this topic in more details *later on* (page 464).

..

We can also use the range syntax (`..`) with array aggregates:

Listing 292: show_array_aggregates.adb

```
pragma Ada_2022;

with Points; use Points;

procedure Show_Array_Aggregates is
   P : Point_3D;
begin
   --  All components have a value of zero.
   P := [1 .. 3 => 0];

   Display (P);

   --  Both first and second components have
   --  a value of three.
   P := [1 .. 2 => 3,
         3      => 4];

   Display (P);

   --  The default value is used for the first
   --  component, and all other components
```

(continues on next page)

(continued from previous page)

```
   --  have a value of five.
   P := [1      => <>,
         2 .. 3 => 5];

   Display (P);
end Show_Array_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Array_
 ↪Aggregates
MD5: bb36de6dcddf4b0bdcd5aa730f0988b1
```

Runtime output

```
(X =>  0,
 Y =>  0,
 Z =>  0)
(X =>  3,
 Y =>  3,
 Z =>  4)
(X => -1004229096,
 Y =>  5,
 Z =>  5)
```

This example is a variation of the previous one. However, in this case, we're using ranges instead of the | and **others** syntax.

Missing components

All aggregate components must have an associated value. If we don't specify a value for a certain component, an exception is raised:

Listing 293: show_array_aggregates.adb

```
pragma Ada_2022;

with Points; use Points;

procedure Show_Array_Aggregates is
   P : Point_3D;
begin
   P := [1 => 4];
   --  ERROR: value of components at indices
   --         2 and 3 are missing

   Display (P);
end Show_Array_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Array_
 ↪Aggregates
MD5: 40d3a65f7fc0602782e548385ae07769
```

Build output

```
show_array_aggregates.adb:8:09: warning: too few elements for type "Point_3D"␣
 ↪defined at points.ads:3 [enabled by default]
```

(continues on next page)

(continued from previous page)

```
show_array_aggregates.adb:8:09: warning: expected 3 elements; found 1 element␣
 ↪[enabled by default]
show_array_aggregates.adb:8:09: warning: Constraint_Error will be raised at run␣
 ↪time [enabled by default]
```

Runtime output

```
raised CONSTRAINT_ERROR : show_array_aggregates.adb:8 range check failed
```

We can use **others** to specify a value to all components that haven't been explicitly mentioned in the aggregate:

Listing 294: show_array_aggregates.adb

```
pragma Ada_2022;

with Points; use Points;

procedure Show_Array_Aggregates is
   P : Point_3D;
begin
   P := [1 => 4, others => 0];
   --  OK: unspecified components have a
   --      value of zero

   Display (P);
end Show_Array_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Array_
 ↪Aggregates
MD5: 63b60de44e7c08eeae19a6a9117818f5
```

Runtime output

```
(X =>  4,
 Y =>  0,
 Z =>  0)
```

However, **others** can only be used when the range is known — compilation fails otherwise:

Listing 295: show_array_aggregates.adb

```
pragma Ada_2022;

with Integer_Arrays; use Integer_Arrays;

procedure Show_Array_Aggregates is
   N1 : Integer_Array := [others => 0];
   --  ERROR: range is unknown

   N2 : Integer_Array (1 .. 3) := [others => 0];
   --  OK: range is known
begin
   Display (N1);
   Display (N2);
end Show_Array_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Array_
 ↪Aggregates_2
MD5: 65b457e017a4eca6051aac777cc429f4
```

Build output

```
show_array_aggregates.adb:6:27: error: "others" choice not allowed here
show_array_aggregates.adb:6:27: error: qualify the aggregate with a constrained␣
 ↪subtype to provide bounds for it
gprbuild: *** compilation phase failed
```

Of course, we could fix the declaration of N1 by specifying a range — e.g. `N1 : Integer_Array (1 .. 10) := [others => 0];`.

Iterated component association

Note: This feature was introduced in Ada 2022.

We can use an iterated component association to specify an aggregate. This is the general syntax:

```
--  All components have a value of zero
P := [for I in 1 .. 3 => 0];
```

Let's see a complete example:

Listing 296: show_array_aggregates.adb

```
pragma Ada_2022;

with Points; use Points;

procedure Show_Array_Aggregates is
   P : Point_3D;
begin
   --  All components have a value of zero
   P := [for I in 1 .. 3 => 0];

   Display (P);

   --  Both first and second components have
   --  a value of three
   P := [for I in 1 .. 3 =>
           (if I = 1 or I = 2
            then 3
            else 4)];

   Display (P);

   --  The first component has a value of 99
   --  and all other components have a value
   --  that corresponds to its index
   P := [1 => 99,
         for I in 2 .. 3 => I];

   Display (P);
end Show_Array_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Array_
 ↪Aggregates
MD5: f11b3119e3fc1ece08f0b01d7e02576d
```

Runtime output

```
(X =>  0,
 Y =>  0,
 Z =>  0)
(X =>  3,
 Y =>  3,
 Z =>  4)
(X =>  99,
 Y =>  2,
 Z =>  3)
```

In this example, we use iterated component associations in different ways:

1. We write a simple iteration (`[for I in 1 .. 3 => 0]`).
2. We use a conditional expression in the iteration: `[for I in 1 .. 3 => (if I = 1 or I = 2 then 3 else 4)]`.
3. We use a named association for the first element, and then iterated component association for the remaining components: `[1 => 99, for I in 2 .. 3 => I]`.

So far, we've used a discrete choice list (in the `for I in Range` form) in the iterated component association. We could use an iterator (in the `for E of` form) instead. For example:

Listing 297: show_array_aggregates.adb

```
1  pragma Ada_2022;
2
3  with Points; use Points;
4
5  procedure Show_Array_Aggregates is
6     P : Point_3D := [for I in Point_3D'Range => I];
7  begin
8     --  Each component is doubled
9     P := [for E of P => E * 2];
10
11    Display (P);
12
13    --  Each component is increased
14    --  by one
15    P := [for E of P => E + 1];
16
17    Display (P);
18 end Show_Array_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Array_
 ↪Aggregates
MD5: b8c1878c1fa516005d1861f1a37c4fb0
```

Runtime output

```
(X =>  2,
 Y =>  4,
 Z =>  6)
(X =>  3,
```

(continues on next page)

(continued from previous page)

```
Y =>  5,
Z =>  7)
```

In this example, we use iterators in different ways:

1. We write [for E of P => E * 2] to double the value of each component.
2. We write [for E of P => E + 1] to increase the value of each component by one.

Of course, we could write more complex operations on E in the iterators.

Multidimensional array aggregates

So far, we've discussed one-dimensional array aggregates. We can also use the same constructs when dealing with multidimensional arrays. Consider, for example, this package:

Listing 298: matrices.ads

```
1  package Matrices is
2
3     type Matrix is array (Positive range <>,
4                           Positive range <>)
5                           of Integer;
6
7     procedure Display (M : Matrix);
8
9  end Matrices;
```

Listing 299: matrices.adb

```
1  pragma Ada_2022;
2
3  with Ada.Text_IO; use Ada.Text_IO;
4
5  package body Matrices is
6
7     procedure Display (M : Matrix) is
8
9        procedure Display_Row (M : Matrix;
10                              I : Integer) is
11       begin
12          Put_Line ("  (");
13          for J in M'Range (2) loop
14             Put ("    "
15                  & J'Image
16                  & " => "
17                  & M (I, J)'Image);
18             if J /= M'Last (2) then
19                Put_Line (",");
20             else
21                New_Line;
22             end if;
23          end loop;
24          Put ("  )");
25       end Display_Row;
26
27    begin
28       Put_Line ("Length (1) = "
29                 & M'Length (1)'Image);
30       Put_Line ("Length (2) = "
```

(continues on next page)

(continued from previous page)

```
                & M'Length (2)'Image);

      Put_Line ("(");
      for I in M'Range (1) loop
         Display_Row (M, I);
         if I /= M'Last (1) then
            Put_Line (",");
         else
            New_Line;
         end if;
      end loop;
      Put_Line (")");

   end Display;

end Matrices;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Matrix_
 ↪Aggregates
MD5: 748c7c695dfef43d7d4926edf5ddd3ae
```

We can assign multidimensional aggregates to a matrix M using positional or named component association:

Listing 300: show_array_aggregates.adb

```
pragma Ada_2022;

with Matrices; use Matrices;

procedure Show_Array_Aggregates is
   M : Matrix (1 .. 2, 1 .. 3);
begin
   --  Positional component association
   M := [[0, 1, 2],
         [3, 4, 5]];

   Display (M);

   --  Named component association
   M := [[1 => 3,
          2 => 4,
          3 => 5],
         [1 => 6,
          2 => 7,
          3 => 8]];

   Display (M);

end Show_Array_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Matrix_
 ↪Aggregates
MD5: 78e1fad3b90c4f4d0f9d45f299e5ae10
```

Runtime output

```
Length (1) =  2
Length (2) =  3
(
  (
     1 =>  0,
     2 =>  1,
     3 =>  2
  ),
  (
     1 =>  3,
     2 =>  4,
     3 =>  5
  )
)
Length (1) =  2
Length (2) =  3
(
  (
     1 =>  3,
     2 =>  4,
     3 =>  5
  ),
  (
     1 =>  6,
     2 =>  7,
     3 =>  8
  )
)
```

The first aggregate we use in this example is `[[0, 1, 2], [3, 4, 5]]`. Here, `[0, 1, 2]` and `[3, 4, 5]` are subaggregates of the multidimensional aggregate. Subaggregates don't have a type themselves, but are rather just considered part of a multidimensional aggregate (which, of course, has an array type). In this sense, a subaggregate such as `[0, 1, 2]` is different from a one-dimensional aggregate (such as `[0, 1, 2]`), even though they are written in the same way.

Strings in subaggregates

In the case of matrices using characters, we can use strings in the corresponding array aggregates. Consider this package:

Listing 301: string_lists.ads

```
package String_Lists is

   type String_List is array (Positive range <>,
                              Positive range <>)
                              of Character;

   procedure Display (SL : String_List);

end String_Lists;
```

Listing 302: string_lists.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

```

(continues on next page)

(continued from previous page)

```
package body String_Lists is

   procedure Display (SL : String_List) is

      procedure Display_Row (SL : String_List;
                             I  : Integer) is
      begin
         Put ("  (");
         for J in SL'Range (2) loop
            Put (SL (I, J));
         end loop;
         Put (")");
      end Display_Row;

   begin
      Put_Line ("Length (1) = "
                & SL'Length (1)'Image);
      Put_Line ("Length (2) = "
                & SL'Length (2)'Image);

      Put_Line ("(");
      for I in SL'Range (1) loop
         Display_Row (SL, I);
         if I /= SL'Last (1) then
            Put_Line (",");
         else
            New_Line;
         end if;
      end loop;
      Put_Line (")");
   end Display;

end String_Lists;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.String_
 ↪Aggregates
MD5: 87b2e593cab823218a39c07d85f40c22
```

Then, when assigning to an object SL of `String_List` type, we can use strings in the aggregates:

Listing 303: show_array_aggregates.adb

```
pragma Ada_2022;

with String_Lists; use String_Lists;

procedure Show_Array_Aggregates is
   SL : String_List (1 .. 2, 1 .. 3);
begin
   --  Positional component association
   SL := ["ABC",
          "DEF"];

   Display (SL);

   --  Named component associations
   SL := [[1 => 'A',
           2 => 'B',
```

(continues on next page)

(continued from previous page)

```
            3 => 'C'],
           [1 => 'D',
            2 => 'E',
            3 => 'F']];

   Display (SL);

   SL := [[1 => 'X',
           2 => 'Y',
           3 => 'Z'],
          [others => ' ']];

   Display (SL);
end Show_Array_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.String_
 ↪Aggregates
MD5: 82e376269e3be935d5cbd66202f26ec7
```

Runtime output

```
Length (1) =  2
Length (2) =  3
(
  (ABC),
  (DEF)
)
Length (1) =  2
Length (2) =  3
(
  (ABC),
  (DEF)
)
Length (1) =  2
Length (2) =  3
(
  (XYZ),
  (   )
)
```

In the first assignment to SL, we have the aggregate `["ABC", "DEF"]`, which uses strings as subaggregates. (Of course, we can use a named aggregate and assign characters to the individual components.)

<> and default values

As we indicated earlier, the <> syntax sets a component to its default value — if such a default value is available. If a default value isn't defined, however, the component will remain uninitialized, so that the behavior is undefined. Let's look at more complex example to illustrate this situation. Consider this package, for example:

Listing 304: points.ads

```
package Points is

   subtype Point_Value is Integer;

```

(continues on next page)

(continued from previous page)

```
   type Point_3D is record
      X, Y, Z : Point_Value;
   end record;

   procedure Display (P : Point_3D);

   type Point_3D_Array is
     array (Positive range <>) of Point_3D;

   procedure Display (PA : Point_3D_Array);

end Points;
```

Listing 305: points.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Points is

   procedure Display (P : Point_3D) is
   begin
      Put ("      (X => "
           & Point_Value'Image (P.X)
           & ",");
      New_Line;
      Put ("       Y => "
           & Point_Value'Image (P.Y)
           & ",");
      New_Line;
      Put ("       Z => "
           & Point_Value'Image (P.Z)
           & ")");
   end Display;

   procedure Display (PA : Point_3D_Array) is
   begin
      Put_Line ("(");
      for I in PA'Range (1) loop
         Put_Line ("  "
                   & Integer'Image (I)
                   & " =>");
         Display (PA (I));
         if I /= PA'Last (1) then
            Put_Line (",");
         else
            New_Line;
         end if;
      end loop;
      Put_Line (")");
   end Display;

end Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Rec_Array_
 ↪Aggregates
MD5: ffaf3745621a30362c6aadaec2c3cef2
```

Then, let's use <> for the array components:

Listing 306: show_record_aggregates.adb

```
pragma Ada_2022;

with Points; use Points;

procedure Show_Record_Aggregates is
   PA : Point_3D_Array (1 .. 2);
begin
   PA := [ (X => 3,
            Y => 4,
            Z => 5),
           (X => 6,
            Y => 7,
            Z => 8) ];
   Display (PA);

   --  Array components are
   --  uninitialized.
   PA := [1 => <>,
          2 => <>];
   Display (PA);
end Show_Record_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Rec_Array_
 ↪Aggregates
MD5: 1dee9505222fe9837cd5aa3bf119ee3a
```

Runtime output

```
(
   1 =>
      (X =>  3,
       Y =>  4,
       Z =>  5),
   2 =>
      (X =>  6,
       Y =>  7,
       Z =>  8)
)
(
   1 =>
      (X =>  0,
       Y =>  0,
       Z => -278340979),
   2 =>
      (X =>  32609,
       Y => -276826432,
       Z =>  32609)
)
```

Because the record components (of the `Point_3D` type) don't have default values, they remain uninitialized when we write `[1 => <>, 2 => <>]`. (In fact, you may see *garbage* in the values displayed by the `Display` procedure.)

When a default value is specified, it is used whenever `<>` is specified. For example, we could use a type that has the `Default_Value` aspect in its specification:

Listing 307: integer_arrays.ads

```
package Integer_Arrays is

   type Value is new Integer
     with Default_Value => 99;

   type Integer_Array is
     array (Positive range <>) of Value;

   procedure Display (A : Integer_Array);

end Integer_Arrays;
```

Listing 308: show_array_aggregates.adb

```
pragma Ada_2022;

with Integer_Arrays; use Integer_Arrays;

procedure Show_Array_Aggregates is
   N : Integer_Array (1 .. 4);
begin
   N := [for I in N'Range => Value (I)];
   Display (N);

   N := [others => <>];
   Display (N);
end Show_Array_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Array_
 ↪Aggregates_2
MD5: 17641d696172b052925d5549f53b9712
```

Runtime output

```
Length =  4
(
   1 =>  1,
   2 =>  2,
   3 =>  3,
   4 =>  4
)
Length =  4
(
   1 =>  99,
   2 =>  99,
   3 =>  99,
   4 =>  99
)
```

When writing an aggregate for the `Point_3D` type, any component that has `<>` gets the default value of the `Point` type (99):

For further reading...

Similarly, we could specify the `Default_Component_Value` aspect (which we discussed *earlier on* (page 335)) in the declaration of the array type:

Listing 309: integer_arrays.ads

```
package Integer_Arrays is

   type Value is new Integer;

   type Integer_Array is
     array (Positive range <>) of Value
       with Default_Component_Value => 9999;

   procedure Display (A : Integer_Array);

end Integer_Arrays;
```

Listing 310: show_array_aggregates.adb

```
pragma Ada_2022;

with Integer_Arrays; use Integer_Arrays;

procedure Show_Array_Aggregates is
   N : Integer_Array (1 .. 4);
begin
   N := [for I in N'Range => Value (I)];
   Display (N);

   N := [others => <>];
   Display (N);
end Show_Array_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Array_
 ↪Aggregates_2
MD5: c6b38711937a1a7bbb92ddb4c207404e
```

Runtime output

```
Length =  4
(
   1 =>  1,
   2 =>  2,
   3 =>  3,
   4 =>  4
)
Length =  4
(
   1 =>  9999,
   2 =>  9999,
   3 =>  9999,
   4 =>  9999
)
```

In this case, when writing <> for a component, the value specified in the `Default_Component_Value` aspect is used.

Finally, we might want to use both `Default_Value` (which we discussed *previously* (page 334)) and `Default_Component_Value` aspects at the same time. In this case, the value specified in the `Default_Component_Value` aspect has higher priority:

Listing 311: integer_arrays.ads

```
package Integer_Arrays is

   type Value is new Integer
     with Default_Value => 99;

   type Integer_Array is
     array (Positive range <>) of Value
       with Default_Component_Value => 9999;

   procedure Display (A : Integer_Array);

end Integer_Arrays;
```

Listing 312: show_array_aggregates.adb

```
pragma Ada_2022;

with Integer_Arrays; use Integer_Arrays;

procedure Show_Array_Aggregates is
   N : Integer_Array (1 .. 4);
begin
   N := [for I in N'Range => Value (I)];
   Display (N);

   N := [others => <>];
   Display (N);
end Show_Array_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Array_Aggregates.Array_
 ↪Aggregates_2
MD5: c5b6d45576d59e2d3ba1634953c58b02
```

Runtime output

```
Length =  4
(
   1 =>  1,
   2 =>  2,
   3 =>  3,
   4 =>  4
)
Length =  4
(
   1 =>  9999,
   2 =>  9999,
   3 =>  9999,
   4 =>  9999
)
```

Here, 9999 is used when we specify <> for a component.

25.4.5 Extension Aggregates

Extension aggregates provide a convenient way to express an aggregate for a type that extends — adds components to — some existing type (the "ancestor"). Although mainly a matter of convenience, an extension aggregate is essential when we want to express an aggregate for an extension of a private ancestor type, that is, when we don't have compile-time visibility to the ancestor type's components.

In the Ada Reference Manual

- 4.3.2 Extension Aggregates[75]

Assignments to objects of derived types

Before we discuss extension aggregates in more detail, though, let's start with a simple use-case. Let's say we have:

- an object A of tagged type T1, and
- an object B of tagged type T2, which extends T1.

We can initialize object B by:

- copying the T1 specific information from A to B, and
- initializing the T2 specific components of B.

We can translate the description above to the following code:

```
   A : T1;
   B : T2;
begin
   T1 (B) := A;

   B.Extended_Component_1 := Some_Value;
   --  [...]
```

Here, we use `T1 (B)` to select the ancestor view of object B, and we copy all the information from A to this part of B. Then, we initialize the remaining components of B. We'll elaborate on this kind of assignments later on.

Example: `Points`

To present a more concrete example, let's start with a package that defines one, two and three-dimensional point types:

Listing 313: points.ads

```
1  package Points is
2
3     type Point_1D is tagged record
4        X : Float;
5     end record;
6
7     procedure Display (P : Point_1D);
8
9     type Point_2D is new Point_1D with record
```

(continues on next page)

[75] http://www.ada-auth.org/standards/22rm/html/RM-4-3-2.html

(continued from previous page)

```
      Y : Float;
   end record;

   procedure Display (P : Point_2D);

   type Point_3D is new Point_2D with record
      Z : Float;
   end record;

   procedure Display (P : Point_3D);

end Points;
```

Listing 314: points.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Points is

   procedure Display (P : Point_1D) is
   begin
      Put_Line ("(X => " & P.X'Image & ")");
   end Display;

   procedure Display (P : Point_2D) is
   begin
      Put_Line ("(X => " & P.X'Image
                & ", Y => " & P.Y'Image & ")");
   end Display;

   procedure Display (P : Point_3D) is
   begin
      Put_Line ("(X => " & P.X'Image
                & ", Y => " & P.Y'Image
                & ", Z => " & P.Z'Image & ")");
   end Display;

end Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Extension_Aggregates.Extension_
 ↪Aggregate_Points
MD5: 0acc05ae2310ab4ba038dfdb6bae0495
```

Let's now focus on the Show_Points procedure below, where we initialize a two-dimensional point using a one-dimensional point.

Listing 315: show_points.adb

```
with Points; use Points;

procedure Show_Points is
   P_1D : Point_1D;
   P_2D : Point_2D;
begin
   P_1D := (X => 0.5);
   Display (P_1D);

   Point_1D (P_2D) := P_1D;
   --  Equivalent to: "P_2D.X := P_1D.X;"
```

(continues on next page)

(continued from previous page)

```
12
13    P_2D.Y := 0.7;
14
15    Display (P_2D);
16 end Show_Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Extension_Aggregates.Extension_
 ↪Aggregate_Points
MD5: 68ae6fa8e6f779aebea97085bd75e082
```

Runtime output

```
(X =>  5.00000E-01)
(X =>  5.00000E-01, Y =>  7.00000E-01)
```

In this example, we're initializing P_2D using the information stored in P_1D. By writing `Point_1D (P_2D)` on the left side of the assignment, we specify that we want to limit our focus on the `Point_1D` view of the P_2D object. Then, we assign P_1D to the `Point_1D` view of the P_2D object. This assignment initializes the X component of the P_2D object. The `Point_2D` specific components are not changed by this assignment. (In other words, this is equivalent to just writing `P_2D.X := P_1D.X`, as the `Point_1D` type only has the X component.) Finally, in the next line, we initialize the Y component with 0.7.

Using extension aggregates

Note that, in the assignment to P_1D, we use a record aggregate. Extension aggregates are similar to record aggregates, but they include the **`with`** keyword — for example: `(Obj1 with Y => 0.5)`. This allows us to assign to an object with information from another object `Obj1` of a parent type and, in the same expression, set the value of the Y component of the type extension.

Let's rewrite the previous `Show_Points` procedure using extension aggregates:

Listing 316: show_points.adb

```
1  with Points; use Points;
2
3  procedure Show_Points is
4     P_1D : Point_1D;
5     P_2D : Point_2D;
6  begin
7     P_1D := (X => 0.5);
8     Display (P_1D);
9
10    P_2D := (P_1D with Y => 0.7);
11    Display (P_2D);
12 end Show_Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Extension_Aggregates.Extension_
 ↪Aggregate_Points
MD5: 4d03f6a565126b602d6f21fe5ee6dd27
```

Runtime output

```
(X =>  5.00000E-01)
(X =>  5.00000E-01, Y =>  7.00000E-01)
```

When we write P_2D := (P_1D with Y => 0.7), we're initializing P_2D using:

- the information from the P_1D object — of Point_1D type, which is an ancestor of the Point_2D type —, and
- the information from the record component association list for the remaining components of the Point_2D type. (In this case, the only remaining component of the Point_2D type is Y.)

We could also specify the type of the extension aggregate. For example, in the previous assignment to P_2D, we could write Point_2D'(...) to indicate that we expect the Point_2D type for the extension aggregate.

```
--  Explicitly state that the type of the
--  extension aggregate is Point_2D:

P_2D := Point_2D'(P_1D with Y => 0.7);
```

Also, we don't have to use named association in extension aggregates. We could just use positional association instead. Therefore, we could simplify the assignment to P_2D in the previous example by just writing:

```
P_2D := (P_1D with 0.7);
```

More extension aggregates

We can use extension aggregates for descendants of the Point_2D type as well. For example, let's extend our previous code example by declaring an object of Point_3D type (called P_3D) and use extension aggregates in assignments to this object:

Listing 317: show_points.adb

```
with Points; use Points;

procedure Show_Points is
   P_1D : Point_1D;
   P_2D : Point_2D;
   P_3D : Point_3D;
begin
   P_1D := (X => 0.5);
   Display (P_1D);

   P_2D := (P_1D with Y => 0.7);
   Display (P_2D);

   P_3D := (P_2D with Z => 0.3);
   Display (P_3D);

   P_3D := (P_1D with Y | Z => 0.1);
   Display (P_3D);
end Show_Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Extension_Aggregates.Extension_
 ↪Aggregate_Points
MD5: 2ec6831557c43f697bffce8496962b53
```

Runtime output

```
(X =>  5.00000E-01)
(X =>  5.00000E-01, Y =>  7.00000E-01)
(X =>  5.00000E-01, Y =>  7.00000E-01, Z =>  3.00000E-01)
(X =>  5.00000E-01, Y =>  1.00000E-01, Z =>  1.00000E-01)
```

In the first assignment to P_3D in the example above, we're initializing this object with information from P_2D and specifying the value of the Z component. Then, in the next assignment to the P_3D object, we're using an aggregate with information from P_1 and specifying values for the Y and Z components. (Just as a reminder, we can write `Y | Z => 0.1` to assign 0.1 to both Y and Z components.)

with others

Other versions of extension aggregates are possible as well. For example, we can combine keywords and write `with others` to focus on all remaining components of an extension aggregate.

Listing 318: show_points.adb

```
with Points; use Points;

procedure Show_Points is
   P_1D : Point_1D;
   P_2D : Point_2D;
   P_3D : Point_3D;
begin
   P_1D := (X => 0.5);
   P_2D := (P_1D with Y => 0.7);

   --  Initialize P_3D with P_1D and set other
   --  components to 0.6.
   --
   P_3D := (P_1D with others => 0.6);
   Display (P_3D);

   --  Initialize P_3D with P_2D, and other
   --  components with their default value.
   --
   P_3D := (P_2D with others => <>);
   Display (P_3D);
end Show_Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Extension_Aggregates.Extension_
 ↪Aggregate_Points
MD5: 0594586fc59ead106258cef8682927e9
```

Runtime output

```
(X =>  5.00000E-01, Y =>  6.00000E-01, Z =>  6.00000E-01)
(X =>  5.00000E-01, Y =>  7.00000E-01, Z =>  5.93170E-39)
```

In this example, the first assignment to P_3D has an aggregate with information from P_1D, while the remaining components — in this case, Y and Z — are just set to 0.6.

Continuing with this example, in the next assignment to P_3D, we're using information from P_2 in the extension aggregate. This covers the `Point_2D` part of the P_3D object — components X and Y, to be more specific. The `Point_3D` specific components of P_3D — component

Z in this case — receive their corresponding default value. In this specific case, however, we haven't specified a default value for component Z in the declaration of the Point_3D type, so we cannot rely on any specific value being assigned to that component when using **others** => <>.

with null record

We can also use extension aggregates with null records. Let's focus on the P_3D_Ext object of Point_3D_Ext type. This object is declared in the Show_Points procedure of the next code example.

Listing 319: points-extensions.ads

```
package Points.Extensions is

   type Point_3D_Ext is new
     Point_3D with null record;

end Points.Extensions;
```

Listing 320: show_points.adb

```
with Points;            use Points;
with Points.Extensions; use Points.Extensions;

procedure Show_Points is
   P_3D     : Point_3D;
   P_3D_Ext : Point_3D_Ext;
begin
   P_3D := (X => 0.0, Y => 0.5, Z => 0.4);

   P_3D_Ext := (P_3D with null record);
   Display (P_3D_Ext);
end Show_Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Extension_Aggregates.Extension_
 ↪Aggregate_Points
MD5: 8ec3ddb3a1f2a6e550ac4d622e97124c
```

Runtime output

```
(X =>  0.00000E+00, Y =>  5.00000E-01, Z =>  4.00000E-01)
```

The P_3D_Ext object is of Point_3D_Ext type, which is declared in the Points.Extensions package and derived from the Point_3D type. Note that we're not extending Point_3D_Ext with new components, but using a null record instead in the declaration. Therefore, as the Point_3D_Ext type doesn't own any new components, we just write (P_3D **with** null **record**) to initialize the P_3D_Ext object.

Extension aggregates and descendent types

In the examples above, we've been initializing objects of descendent types by using objects of ascending types in extension aggregates. We could, however, do the opposite and initialize objects of ascending types using objects of descendent type in extension aggregates. Consider this code example:

Listing 321: show_points.adb

```
with Points; use Points;

procedure Show_Points is
   P_2D : Point_2D;
   P_3D : Point_3D;
begin
   P_3D := (X => 0.5, Y => 0.7, Z => 0.3);
   Display (P_3D);

   P_2D := (Point_1D (P_3D) with Y => 0.3);
   Display (P_2D);
end Show_Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Extension_Aggregates.Extension_
↪Aggregate_Points
MD5: ae5e88a36c58b1eb495d5ba8752e50e7
```

Runtime output

```
(X =>  5.00000E-01, Y =>  7.00000E-01, Z =>  3.00000E-01)
(X =>  5.00000E-01, Y =>  3.00000E-01)
```

Here, we're using `Point_1D (P_3D)` to select the `Point_1D` view of an object of `Point_3D` type. At this point, we have specified the `Point_1D` part of the aggregate, so we still have to specify the remaining components of the `Point_2D` type — the `Y` component, to be more specific. When we do that, we get the appropriate aggregate for the `Point_2D` type. In summary, by carefully selecting the appropriate view, we're able to initialize an object of ascending type (`Point_2D`), which contains less components, using an object of a descendent type (`Point_3D`), which contains more components.

25.4.6 Delta Aggregates

Note: This feature was introduced in Ada 2022.

Previously, we've discussed *extension aggregates* (page 472), which are used to assign an object `Obj_From` of a tagged type to an object `Obj_To` of a descendent type.

We may want also to assign an object `Obj_From` of to an object `Obj_To` of the same type, but change some of the components in this assignment. To do this, we use delta aggregates.

Delta Aggregates for Tagged Records

Let's reuse the Points package from a previous example:

Listing 322: points.ads

```
package Points is

   type Point_1D is tagged record
      X : Float;
   end record;

   type Point_2D is new Point_1D with record
      Y : Float;
   end record;

   type Point_3D is new Point_2D with record
      Z : Float;
   end record;

   procedure Display (P : Point_3D);

end Points;
```

Listing 323: points.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Points is

   procedure Display (P : Point_3D) is
   begin
      Put_Line ("(X => " & P.X'Image
                & ", Y => " & P.Y'Image
                & ", Z => " & P.Z'Image & ")");
   end Display;

end Points;
```

Listing 324: show_points.adb

```
pragma Ada_2022;

with Points; use Points;

procedure Show_Points is
   P1, P2, P3 : Point_3D;
begin
   P1 := (X => 0.5, Y => 0.7, Z => 0.3);
   Display (P1);

   P2 := (P1 with delta X => 1.0);
   Display (P2);

   P3 := (P1 with delta X => 0.2, Y => 0.3);
   Display (P3);
end Show_Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Delta_Aggregates.Delta_
```

(continues on next page)

(continued from previous page)

```
↪Aggregates_Tagged
MD5: affbd4304a683699de48fc44db44f09e
```

Runtime output

```
(X =>  5.00000E-01, Y =>  7.00000E-01, Z =>  3.00000E-01)
(X =>  1.00000E+00, Y =>  7.00000E-01, Z =>  3.00000E-01)
(X =>  2.00000E-01, Y =>  3.00000E-01, Z =>  3.00000E-01)
```

Here, we assign P1 to P2, but change the X component. Also, we assign P1 to P3, but change the X and Y components.

We can use class-wide types with delta aggregates. Consider this example:

Listing 325: show_points.adb

```
pragma Ada_2022;

with Points; use Points;

procedure Show_Points is

   P_3D : Point_3D;

   function Reset (P_2D : Point_2D'Class)
                   return Point_2D'Class is
     ((P_2D with delta X | Y => 0.0));

begin
   P_3D := [X => 0.1, Y => 0.2, Z => 0.3];
   Display (P_3D);

   P_3D := Point_3D (Reset (P_3D));
   Display (P_3D);

end Show_Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Delta_Aggregates.Delta_
↪Aggregates_Tagged
MD5: 30e62d564d1b35829a5002223966c101
```

Runtime output

```
(X =>  1.00000E-01, Y =>  2.00000E-01, Z =>  3.00000E-01)
(X =>  0.00000E+00, Y =>  0.00000E+00, Z =>  3.00000E-01)
```

In this example, the `Reset` function returns an object of `Point_2D'Class` where all components of `Point_2D'Class` type are zero. We call the `Reset` function for the `P_3D` object of `Point_3D` type, so that only the `Z` component remains untouched.

Note that we use the syntax `X | Y` in the body of the `Reset` function and assign the same value to both components.

For further reading...

We could have implemented `Reset` as a procedure — in this case, without using delta aggregates:

Listing 326: show_points.adb

```
with Points; use Points;

procedure Show_Points is

   P_3D : Point_3D;

   procedure Reset
     (P_2D : in out Point_2D'Class) is
   begin
      Point_2D (P_2D) := (others => 0.0);
   end Reset;

begin
   P_3D := (X => 0.1, Y => 0.2, Z => 0.3);
   Display (P_3D);

   Reset (P_3D);
   Display (P_3D);

end Show_Points;
```

Delta Aggregates for Non-Tagged Records

The examples above use tagged types. We can also use delta aggregates with non-tagged types. Let's rewrite the `Points` package and convert `Point_3D` to a non-tagged record type.

Listing 327: points.ads

```
package Points is

   type Point_3D is record
      X : Float;
      Y : Float;
      Z : Float;
   end record;

   procedure Display (P : Point_3D);

end Points;
```

Listing 328: points.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Points is

   procedure Display (P : Point_3D) is
   begin
      Put_Line ("(X => " & P.X'Image
                & ", Y => " & P.Y'Image
                & ", Z => " & P.Z'Image & ")");
   end Display;

end Points;
```

Listing 329: show_points.adb

```
pragma Ada_2022;

with Points; use Points;

procedure Show_Points is
   P1, P2, P3 : Point_3D;
begin
   P1 := (X => 0.5, Y => 0.7, Z => 0.3);
   Display (P1);

   P2 := (P1 with delta X => 1.0);
   Display (P2);

   P3 := (P1 with delta X => 0.2, Y => 0.3);
   Display (P3);
end Show_Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Delta_Aggregates.Delta_
 ↪Aggregates_Non_Tagged
MD5: 71a3b76ee1988ddea7246d0b8f897865
```

Runtime output

```
(X =>  5.00000E-01, Y =>  7.00000E-01, Z =>  3.00000E-01)
(X =>  1.00000E+00, Y =>  7.00000E-01, Z =>  3.00000E-01)
(X =>  2.00000E-01, Y =>  3.00000E-01, Z =>  3.00000E-01)
```

In this example, `Point_3D` is a non-tagged type. Note that we haven't changed anything in the `Show_Points` procedure: it still works as it did with tagged types.

Delta Aggregates for Arrays

We can use delta aggregates for arrays. Let's change the declaration of `Point_3D` and use an array to represent a 3-dimensional point:

Listing 330: points.ads

```
package Points is

   type Float_Array is
     array (Positive range <>) of Float;

   type Point_3D is new Float_Array (1 .. 3);

   procedure Display (P : Point_3D);

end Points;
```

Listing 331: points.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Points is

   procedure Display (P : Point_3D) is
```

(continues on next page)

(continued from previous page)

```
   begin
      Put ("(");
      for I in P'Range loop
         Put (I'Image
              & " => "
              & P (I)'Image);
      end loop;
      Put_Line (")");
   end Display;

end Points;
```

Listing 332: show_points.adb

```
pragma Ada_2022;

with Points; use Points;

procedure Show_Points is
   P1, P2, P3 : Point_3D;
begin
   P1 := [0.5, 0.7, 0.3];
   Display (P1);

   P2 := [P1 with delta 1 => 1.0];
   Display (P2);

   P3 := [P1 with delta 1 => 0.2, 2 => 0.3];
   --  Alternatively:
   --  P3 := [P1 with delta 1 .. 2 => 0.2, 0.3];

   Display (P3);
end Show_Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Delta_Aggregates.Delta_
 ↪Aggregates_Array
MD5: d32ba51746d7db9cd30f183e64ab0017
```

Runtime output

```
( 1 =>  5.00000E-01 2 =>  7.00000E-01 3 =>  3.00000E-01)
( 1 =>  1.00000E+00 2 =>  7.00000E-01 3 =>  3.00000E-01)
( 1 =>  2.00000E-01 2 =>  3.00000E-01 3 =>  3.00000E-01)
```

The implementation of Show_Points in this example is very similar to the version where use a record type. In this case, we:

- assign P1 to P2, but change the first component, and
- we assign P1 to P3, but change the first and second components.

Using slices

In the assignment to P3, we can either specify each component of the delta individually or use a slice: both forms are equivalent. Also, we can use slices to assign the same number to multiple components:

Listing 333: show_points.adb

```
pragma Ada_2022;

with Points; use Points;

procedure Show_Points is
   P1, P3 : Point_3D;
begin
   P1 := [0.5, 0.7, 0.3];
   Display (P1);

   P3 := [P1 with delta
            P3'First + 1 .. P3'Last => 0.0];
   Display (P3);
end Show_Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Delta_Aggregates.Delta_
 ↪Aggregates_Array
MD5: 6d1db1634c42a885f7bfce7f7eecc359
```

Runtime output

```
( 1 =>  5.00000E-01 2 =>  7.00000E-01 3 =>  3.00000E-01)
( 1 =>  5.00000E-01 2 =>  0.00000E+00 3 =>  0.00000E+00)
```

In this example, we're assigning P1 to P3, but resetting all components of the array starting by the second one.

Multiple components

We can also assign multiple components or slices:

Listing 334: float_arrays.ads

```
package Float_Arrays is

   type Float_Array is
     array (Positive range <>) of Float;

   procedure Display (P : Float_Array);

end Float_Arrays;
```

Listing 335: float_arrays.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Float_Arrays is

   procedure Display (P : Float_Array) is
```

(continues on next page)

(continued from previous page)

```
   begin

      Put ("(");
      for I in P'Range loop
         Put (I'Image
              & " => "
              & P (I)'Image);
      end loop;
      Put_Line (")");

   end Display;

end Float_Arrays;
```

Listing 336: show_multiple_delta_slices.adb

```
pragma Ada_2022;

with Float_Arrays; use Float_Arrays;

procedure Show_Multiple_Delta_Slices is

   P1, P2 : Float_Array (1 .. 5);

begin
   P1 := [1.0, 2.0, 3.0, 4.0, 5.0];
   Display (P1);

   P2 := [P1 with delta
            P2'First + 1 .. P2'Last - 2 => 0.0,
            P2'Last - 1  .. P2'Last => 0.2];
   Display (P2);
end Show_Multiple_Delta_Slices;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Aggregates.Delta_Aggregates.Delta_
 ↪Aggregates_Array

```

Runtime output

```
( 1 =>  1.00000E+00 2 =>  2.00000E+00 3 =>  3.00000E+00 4 =>  4.00000E+00 5 =>  5.
 ↪00000E+00)
( 1 =>  1.00000E+00 2 =>  0.00000E+00 3 =>  0.00000E+00 4 =>  2.00000E-01 5 =>  2.
 ↪00000E-01)
```

In this example, we have two arrays P1 and P2 of `Float_Array` type. We assign P1 to P2, but change:

- the second to the last-but-two components to 0.0, and
- the last-but-one and last components to 0.2.

- Delta Aggregates[76]

[76] http://www.ada-auth.org/standards/22rm/html/RM-4-3-4.html

25.5 Arrays

25.5.1 Unconstrained Arrays

In the *Introduction to Ada course* (page 78), we've seen that we can declare array types whose bounds are not fixed: in that case, the bounds are provided when creating objects of those types. For example:

Listing 337: measurement_defs.ads

```
package Measurement_Defs is

   type Measurements is
     array (Positive range <>) of Float;
   --       ^ Bounds are of type Positive,
   --         but not known at this point.

end Measurement_Defs;
```

Listing 338: show_measurements.adb

```
with Ada.Text_IO;      use Ada.Text_IO;

with Measurement_Defs; use Measurement_Defs;

procedure Show_Measurements is
   M : Measurements (1 .. 10);
   --                ^ Providing bounds here!
begin
   Put_Line ("First index: " & M'First'Image);
   Put_Line ("Last index:  " & M'Last'Image);
end Show_Measurements;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Arrays.Unconstrained_Arrays.Unconstrained_
 ↪Array_Example
MD5: a5cdc74dd61e36476431cf675452d1d5
```

Build output

```
show_measurements.adb:6:04: warning: variable "M" is read but never assigned [-
 ↪gnatwv]
```

Runtime output

```
First index:  1
Last index:   10
```

In this example, the `Measurements` array type from the `Measurement_Defs` package is unconstrained. In the `Show_Measurements` procedure, we declare a constrained object (`M`) of this type.

The *Introduction to Ada course* (page 79) also highlights the fact that the bounds are fixed once an object is declared:

> Although different instances of the same unconstrained array type can have different bounds, a specific instance has the same bounds throughout its lifetime. This allows Ada to implement unconstrained arrays efficiently; instances can be stored on the stack and do not require heap allocation as in languages like Java.

In the Show_Measurements procedure above, once we declare M, its bounds are fixed for the whole lifetime of M. We cannot *add* another component to this array. In other words, M will have 10 components for its whole lifetime.

In the Ada Reference Manual

- 3.6 Array Types[77]

Unconstrained Arrays vs. Vectors

If you need, however, the flexibility of increasing the length of an array, you could use vectors instead. This is how we could rewrite the previous example using vectors:

Listing 339: measurement_defs.ads

```
with Ada.Containers; use Ada.Containers;
with Ada.Containers.Vectors;

package Measurement_Defs is

   package Vectors is new Ada.Containers.Vectors
     (Index_Type   => Positive,
      Element_Type => Float);

   subtype Measurements is Vectors.Vector;

end Measurement_Defs;
```

Listing 340: show_measurements.adb

```
with Ada.Text_IO;      use Ada.Text_IO;

with Measurement_Defs; use Measurement_Defs;

procedure Show_Measurements is
   use Measurement_Defs.Vectors;

   M : Measurements := To_Vector (10);
   --                  ^ Creating 10-element
   --                    vector.
begin
   Put_Line ("First index: "
             & M.First_Index'Image);
   Put_Line ("Last index:  "
             & M.Last_Index'Image);

   Put_Line ("Adding element...");
   M.Append (1.0);

   Put_Line ("First index: "
             & M.First_Index'Image);
   Put_Line ("Last index:  "
             & M.Last_Index'Image);
end Show_Measurements;
```

Code block metadata

[77] http://www.ada-auth.org/standards/22rm/html/RM-3-6.html

```
Project: Courses.Advanced_Ada.Data_Types.Arrays.Unconstrained_Arrays.Unconstrained_
↪Array_Example
MD5: afec7a4b898392be4dd1f60e1519da88
```

Runtime output

```
First index:  1
Last index:   10
Adding element...
First index:  1
Last index:   11
```

In the declaration of `M` in this example, we're creating a 10-element vector by calling `To_Vector` and specifying the element count. Later on, with the call to `Append`, we're increasing the length of the `M` to 11 elements.

As you might expect, the flexibility of vectors comes with a price: every time we add an element that doesn't fit in the current capacity of the vector, the container has to reallocate memory in the background due to that new element. Therefore, arrays are more efficient, as the memory allocation only happens once for each object.

In the Ada Reference Manual

- 3.6 Array Types[78]
- A.18.2 The Generic Package Containers.Vectors[79]

25.5.2 Multidimensional Arrays

So far, we've discussed unidimensional arrays, since they are very common in Ada. However, Ada also supports multidimensional arrays using the same facilities as for unidimensional arrays. For example, we can use the `First`, `Last`, **`Range`** and `Length` attributes for each dimension of a multidimensional array. This section presents more details on this topic.

To create a multidimensional array, we simply separate the ranges of each dimension with a comma. The following example presents the one-dimensional array `A1`, the two-dimensional array `A2` and the three-dimensional array `A3`:

Listing 341: multidimensional_arrays_decl.ads

```
1  package Multidimensional_Arrays_Decl is
2
3     A1 : array (1 .. 10) of Float;
4     A2 : array (1 .. 5, 1 .. 10) of Float;
5     --          ^ first dimension
6     --                ^ second dimension
7     A3 : array (1 .. 2, 1 .. 5, 1 .. 10) of Float;
8     --          ^ first dimension
9     --                ^ second dimension
10    --                      ^ third dimension
11 end Multidimensional_Arrays_Decl;
```

Code block metadata

[78] http://www.ada-auth.org/standards/22rm/html/RM-3-6.html
[79] http://www.ada-auth.org/standards/22rm/html/RM-A-18-2.html

```
Project: Courses.Advanced_Ada.Data_Types.Arrays.Multidimensional_Arrays.
 ↪Multidimensional_Arrays
MD5: 928243b293c67a078d729c3cac68bb92
```

The two-dimensional array A2 has 5 components in the first dimension and 10 components in the second dimension. The three-dimensional array A3 has 2 components in the first dimension, 5 components in the second dimension, and 10 components in the third dimension. Note that the ranges we've selected for A1, A2 and A3 are completely arbitrary. You may select ranges for each dimension that are the most appropriate in the context of your application. Also, the number of dimensions is not limited to three, so you could declare higher-dimensional arrays if needed.

We can use the `Length` attribute to retrieve the length of each dimension. We use an integer value in parentheses to specify which dimension we're referring to. For example, if we write `A'Length (2)`, we're referring to the length of the second dimension of a multidimensional array A. Note that `A'Length` is equivalent to `A'Length (1)`. The same equivalence applies to other array-related attributes such as `First`, `Last` and **`Range`**.

Let's use the `Length` attribute for the arrays we declared in the `Multidimensional_Arrays_Decl` package:

Listing 342: show_multidimensional_arrays.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  with Multidimensional_Arrays_Decl;
4  use Multidimensional_Arrays_Decl;
5
6  procedure Show_Multidimensional_Arrays is
7  begin
8     Put_Line ("A1'Length:     "
9               & A1'Length'Image);
10    Put_Line ("A1'Length (1): "
11              & A1'Length (1)'Image);
12    Put_Line ("A2'Length (1): "
13              & A2'Length (1)'Image);
14    Put_Line ("A2'Length (2): "
15              & A2'Length (2)'Image);
16    Put_Line ("A3'Length (1): "
17              & A3'Length (1)'Image);
18    Put_Line ("A3'Length (2): "
19              & A3'Length (2)'Image);
20    Put_Line ("A3'Length (3): "
21              & A3'Length (3)'Image);
22 end Show_Multidimensional_Arrays;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Arrays.Multidimensional_Arrays.
 ↪Multidimensional_Arrays
MD5: 70b9b8df7e46302b92613fa484ef71ca
```

Runtime output

```
A1'Length:      10
A1'Length (1):  10
A2'Length (1):  5
A2'Length (2):  10
A3'Length (1):  2
A3'Length (2):  5
A3'Length (3):  10
```

As this simple example shows, we can easily retrieve the length of each dimension. Also, as we've just mentioned, `A1'Length` is equal to `A1'Length (1)`.

Let's consider an application where we make hourly measurements for the first 12 hours of the day, on each day of the week. We can create a two-dimensional array type called `Measurements` to store this data. Also, we can have three procedures for this array:

- `Show_Indices`, which presents the indices (days and hours) of the two-dimensional array;
- `Show_Values`, which presents the values stored in the array; and
- `Reset`, which resets each value of the array.

This is the complete code for this application:

Listing 343: measurement_defs.ads

```
package Measurement_Defs is

   type Days is
     (Mon, Tue, Wed, Thu, Fri, Sat, Sun);

   type Hours is range 0 .. 11;

   subtype Measurement is Float;

   type Measurements is
     array (Days, Hours) of Measurement;

   procedure Show_Indices (M : Measurements);

   procedure Show_Values (M : Measurements);

   procedure Reset (M : out Measurements);

end Measurement_Defs;
```

Listing 344: measurement_defs.adb

```
with Ada.Text_IO;      use Ada.Text_IO;

package body Measurement_Defs is

   procedure Show_Indices (M : Measurements) is
   begin
      Put_Line ("---- Indices ----");

      for D in M'Range (1) loop
         Put (D'Image & " ");

         for H in M'First (2) ..
                  M'Last (2) - 1
         loop
            Put (H'Image & " ");
         end loop;
         Put_Line (M'Last (2)'Image);
      end loop;
   end Show_Indices;

   procedure Show_Values (M : Measurements) is
      package H_IO is
        new Ada.Text_IO.Integer_IO (Hours);
      package M_IO is
```

(continues on next page)

(continued from previous page)

```
        new Ada.Text_IO.Float_IO (Measurement);

        procedure Set_IO_Defaults is
        begin
           H_IO.Default_Width := 5;

           M_IO.Default_Fore  := 1;
           M_IO.Default_Aft   := 2;
           M_IO.Default_Exp   := 0;
        end Set_IO_Defaults;
   begin
      Set_IO_Defaults;

      Put_Line ("---- Values ----");
      Put ("   ");
      for H in M'Range (2) loop
         H_IO.Put (H);
      end loop;
      New_Line;

      for D in M'Range (1) loop
         Put (D'Image & " ");

         for H in M'Range (2) loop
            M_IO.Put (M (D, H));
            Put (" ");
         end loop;
         New_Line;
      end loop;
   end Show_Values;

   procedure Reset (M : out Measurements) is
   begin
      M := (others => (others => 0.0));
   end Reset;

end Measurement_Defs;
```

Listing 345: show_measurements.adb

```

```

We recommend that you spend some time analyzing this example. Also, we'd like to highlight the following aspects:

- We access a value from a multidimensional array by using commas to separate the index values within the parentheses. For example: `M (D, H)` allows us to access the value on day `D` and hour `H` from the multidimensional array `M`.
- To loop over the multidimensional array `M`, we write `for D in M'Range (1) loop` and `for H in M'Range (2) loop` for the first and second dimensions, respectively.
- To reset all values of the multidimensional array, we use an aggregate with this form: `(others => (others => 0.0))`.

In the Ada Reference Manual

- 3.6 Array Types[80]

Unconstrained Multidimensional Arrays

Previously, we've discussed unconstrained arrays for the unidimensional case. It's possible to declare unconstrained multidimensional arrays as well. For example:

Listing 346: multidimensional_arrays_decl.ads

```
1  package Multidimensional_Arrays_Decl is
2
3     type F1 is array (Positive range <>) of Float;
4     type F2 is array (Positive range <>,
5                       Positive range <>) of Float;
6     type F3 is array (Positive range <>,
7                       Positive range <>,
8                       Positive range <>) of Float;
9
10 end Multidimensional_Arrays_Decl;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Arrays.Multidimensional_Arrays.
 ↪Unconstrained_Multidimensional_Arrays
MD5: 8637e93db355fddafa3ffa5ce453a0e1
```

Here, we're declaring the one-dimensional type F1, the two-dimensional type F2 and the three-dimensional type F3.

[80] http://www.ada-auth.org/standards/22rm/html/RM-3-6.html

As is the case with unidimensional arrays, we must specify the bounds when declaring objects of unconstrained multidimensional array types:

Listing 347: show_multidimensional_arrays.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Multidimensional_Arrays_Decl;
use  Multidimensional_Arrays_Decl;

procedure Show_Multidimensional_Arrays is
   A1 : F1 (1 .. 2);
   A2 : F2 (1 .. 4, 10 .. 20);
   A3 : F3 (2 .. 3, 1 .. 5, 1 .. 2);
begin
   Put_Line ("A1'Length (1): "
             & A1'Length (1)'Image);
   Put_Line ("A2'Length (1): "
             & A2'Length (1)'Image);
   Put_Line ("A2'Length (2): "
             & A2'Length (2)'Image);
   Put_Line ("A3'Length (1): "
             & A3'Length (1)'Image);
   Put_Line ("A3'Length (2): "
             & A3'Length (2)'Image);
   Put_Line ("A3'Length (3): "
             & A3'Length (3)'Image);
end Show_Multidimensional_Arrays;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Arrays.Multidimensional_Arrays.
 ↪Unconstrained_Multidimensional_Arrays
MD5: 9fb007abbfe238345d80cb315bb834c9
```

Build output

```

```

Runtime output

```
A1'Length (1):  2
A2'Length (1):  4
A2'Length (2):  11
A3'Length (1):  2
A3'Length (2):  5
A3'Length (3):  2
```

Arrays of arrays

It's important to distinguish between multidimensional arrays and arrays of arrays. Both are supported in Ada, but they're very distinct from each other. We can create an array of an array by first specifying a one-dimensional array type T1, and then specifying another one-dimensional array type T2 where each component of T2 is of T1 type:

Listing 348: array_of_arrays_decl.ads

```
package Array_Of_Arrays_Decl is

   type T1 is
     array (Positive range <>) of Float;

   type T2 is
     array (Positive range <>) of T1 (1 .. 10);
   --                                 ^^^^^^^
   --                            bounds must be set!

end Array_Of_Arrays_Decl;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Arrays.Array_Of_Arrays.Array_Of_Arrays
MD5: fd67739bb21f202615180aa02f5284aa
```

Note that, in the declaration of T2, we must set the bounds for the T1 type. This is a major difference to multidimensional arrays, which allow for unconstrained ranges in multiple dimensions.

We can rewrite the previous application for measurements using arrays of arrays. This is the adapted code:

Listing 349: measurement_defs.ads

```
package Measurement_Defs is

   type Days is
     (Mon, Tue, Wed, Thu, Fri, Sat, Sun);

   type Hours is range 0 .. 11;

   subtype Measurement is Float;

   type Hourly_Measurements is
     array (Hours) of Measurement;

   type Measurements is
     array (Days) of Hourly_Measurements;

   procedure Show_Indices (M : Measurements);

   procedure Show_Values (M : Measurements);

   procedure Reset (M : out Measurements);

end Measurement_Defs;
```

Listing 350: measurement_defs.adb

```
with Ada.Text_IO;      use Ada.Text_IO;

```

(continues on next page)

(continued from previous page)

```
package body Measurement_Defs is

   procedure Show_Indices (M : Measurements) is
   begin
      Put_Line ("---- Indices ----");

      for D in M'Range loop
         Put (D'Image & " ");

         for H in M (D)'First ..
                  M (D)'Last - 1
         loop
            Put (H'Image & " ");
         end loop;
         Put_Line (M (D)'Last'Image);
      end loop;
   end Show_Indices;

   procedure Show_Values (M : Measurements) is
      package H_IO is
        new Ada.Text_IO.Integer_IO (Hours);
      package M_IO is
        new Ada.Text_IO.Float_IO (Measurement);

        procedure Set_IO_Defaults is
        begin
           H_IO.Default_Width := 5;

           M_IO.Default_Fore  := 1;
           M_IO.Default_Aft   := 2;
           M_IO.Default_Exp   := 0;
        end Set_IO_Defaults;
   begin
      Set_IO_Defaults;

      Put_Line ("---- Values ----");
      Put ("   ");
      for H in M (M'First)'Range loop
         H_IO.Put (H);
      end loop;
      New_Line;

      for D in M'Range loop
         Put (D'Image & " ");

         for H in M (D)'Range loop
            M_IO.Put (M (D) (H));
            Put (" ");
         end loop;
         New_Line;
      end loop;
   end Show_Values;

   procedure Reset (M : out Measurements) is
   begin
      M := (others => (others => 0.0));
   end Reset;

end Measurement_Defs;
```

Listing 351: show_measurements.adb

```
with Measurement_Defs; use Measurement_Defs;

procedure Show_Measurements is
   M : Measurements;
begin
   Reset (M);
   Show_Indices (M);
   Show_Values (M);
end Show_Measurements;

```

Again, we recommend that you spend some time analyzing this example and comparing it to the previous version that uses multidimensional arrays. Also, we'd like to highlight the following aspects:

- We access a value from an array of arrays by specifying the index of each array separately. For example: `M (D) (H)` allows us to access the value on day `D` and hour `H` from the array of arrays `M`.
- To loop over an array of arrays `M`, we write `for D in M'Range loop` for the first level of `M` and `for H in M (D)'Range loop` for the second level of `M`.
- Resetting all values of an array of arrays is very similar to how we do it for multidimensional arrays. In fact, we can still use an aggregate with this form: `(others => (others => 0.0))`.

25.6 Strings

25.6.1 Wide and Wide-Wide Strings

We've seen many source-code examples so far that includes strings. In most of them, we were using the standard string type: `String`. This type is useful for the common use-case of displaying messages or dealing with information in plain English. Here, we define "plain English" as the use of the language that avoids French accents or German umlaut, for example, and doesn't make use of any characters in non-Latin alphabets.

There are two additional string types in Ada: `Wide_String`, and `Wide_Wide_String`. These types are particularly important when dealing with textual information in non-standard English, or in various other languages, non-Latin alphabets and special symbols.

These string types use different bit widths for their characters. This becomes more apparent when looking at the type definitions:

```
type String is
  array (Positive range <>) of Character;

type Wide_String is
  array (Positive range <>) of Wide_Character;

type Wide_Wide_String is
  array (Positive range <>) of
    Wide_Wide_Character;
```

The following table shows the typical bit-width of each character of the string types:

Character Type	Width
`Character`	8 bits
`Wide_Character`	16 bits
`Wide_Wide_Character`	32 bits

We can see that when running this example:

Listing 352: show_wide_char_types.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Wide_Char_Types is
begin
   Put_Line ("Character'Size:           "
             & Integer'Image
                 (Character'Size));
   Put_Line ("Wide_Character'Size:      "
             & Integer'Image
                 (Wide_Character'Size));
   Put_Line ("Wide_Wide_Character'Size: "
             & Integer'Image
                 (Wide_Wide_Character'Size));
end Show_Wide_Char_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Wide_Wide-Wide_Strings.Wide_Char_
 ↪Types
MD5: a0e9fb9e8d43e9fa707dc8c57f7562f8
```

Runtime output

```
Character'Size:           8
Wide_Character'Size:      16
Wide_Wide_Character'Size: 32
```

Let's look at another example, this time using wide strings:

Listing 353: show_wide_string_types.adb

```
with Ada.Text_IO;
with Ada.Wide_Text_IO;
with Ada.Wide_Wide_Text_IO;

procedure Show_Wide_String_Types is
   package TI   renames Ada.Text_IO;
   package WTI  renames Ada.Wide_Text_IO;
   package WWTI renames Ada.Wide_Wide_Text_IO;

   S   : constant String           := "hello";
   WS  : constant Wide_String      := "hello";
   WWS : constant Wide_Wide_String := "hello";
begin
   TI.Put_Line ("String:           " & S);
   TI.Put_Line ("Length:           "
                & Integer'Image (S'Length));
   TI.Put_Line ("Size:             "
                & Integer'Image (S'Size));
   TI.Put_Line ("Component_Size:   "
                & Integer'Image
                   (S'Component_Size));
   TI.Put_Line ("------------------------");

   WTI.Put_Line ("Wide string:      " & WS);
   TI.Put_Line ("Length:           "
                & Integer'Image (WS'Length));
   TI.Put_Line ("Size:             "
                & Integer'Image (WS'Size));
   TI.Put_Line ("Component_Size:   "
                & Integer'Image
                   (WS'Component_Size));
   TI.Put_Line ("------------------------");

   WWTI.Put_Line ("Wide-wide string: " & WWS);
   TI.Put_Line ("Length:           "
                & Integer'Image (WWS'Length));
   TI.Put_Line ("Size:             "
                & Integer'Image (WWS'Size));
   TI.Put_Line ("Component_Size:   "
                & Integer'Image
                   (WWS'Component_Size));
   TI.Put_Line ("------------------------");
end Show_Wide_String_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Wide_Wide-Wide_Strings.Wide_
 ↪String_Types
MD5: 137816c6fd78add34287a72e45cf4fb7
```

Runtime output

```
String:           hello
Length:            5
Size:              40
Component_Size:    8
------------------------
Wide string:      hello
Length:            5
Size:              80
Component_Size:    16
------------------------
Wide-wide string: hello
Length:            5
Size:              160
Component_Size:    32
------------------------
```

Here, all strings (`S`, `WS` and `WWS`) have the same length of 5 characters. However, the size of each character is different — thus, each string has a different overall size.

The recommendation is to use the **`String`** type when the textual information you're processing is in standard English. In case any kind of internationalization is needed, using `Wide_Wide_String` is probably the best choice, as it covers all possible use-cases.

In the Ada Reference Manual

- 3.6.3 String Types[81]

Text I/O

Note that, in the previous example, we were using different versions of the `Ada.Text_IO` package depending on the string type we were using:

- `Ada.Text_IO` for objects of **`String`** type,
- `Ada.Wide_Text_IO` for objects of **`Wide_String`** type,
- `Ada.Wide_Wide_Text_IO` for objects of `Wide_Wide_String` type.

In that example, we were also using package renaming to differentiate among those packages.

Similarly, there are different versions of text I/O packages for individual types. For example, if we want to display the value of a **`Long_Integer`** variable based on the `Wide_Wide_String` type, we can select the `Ada.Long_Integer_Wide_Wide_Text_IO` package. In fact, the list of packages resulting from the combination of those types is quite long:

[81] http://www.ada-auth.org/standards/22rm/html/RM-3-6-3.html

Scalar Type	Text I/O Packages
Integer	• Ada.Integer_Text_IO • Ada.Integer_Wide_Text_IO • Ada.Integer_Wide_Wide_Text_IO
Long_Integer	• Ada.Long_Integer_Text_IO • Ada.Long_Integer_Wide_Text_IO • Ada.Long_Integer_Wide_Wide_Text_IO
Long_Long_Integer	• Ada.Long_Long_Integer_Text_IO • Ada.Long_Long_Integer_Wide_Text_IO • Ada.Long_Long_Integer_Wide_Wide_Text_IO
Float	• Ada.Float_Text_IO • Ada.Float_Wide_Text_IO • Ada.Float_Wide_Wide_Text_IO
Long_Float	• Ada.Long_Float_Text_IO • Ada.Long_Float_Wide_Text_IO • Ada.Long_Float_Wide_Wide_Text_IO
Long_Long_Float	• Ada.Long_Long_Float_Text_IO • Ada.Long_Long_Float_Wide_Text_IO • Ada.Long_Long_Float_Wide_Wide_Text_IO

Also, there are different versions of the generic packages `Integer_IO` and `Float_IO`:

Scalar Type	Text I/O Packages
Integer types	• Ada.Text_IO.Integer_IO • Ada.Wide_Text_IO.Integer_IO • Ada.Wide_Wide_Text_IO. Integer_IO
Real types	• Ada.Text_IO.Float_IO • Ada.Wide_Text_IO.Float_IO • Ada.Wide_Wide_Text_IO.Float_IO

In the Ada Reference Manual

- A.10 Text Input-Output[82]
- A.10.1 The Package Text_IO[83]

[82] http://www.ada-auth.org/standards/22rm/html/RM-A-10.html

- A.10.9 Input-Output for Real Types[85]
- A.11 Wide Text Input-Output and Wide Wide Text Input-Output[86]

Wide and Wide-Wide String Handling

As we've just seen, we have different versions of the `Ada.Text_IO` package. The same applies to string handling packages. As we've seen in the *Introduction to Ada course* (page 239), we can use the `Ada.Strings.Fixed` and `Ada.Strings.Maps` packages for string handling. For other formats, we have these packages:

- `Ada.Strings.Wide_Fixed`,
- `Ada.Strings.Wide_Wide_Fixed`,
- `Ada.Strings.Wide_Maps`,
- `Ada.Strings.Wide_Wide_Maps`.

Let's look at *this example* (page 240) from the Introduction to Ada course, which we adapted for wide-wide strings:

Listing 354: show_find_words.adb

```
with Ada.Strings; use Ada.Strings;

with Ada.Strings.Wide_Wide_Fixed;
use  Ada.Strings.Wide_Wide_Fixed;

with Ada.Strings.Wide_Wide_Maps;
use  Ada.Strings.Wide_Wide_Maps;

with Ada.Wide_Wide_Text_IO;
use  Ada.Wide_Wide_Text_IO;

procedure Show_Find_Words is

   S   : constant Wide_Wide_String :=
           "Hello" & 3 * " World";
   F   : Positive;
   L   : Natural;
   I   : Natural := 1;

   Whitespace : constant
     Wide_Wide_Character_Set :=
       To_Set (' ');
begin
   Put_Line ("String: " & S);
   Put_Line ("String length: "
             & Integer'Wide_Wide_Image
                 (S'Length));

   while I in S'Range loop
      Find_Token
        (Source  => S,
         Set     => Whitespace,
```

(continues on next page)

[84] http://www.ada-auth.org/standards/22rm/html/RM-A-10-8.html
[85] http://www.ada-auth.org/standards/22rm/html/RM-A-10-9.html
[86] http://www.ada-auth.org/standards/22rm/html/RM-A-11.html

(continued from previous page)

```
33          From    => I,
34          Test    => Outside,
35          First   => F,
36          Last    => L);
37
38       exit when L = 0;
39
40       Put_Line ("Found word instance at position "
41                 & F'Wide_Wide_Image
42                 & ": '" & S (F .. L) & "'");
43
44       I := L + 1;
45    end loop;
46
47 end Show_Find_Words;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Wide_Wide-Wide_Strings.Wide_Wide_
 ↪String_Handling
MD5: 3b5a4d61e6dc5bd16e85f85580ad82ae
```

Runtime output

```
String: Hello World World World
String length:  23
Found word instance at position  1: 'Hello'
Found word instance at position  7: 'World'
Found word instance at position  13: 'World'
Found word instance at position  19: 'World'
```

In this example, we're using the `Find_Token` procedure to find the words from the phrase stored in the `S` constant. All the operations we're using here are similar to the ones for **`String`** type, but making use of the `Wide_Wide_String` type instead. (We talk about the `Wide_Wide_Image` attribute *later on* (page 514).)

In the Ada Reference Manual

- A.4.6 String-Handling Sets and Mappings[87]
- A.4.7 Wide_String Handling[88]
- A.4.8 Wide_Wide_String Handling[89]

Bounded and Unbounded Wide and Wide-Wide Strings

We've seen in the Introduction to Ada course that other kinds of **`String`** types are available. For example, we can use *bounded* (page 244) and *unbounded strings* (page 246) — those correspond to the `Bounded_String` and `Unbounded_String` types.

Those kinds of string types are available for **`Wide_String`**, and `Wide_Wide_String`. The following table shows the available types and corresponding packages:

[87] http://www.ada-auth.org/standards/22rm/html/RM-A-4-6.html
[88] http://www.ada-auth.org/standards/22rm/html/RM-A-4-7.html
[89] http://www.ada-auth.org/standards/22rm/html/RM-A-4-8.html

Type	Package
Bounded_Wide_String	Ada.Strings.Wide_Bounded
Bounded_Wide_Wide_String	Ada.Strings.Wide_Wide_Bounded
Unbounded_Wide_String	Ada.Strings.Wide_Unbounded
Unbounded_Wide_Wide_String	Ada.Strings.Wide_Wide_Unbounded

The same applies to text I/O for those strings. For the standard case, we have Ada.Text_IO.Bounded_IO for the Bounded_String type and Ada.Text_IO.Unbounded_IO for the Unbounded_String type.

For wider string types, we have:

Type	Text I/O Package
Bounded_Wide_String	Ada.Wide_Text_IO.Wide_Bounded_IO
Bounded_Wide_Wide_String	Ada.Wide_Wide_Text_IO.Wide_Wide_Bounded_IO
Unbounded_Wide_String	Ada.Wide_Text_IO.Wide_Unbounded_IO
Unbounded_Wide_Wide_String	Ada.Wide_Wide_Text_IO.Wide_Wide_Unbounded_IO

Let's look at a simple example:

Listing 355: show_unbounded_wide_wide_string.adb

```
with Ada.Strings.Wide_Wide_Unbounded;
use  Ada.Strings.Wide_Wide_Unbounded;

with Ada.Wide_Wide_Text_IO.Wide_Wide_Unbounded_IO;
use  Ada.Wide_Wide_Text_IO.Wide_Wide_Unbounded_IO;

procedure Show_Unbounded_Wide_Wide_String is
   S : Unbounded_Wide_Wide_String
     := To_Unbounded_Wide_Wide_String ("Hello");
begin
   S := S & Wide_Wide_String'(" hello");
   Put_Line ("Unbounded wide-wide string: " & S);
end Show_Unbounded_Wide_Wide_String;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Wide_Wide-Wide_Strings.Unbounded_
 ↪Wide_Wide_String
MD5: 0d369270e2408b3f1cc8284c13fca806
```

Runtime output

```
Unbounded wide-wide string: Hello hello
```

In this example, we're declaring a variable S and initializing it with the word "Hello." Then, we're concatenating it with " hello" and displaying it. All the operations we're using here are similar to the ones for Unbounded_String type, but they've been adapted for the Unbounded_Wide_Wide_String type.

In the Ada Reference Manual

- A.4.7 Wide_String Handling[90]

[90] http://www.ada-auth.org/standards/22rm/html/RM-A-4-7.html

- A.4.8 Wide_Wide_String Handling[91]
- A.11 Wide Text Input-Output and Wide Wide Text Input-Output[92]

25.6.2 String Encoding

Unicode is one of the most widespread standards for encoding writing systems other than the Latin alphabet. It defines a format called Unicode Transformation Format (UTF)[93] in various versions, which vary according to the underlying precision, support for backwards-compatibility and other requirements.

In the Ada Reference Manual

- A.4.11 String Encoding[94]

UTF-8 encoding and decoding

A common UTF format is UTF-8, which encodes strings using up to four (8-bit) bytes and is backwards-compatible with the ASCII format. While encoding of ASCII characters requires only one byte, Chinese characters require three bytes, for example.

In Ada applications, UTF-8 strings are indicated by using the `UTF_8_String` from the `Ada.Strings.UTF_Encoding` package. In order to encode from and to UTF-8 strings, we can use the `Encode` and `Decode` functions. Those functions are specified in the child packages of the *Ada.Strings.UTF_Encoding* package. We select the appropriate child package depending on the string type we're using, as you can see in the following table:

Child Package of `Ada.Strings.UTF_Encoding`	Convert from / to
`.Strings`	`String` type
`.Wide_Strings`	`Wide_String` type
`.Wide_Wide_Strings`	`Wide_Wide_String` type

Let's look at an example:

Listing 356: show_ww_utf_string.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  with Ada.Strings.UTF_Encoding;
4  use  Ada.Strings.UTF_Encoding;
5
6  with Ada.Strings.UTF_Encoding.Wide_Wide_Strings;
7  use  Ada.Strings.UTF_Encoding.Wide_Wide_Strings;
8
9  with Ada.Strings.Wide_Wide_Unbounded;
10 use  Ada.Strings.Wide_Wide_Unbounded;
11
12 procedure Show_WW_UTF_String is
13
14    function To_UWWS
```

```

(continues on next page)

(continued from previous page)

```
UTF-8 String Length:  37
UTF-8 String Size:    296
```

In this application, we start by storing a string in Arabic in the `Hello_World_Arabic` constant. We then use the `Decode` function to convert that string from `UTF_8_String` type to `Wide_Wide_String` type — we store it in the `WWS_Hello_World_Arabic` constant.

We use a variable of type `Unbounded_Wide_Wide_String` (`UWWS`) to manipulate strings: we append the string in Arabic to the "Hello World: " string and store it in `UWWS`.

In the `Show_WW_String` block, we convert the string — stored in `UWWS` — from the `Unbounded_Wide_Wide_String` type to the `Wide_Wide_String` type and display the length and size of the string. We do something similar in the `Show_UTF_8_String` block, but there, we convert to the `UTF_8_String` type.

Also, in the `Show_UTF_8_String` block, we use the `Encode` function to convert that string from `Wide_Wide_String` type to then `UTF_8_String` type — we store it in the `S_UTF_8` constant.

UTF-8 size and length

As you can see when running the last code example from the previous subsection, we have different sizes and lengths depending on the string type:

String type	Size	Length
`Wide_Wide_String`	832	26
`UTF_8_String`	296	37

The size needed for storing the string when using the `Wide_Wide_String` type is bigger than the one when using the `UTF_8_String` type. This is expected, as the `Wide_Wide_String` uses 32-bit characters, while the `UTF_8_String` type uses 8-bit codes to store the string in a more efficient way (memory-wise).

The length of the string using the `Wide_Wide_String` type is equivalent to the number of symbols we have in the original string: 26 characters / symbols. When using UTF-8, however, we may need more 8-bit codes to represent one symbol from the original string, so we may end up with a length value that is bigger than the actual number of symbols from the original string — as it is the case in this source-code example.

This difference in sizes might not always be the case. In fact, the sizes match when encoding a symbol in UTF-8 that requires four 8-bit codes. For example:

Listing 357: show_utf_8.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  with Ada.Strings.UTF_Encoding;
4  use  Ada.Strings.UTF_Encoding;
5
6  with Ada.Strings.UTF_Encoding.Wide_Wide_Strings;
7  use  Ada.Strings.UTF_Encoding.Wide_Wide_Strings;
8
9  procedure Show_UTF_8 is
10
11    Symbol_UTF_8 : constant UTF_8_String := "x";
12    Symbol_WWS   : constant Wide_Wide_String :=
13                      Decode (Symbol_UTF_8);
```

(continues on next page)

(continued from previous page)

```
14
15 begin
16    Put_Line ("Wide_Wide_String Length: "
17              & Symbol_WWS'Length'Image);
18    Put_Line ("Wide_Wide_String Size:   "
19              & Symbol_WWS'Size'Image);
20    Put_Line ("UTF-8 String Length:     "
21              & Symbol_UTF_8'Length'Image);
22    Put_Line ("UTF-8 String Size:       "
23              & Symbol_UTF_8'Size'Image);
24    New_Line;
25    Put_Line ("UTF-8 String:            "
26              & Symbol_UTF_8);
27 end Show_UTF_8;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.String_Encoding.UTF_8
MD5: 67653dfd377f04b32421cf09b25939fe
```

Runtime output

```
Wide_Wide_String Length:  1
Wide_Wide_String Size:    32
UTF-8 String Length:      4
UTF-8 String Size:        32

UTF-8 String:            x
```

In this case, both strings — using the `Wide_Wide_String` type or the `UTF_8_String` type — have the same size: 32 bits. (Here, we're using the x symbol from the Mathematical Alphanumeric Symbols block[95], not the standard "x" from the Basic Latin block[96].)

UTF-8 encoding in source-code files

In the past, it was common to use different character sets in text files when writing in different (human) languages. By default, Ada source-code files are expected to use the Latin-1 coding, which is a 8-bit character set.

Nowadays, however, using UTF-8 coding for text files — including source-code files — is very common. If your Ada code only uses standard ASCII characters, but you're saving it in a UTF-8 coded file, there's no need to worry about character sets, as UTF-8 is backwards compatible with ASCII.

However, you might want to use Unicode symbols in your Ada source code to declare constants — as we did in the previous sections — and store the source code in a UTF-8 coded file. In this case, you need be careful about how this file is parsed by the compiler.

Let's look at this source-code example:

Listing 358: show_utf_8_strings.adb

```
1 with Ada.Text_IO; use Ada.Text_IO;
2
3 with Ada.Strings.UTF_Encoding;
4 use  Ada.Strings.UTF_Encoding;
5
```

(continues on next page)

[95] https://en.wikipedia.org/wiki/Mathematical_Alphanumeric_Symbols
[96] https://en.wikipedia.org/wiki/Basic_Latin_(Unicode_block)

(continued from previous page)

```
procedure Show_UTF_8_Strings is

    Symbols_UTF_8 : constant
      UTF_8_String := "♥♫";

begin
    Put_Line ("UTF_8_String: "
              & Symbols_UTF_8);

    Put_Line ("Length:       "
              & Symbols_UTF_8'Length'Image);

end Show_UTF_8_Strings;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.String_Encoding.UTF_8_Strings
MD5: fd1aaff161a33365d15adca5bea7b277
```

Runtime output

```
UTF_8_String: ♥♫
Length:        6
```

Here, we're using Unicode symbols to initialize the `Symbols_UTF_8` constant of `UTF_8_String` type.

Now, let's assume this source-code example is stored in a UTF-8 coded file. Because the `"♥♫"` string makes use of non-ASCII Unicode symbols, representing this string in UTF-8 format will require more than 2 bytes. In fact, each one of those Unicode symbols requires 2 bytes to be encoded in UTF-8. (Keep in mind that Unicode symbols may require between 1 to 4 bytes[97] to be encoded in UTF-8 format.) Also, in this case, the UTF-8 encoding process is using two additional bytes. Therefore, the total length of the string is six, which matches what we see when running the `Show_UTF_8_Strings` procedure. In other words, the length of the `Symbols_UTF_8` string doesn't refer to those two characters (`"♥♫"`) that we were using in the constant declaration, but the length of the encoded bytes in its UTF-8 representation.

The UTF-8 format is very useful for storing and transmitting texts. However, if we want to process Unicode symbols, it's probably better to use string types with 32-bit characters — such as `Wide_Wide_String`. For example, let's say we want to use the `"♥♫"` string again to initialize a constant of `Wide_Wide_String` type:

Listing 359: show_wws_strings.adb

```
with Ada.Text_IO;
with Ada.Wide_Wide_Text_IO;

procedure Show_WWS_Strings is

   package TIO   renames Ada.Text_IO;
   package WWTIO renames Ada.Wide_Wide_Text_IO;

   Symbols_WWS : constant
     Wide_Wide_String := "♥♫";

begin
   WWTIO.Put_Line ("Wide_Wide_String: "
                   & Symbols_WWS);
```

(continues on next page)

[97] https://en.wikipedia.org/wiki/UTF-8

(continued from previous page)

```
15
16    TIO.Put_Line ("Length:           "
17                  & Symbols_WWS'Length'Image);
18
19 end Show_WWS_Strings;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.String_Encoding.WWS_Strings_W8
MD5: 1e5e38e62b412de48d3fa4271bb48bf1
```

Runtime output

```
Wide_Wide_String: ♥♫
Length:            2
```

In this case, as mentioned above, if we store this source code in a text file using UTF-8 format, we need to ensure that the UTF-8 coded symbols are correctly interpreted by the compiler when it parses the text file. Otherwise, we might get unexpected behavior. (Interpreting the characters in UTF-8 format as Latin-1 format is certainly an example of what we want to avoid here.)

In the GNAT toolchain

You can use UTF-8 coding in your source-code file and initialize strings of 32-bit characters. However, as we just mentioned, you need to make sure that the UTF-8 coded symbols are correctly interpreted by the compiler when dealing with types such as `Wide_Wide_String`. For this case, GNAT offers the `-gnatW8` switch. Let's run the previous example using this switch:

Listing 360: show_wws_strings.adb

```
1  with Ada.Text_IO;
2  with Ada.Wide_Wide_Text_IO;
3
4  procedure Show_WWS_Strings is
5
6     package TIO   renames Ada.Text_IO;
7     package WWTIO renames Ada.Wide_Wide_Text_IO;
8
9     Symbols_WWS : constant
10      Wide_Wide_String := "♥♫";
11
12 begin
13    WWTIO.Put_Line ("Wide_Wide_String: "
14                    & Symbols_WWS);
15
16    TIO.Put_Line ("Length:           "
17                  & Symbols_WWS'Length'Image);
18
19 end Show_WWS_Strings;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.String_Encoding.WWS_Strings_W8
MD5: 1e5e38e62b412de48d3fa4271bb48bf1
```

Runtime output

```
Wide_Wide_String: ♥♫
Length:            2
```

Because the Wide_Wide_String type has 32-bit characters. we expect the length of the string to match the number of symbols that we're using. Indeed, when running the Show_WWS_Strings procedure, we see that the Symbols_WWS string has a length of two characters, which matches the number of characters of the "♥♫" string.

When we use the -gnatW8 switch, GNAT converts the UTF-8-coded string ("♥♫") to UTF-32 format, so we get two 32-bit characters. It then uses the UTF-32-coded string to initialize the Symbols_WWS string.

If we don't use the -gnatW8 switch, however, we get wrong results. Let's look at the same example again without the switch:

Listing 361: show_wws_strings.adb

```
with Ada.Text_IO;
with Ada.Wide_Wide_Text_IO;

procedure Show_WWS_Strings is

   package TIO   renames Ada.Text_IO;
   package WWTIO renames Ada.Wide_Wide_Text_IO;

   Symbols_WWS : constant
     Wide_Wide_String := "♥♫";

begin
   WWTIO.Put_Line ("Wide_Wide_String: "
                   & Symbols_WWS);

   TIO.Put_Line ("Length:           "
                 & Symbols_WWS'Length'Image);

end Show_WWS_Strings;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.String_Encoding.WWS_Strings_No_W8
MD5: 1e5e38e62b412de48d3fa4271bb48bf1
```

Runtime output

```
Wide_Wide_String: ♥♫
Length:            6
```

Now, the "♥♫" string is being interpreted as a string of six 8-bit characters. (In other words, the UTF-8-coded string isn't converted to the UTF-32 format.) Each of those 8-bit characters is then stored in a 32-bit character of the Wide_Wide_String type. This explains why the Show_WWS_Strings procedure reports a length of 6 components for the Symbols_WWS string.

Portability of UTF-8 in source-code files

In a previous code example, we were assuming that the format that we use for the source-code file is UTF-8. This allows us to simply use Unicode symbols directly in strings:

```
Symbol_UTF_8 : constant UTF_8_String := "★";
```

This approach, however, might not be portable. For example, if the compiler uses a different string encoding for source-code files, it might interpret that Unicode character as something else — or just throw a compilation error.

If you're afraid that format mismatches might happen in your compilation environment, you may want to write strings in your code in a completely portable fashion, which consists in entering the exact sequence of codes in bytes — using the `Character'Val` function — for the symbols you want to use.

We can reuse parts of the previous example and replace the UTF-8 character with the corresponding UTF-8 code:

Listing 362: show_utf_8.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Ada.Strings.UTF_Encoding;
use  Ada.Strings.UTF_Encoding;

procedure Show_UTF_8 is

   Symbol_UTF_8 : constant
     UTF_8_String :=
       Character'Val (16#e2#)
       & Character'Val (16#98#)
       & Character'Val (16#85#);

begin
   Put_Line ("UTF-8 String: "
             & Symbol_UTF_8);
end Show_UTF_8;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.String_Encoding.UTF_8
MD5: 8ff02bc1793c0c5ac1ff24f62941af73
```

Runtime output

```
UTF-8 String: ★
```

Here, we use a sequence of three calls to the `Character'Val(code)` function for the UTF-8 code that corresponds to the "★" symbol.

UTF-16 encoding and decoding

So far, we've discussed the UTF-8 encoding scheme. However, other encoding schemes exist and are supported as well. In fact, the `Ada.Strings.UTF_Encoding` package defines three encoding schemes:

```
type Encoding_Scheme is (UTF_8,
                         UTF_16BE,
                         UTF_16LE);
```

For example, instead of using UTF-8 encoding, we can use UTF-16 encoding — either in the big-endian or in the little-endian version. To convert between UTF-8 and UTF-16 encoding schemes, we can make use of the conversion functions from the `Ada.Strings.UTF_Encoding.Conversions` package.

To declare a UTF-16 encoded string, we can use one of the following data types:

- the 8-bit-character based `UTF_String` type, or
- the 16-bit-character based `UTF_16_Wide_String` type.

When using the 8-bit version, though, we have to specify the input and output schemes when converting between UTF-8 and UTF-16 encoding schemes.

Let's see a code example that makes use of both `UTF_String` and `UTF_16_Wide_String` types:

Listing 363: show_utf16_types.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Ada.Strings.UTF_Encoding;
use  Ada.Strings.UTF_Encoding;

with Ada.Strings.UTF_Encoding.Conversions;
use  Ada.Strings.UTF_Encoding.Conversions;

procedure Show_UTF16_Types is
   Symbols_UTF_8  : constant
     UTF_8_String := "♥♫";

   Symbols_UTF_16 : constant
     UTF_16_Wide_String :=
       Convert (Symbols_UTF_8);
   --  ^ Calling Convert for UTF_8_String
   --    to UTF_16_Wide_String conversion.

   Symbols_UTF_16BE : constant
     UTF_String :=
       Convert (Item          => Symbols_UTF_8,
                Input_Scheme  => UTF_8,
                Output_Scheme => UTF_16BE);
   --  ^ Calling Convert for UTF_8_String
   --    to UTF_String conversion in UTF-16BE
   --    encoding.
begin
   Put_Line ("UTF_8_String:          "
             & Symbols_UTF_8);

   Put_Line ("UTF_16_Wide_String:    "
             & Convert (Symbols_UTF_16));
   --          ^ Calling Convert for
   --            the UTF_16_Wide_String to
```

(continues on next page)

(continued from previous page)

```
   --            UTF_8_String conversion.

   Put_Line
     ("UTF_String / UTF_16BE: "
      & Convert
          (Item          => Symbols_UTF_16BE,
           Input_Scheme  => UTF_16BE,
           Output_Scheme => UTF_8));
end Show_UTF16_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.String_Encoding.UTF_16_Types
MD5: 905e20e83a6199fdc91a6b15bb71bb01
```

Runtime output

```
UTF_8_String:          ♥♫
UTF_16_Wide_String:    ♥♫
UTF_String / UTF_16BE: ♥♫
```

In this example, we're declaring a UTF-8 encoded string and storing it in the `Symbols_UTF_8` constant. Then, we're calling the `Convert` functions to convert between UTF-8 and UTF-16 encoding schemes. We're using two versions of this function:

- the `Convert` function that returns an object of `UTF_16_Wide_String` type for an input of `UTF_8_String` type, and
- the `Convert` function that returns an object of `UTF_String` type for an input of `UTF_8_String` type.
  - In this case, we need to specify the input and output schemes (see `Input_Scheme` and `Output_Scheme` parameters in the code example).

Previously, we've seen that the `Ada.Strings.UTF_Encoding.Wide_Wide_Strings` package offers functions to convert between UTF-8 and the `Wide_Wide_String` type. The same kind of conversion functions exist for UTF-16 strings as well. Let's look at this code example:

Listing 364: show_ww_utf16_string.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Ada.Strings.UTF_Encoding;
use  Ada.Strings.UTF_Encoding;

with Ada.Strings.UTF_Encoding.Wide_Wide_Strings;
use  Ada.Strings.UTF_Encoding.Wide_Wide_Strings;

with Ada.Strings.UTF_Encoding.Conversions;
use  Ada.Strings.UTF_Encoding.Conversions;

procedure Show_WW_UTF16_String is
   Symbols_UTF_16 : constant
     UTF_16_Wide_String :=
       Wide_Character'Val (16#2665#) &
       Wide_Character'Val (16#266B#);
   --  ^ Calling Wide_Character'Val
   --    to specify the UTF-16 BE code
   --    for "♥" and "♫".

   Symbols_WWS : constant
     Wide_Wide_String :=
```

(continues on next page)

(continued from previous page)

```
23          Decode (Symbols_UTF_16);
24       --  ^ Calling Decode for UTF_16_Wide_String
25       --    to Wide_Wide_String conversion.
26    begin
27       Put_Line ("UTF_16_Wide_String: "
28                 & Convert (Symbols_UTF_16));
29       --          ^ Calling Convert for the
30       --            UTF_16_Wide_String to
31       --            UTF_8_String conversion.
32
33       Put_Line ("Wide_Wide_String:   "
34                 & Encode (Symbols_WWS));
35       --          ^ Calling Encode for the
36       --            Wide_Wide_String to
37       --            UTF_8_String conversion.
38    end Show_WW_UTF16_String;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.String_Encoding.WW_UTF_16_String
MD5: 900af8f5c6aad7303c3e49c1c4a68d73
```

Runtime output

```
UTF_16_Wide_String: ♥♫
Wide_Wide_String:   ♥♫
```

In this example, we're calling the `Wide_Character'Val` function to specify the UTF-16 BE code of the "♥" and "♫" symbols. We're then using the Decode function to convert between the `UTF_16_Wide_String` and the `Wide_Wide_String` types.

25.6.3 Image attribute

Overview

In the *Introduction to Ada* (page 13) course, we've seen that the `Image` attribute returns a string that contains a textual representation of an object. For example, we write `Integer'Image (V)` to get a string for the integer variable `V`:

Listing 365: show_simple_image.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Simple_Image is
4     V : Integer;
5  begin
6     V := 10;
7     Put_Line ("V: " & Integer'Image (V));
8  end Show_Simple_Image;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Image_Attribute.Simple_Image
MD5: e38f6f1a0808f12bd53c1f3cf4983353
```

Runtime output

```
V:  10
```

Naturally, we can use the Image attribute with other scalar types. For example:

Listing 366: show_simple_image.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Simple_Image is
   type Status is (Unknown, Off, On);

   V : Float;
   S : Status;
begin
   V := 10.0;
   S := Unknown;

   Put_Line ("V: " & Float'Image (V));
   Put_Line ("S: " & Status'Image (S));
end Show_Simple_Image;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Image_Attribute.Simple_Image
MD5: d3369518b610b7bf6c8dcefdecdb0c44
```

Runtime output

```
V:  1.00000E+01
S: UNKNOWN
```

In this example, we retrieve a string representing the floating-point variable V. Also, we use `Status'Image (V)` to retrieve a string representing the textual version of the Status.

In the Ada Reference Manual

- Image Attributes[98]

Type'Image and Obj'Image

We can also apply the Image attribute to an object directly:

Listing 367: show_simple_image.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Simple_Image is
   V : Integer;
begin
   V := 10;
   Put_Line ("V: " & V'Image);

   --  Equivalent to:
   --  Put_Line ("V: " & Integer'Image (V));
end Show_Simple_Image;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Image_Attribute.Simple_Image
MD5: c8b2e458de47b403568dd795b3d3fc24
```

[98] http://www.ada-auth.org/standards/22rm/html/RM-4-10.html

Runtime output

```
V:  10
```

In this example, the `Integer'Image (V)` and `V'Image` forms are equivalent.

Wider versions of Image

Although we've been talking only about the Image attribute, it's important to mention that each of the wider versions of the string types also has a corresponding Image attribute. In fact, this is the attribute for each string type:

Attribute	Type of Returned String
Image	**String**
Wide_Image	**Wide_String**
Wide_Wide_Image	Wide_Wide_String

Let's see a simple example:

Listing 368: show_wide_wide_image.adb

```
1  with Ada.Wide_Wide_Text_IO;
2  use  Ada.Wide_Wide_Text_IO;
3
4  procedure Show_Wide_Wide_Image is
5     F : Float;
6  begin
7     F := 100.0;
8     Put_Line ("F = "
9               & F'Wide_Wide_Image);
10 end Show_Wide_Wide_Image;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Image_Attribute.Wide_Wide_Image
MD5: ff542ef93286529343466c27935d5c21
```

Runtime output

```
F =  1.00000E+02
```

In this example, we use the `Wide_Wide_Image` attribute to retrieve a string of `Wide_Wide_String` type for the floating-point variable F.

Image attribute for non-scalar types

Note: This feature was introduced in Ada 2022.

In the previous code examples, we were using the Image attribute with scalar types, but it isn't restricted to those types. In fact, we can also use this attribute when dealing with non-scalar types. For example:

Listing 369: simple_records.ads

```
package Simple_Records is

   type Rec is limited private;

   type Rec_Access is access Rec;

   function Init return Rec;

   type Null_Rec is null record;

private

   type Rec is limited record
      F : Float;
      I : Integer;
   end record;

   function Init return Rec is
      ((F => 10.0, I => 4));

end Simple_Records;
```

Listing 370: show_non_scalar_image.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;
with Ada.Unchecked_Deallocation;

with Simple_Records;
use  Simple_Records;

procedure Show_Non_Scalar_Image is

   procedure Free is
     new Ada.Unchecked_Deallocation
       (Object => Rec,
        Name   => Rec_Access);

   R_A : Rec_Access :=
     new Rec'(Init);

   N_R : Null_Rec :=
     (null record);
begin
   R_A := new Rec'(Init);
   N_R := (null record);

   Put_Line ("R_A:     " & R_A'Image);
   Put_Line ("R_A.all: " & R_A.all'Image);
   Put_Line ("N_R:     " & N_R'Image);

   Free (R_A);
   Put_Line ("R_A:     " & R_A'Image);
end Show_Non_Scalar_Image;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Image_Attribute.Non_Scalar_Image
MD5: d7d15e96a03c882995262a5cfca5e771
```

Runtime output

```
R_A:     (access ea02c0)
R_A.all:
(F =>  1.00000E+01,
 I =>  4)
N_R:     (NULL RECORD)
R_A:     null
```

In the Show_Non_Scalar_Image procedure from this example, we display the access value of R_A and the contents of the dereferenced access object (R_A.**all**). Also, we see the indication that N_R is a null record and R_A is null after the call to Free.

Historically

Since Ada 2022, the Image attribute is available for all types. Prior to this version of the language, it was only available for scalar types. (For other kind of types, programmers had to use the Image attribute for each component of a record, for example.)

In fact, prior to Ada 2022, the Image attribute was described in the 3.5 Scalar Types[99] section of the Ada Reference Manual, as it was only applied to those types. Now, it is part of the new Image Attributes[100] section.

Let's see another example, this time with arrays:

Listing 371: show_array_image.adb

```
1  pragma Ada_2022;
2
3  with Ada.Text_IO; use Ada.Text_IO;
4
5  procedure Show_Array_Image is
6
7     type Float_Array is
8       array (Positive range <>) of Float;
9
10    FA_3C   : Float_Array (1 .. 3);
11    FA_Null : Float_Array (1 .. 0);
12
13 begin
14    FA_3C   := [1.0, 3.0, 2.0];
15    FA_Null := [];
16
17    Put_Line ("FA_3C:   " & FA_3C'Image);
18    Put_Line ("FA_Null: " & FA_Null'Image);
19 end Show_Array_Image;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Image_Attribute.Array_Image
MD5: 2d3fcdd5e57451f08185618d357b705f
```

Runtime output

```
FA_3C:
[ 1.00000E+00,  3.00000E+00,  2.00000E+00]
FA_Null:
[]
```

[99] http://www.ada-auth.org/standards/22rm/html/RM-3-5.html
[100] http://www.ada-auth.org/standards/22rm/html/RM-4-10.html

In this example, we display the values of the three components of the FA_3C array. Also, we display the null array FA_Null.

Image attribute for tagged types

In addition to untagged types, we can also use the Image attribute with tagged types. For example:

Listing 372: simple_records.ads

```
package Simple_Records is

   type Rec is tagged limited private;

   function Init return Rec;

   type Rec_Child is new Rec with private;

   overriding function Init return Rec_Child;

private

   type Status is (Unknown, Off, On);

   type Rec is tagged limited record
      F : Float;
      I : Integer;
   end record;

   function Init return Rec is
      ((F => 10.0, I => 4));

   type Rec_Child is new Rec with record
      Z : Status;
   end record;

   function Init return Rec_Child is
      (Rec'(Init) with Z => Off);

end Simple_Records;
```

Listing 373: show_tagged_image.adb

```
pragma Ada_2022;

with Ada.Text_IO;    use Ada.Text_IO;

with Simple_Records; use Simple_Records;

procedure Show_Tagged_Image is
   R       : constant Rec       := Init;
   R_Class : constant Rec'Class := Rec'(Init);
   R_C     : constant Rec_Child := Init;
begin
   Put_Line ("R:       " & R'Image);
   Put_Line ("R_Class: " & R_Class'Image);
   Put_Line ("R_A:     " & R_C'Image);
end Show_Tagged_Image;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Image_Attribute.Tagged_Image
MD5: 164bd17c99115acafb09c99f40c1578c
```

Runtime output

```
R:       {SIMPLE_RECORDS.RECobject}
R_Class: SIMPLE_RECORDS.REC'{SIMPLE_RECORDS.RECobject}
R_A:     {SIMPLE_RECORDS.REC_CHILDobject}
```

In the Show_Tagged_Image procedure from this example, we display the contents of the R object of Rec type and the R_Class object of Rec'Class type. Also, we display the contents of the R_C object of the Rec_Child type, which is derived from the Rec type.

Image attribute for task and protected types

We can also apply the Image attribute to protected objects and tasks:

Listing 374: simple_tasking.ads

```
package Simple_Tasking is

   protected type Protected_Float (I : Integer) is

   private
      V : Float := Float (I);
   end Protected_Float;

   protected type Protected_Null is
   private
   end Protected_Null;

   task type T is
      entry Start;
   end T;

end Simple_Tasking;
```

Listing 375: simple_tasking.adb

```
package body Simple_Tasking is

   protected body Protected_Float is

   end Protected_Float;

   protected body Protected_Null is

   end Protected_Null;

   task body T is
   begin
      accept Start;
   end T;

end Simple_Tasking;
```

Listing 376: show_protected_task_image.adb

```
pragma Ada_2022;

with Ada.Text_IO;    use Ada.Text_IO;

with Simple_Tasking; use Simple_Tasking;

procedure Show_Protected_Task_Image is

   PF : Protected_Float (0);
   PN : Protected_Null;
   T1 : T;

begin
   Put_Line ("PF: " & PF'Image);
   Put_Line ("PN: " & PN'Image);
   Put_Line ("T1: " & T1'Image);

   T1.Start;
end Show_Protected_Task_Image;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Image_Attribute.Protected_Task_
 ↪Image
MD5: 9d8c667015878eb14e5b3950a70b86b1
```

Runtime output

```
PF: (protected object)
PN: (protected object)
T1: (task t1_0000000000E94090)
```

In this example, we display information about the protected object PF, the componentless protected object PN and the task T1.

25.6.4 Put_Image aspect

Note: This feature was introduced in Ada 2022.

Overview

In the previous section, we discussed many details about the Image attribute. In the code examples from that section, we've seen the default behavior of this attribute: the string returned by the calls to Image was always in the format defined by the Ada standard.

In some situations, however, we might want to customize the string that is returned by the Image attribute of a type T. Ada allows us to do that via the Put_Image aspect. This is what we have to do:

1. Specify the Put_Image aspect for the type T and indicate a procedure with a specific parameter profile — let's say, for example, a procedure named P.
2. Implement the procedure P and write the information we want to use into a buffer (by calling the routines defined for Root_Buffer_Type, such as the Put procedure).

We can see these steps performed in the code example below:

Listing 377: show_put_image.ads

```
pragma Ada_2022;

with Ada.Strings.Text_Buffers;

package Show_Put_Image is

   type T is null record
     with Put_Image => Put_Image_T;
   --      ^ Custom version of Put_Image

   use Ada.Strings.Text_Buffers;

   procedure Put_Image_T
     (Buffer : in out Root_Buffer_Type'Class;
      Arg    :        T);

end Show_Put_Image;
```

Listing 378: show_put_image.adb

```
package body Show_Put_Image is

   procedure Put_Image_T
     (Buffer : in out Root_Buffer_Type'Class;
      Arg    :        T) is
      pragma Unreferenced (Arg);
   begin
      --  Call Put with customized
      --  information
      Buffer.Put ("<custom info>");
   end Put_Image_T;

end Show_Put_Image;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Put_Image.Simple_Put_Image
MD5: cbdd77a9e6cc30f3604c0901536d87aa
```

In the Show_Put_Image package, we use the Put_Image aspect in the declaration of the T type. There, we indicate that the Image attribute shall use the Put_Image_T procedure instead of the default version.

In the body of the Put_Image_T procedure, we implement our custom version of the Image attribute. We do that by calling the Put procedure with the information we want to provide in the Image attribute. Here, we access a buffer of Root_Buffer_Type type, which is defined in the Ada.Strings.Text_Buffers package. (We discuss more about this package *later on* (page 527).)

In the Ada Reference Manual

- Image Attributes[101]

[101] http://www.ada-auth.org/standards/22rm/html/RM-4-10.html

Complete Example of Put_Image

Let's see a complete example in which we use the Put_Image aspect and write useful information to the buffer:

Listing 379: custom_numerics.ads

```
pragma Ada_2022;

with Ada.Strings.Text_Buffers;

package Custom_Numerics is

   type Float_Integer is record
     F : Float   := 0.0;
     I : Integer := 0;
   end record
     with Dynamic_Predicate =>
            Integer (Float_Integer.F) =
              Float_Integer.I,
          Put_Image         => Put_Float_Integer;
   --      ^ Custom version of Put_Image

   use Ada.Strings.Text_Buffers;

   procedure Put_Float_Integer
     (Buffer : in out Root_Buffer_Type'Class;
      Arg    :        Float_Integer);

end Custom_Numerics;
```

Listing 380: custom_numerics.adb

```
package body Custom_Numerics is

   procedure Put_Float_Integer
     (Buffer : in out Root_Buffer_Type'Class;
      Arg    :        Float_Integer) is
   begin
      --  Call Wide_Wide_Put with customized
      --  information
      Buffer.Wide_Wide_Put
        ("(F : "  & Arg.F'Wide_Wide_Image & ", "
         & "I : " & Arg.I'Wide_Wide_Image & ")");
   end Put_Float_Integer;

end Custom_Numerics;
```

Listing 381: show_put_image.adb

```
pragma Ada_2022;

with Ada.Text_IO;     use Ada.Text_IO;

with Custom_Numerics; use Custom_Numerics;

procedure Show_Put_Image is
   V : Float_Integer;
begin
   V := (F => 100.2,
         I => 100);
```

(continues on next page)

(continued from previous page)

```
12    Put_Line ("V = "
13              & V'Image);
14 end Show_Put_Image;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Put_Image.Put_Image_Custom_
 ↪Numerics
MD5: 18d31150d7a9ff9af0359495543c011f
```

Runtime output

```
V = (F :  1.00200E+02, I :  100)
```

In the `Custom_Numerics` package of this example, we specify the `Put_Image` aspect and indicate the `Put_Float_Integer` procedure. In that procedure, we display the information of components `F` and `I`. Then, in the `Show_Put_Image` procedure, we use the `Image` attribute for the `V` variable and see the information in the exact format we specified. (If you like to see the default version of the `Put_Image` instead, you may comment out the `Put_Image` aspect part in the declaration of `Float_Integer`.)

Relation to the `Image` attribute

Note that we cannot override the `Image` attribute directly — there's no `Image` *aspect* that we could specify. However, as we've just seen, we can do this indirectly by using our own version of the `Put_Image` procedure for a type `T`.

The `Image` attribute of a type `T` makes use of the procedure indicated in the `Put_Image` aspect. Let's say we have the following declaration:

```
type T is null record
  with Put_Image => Put_Image_T;
```

When we then use the `T'Image` attribute in our code, the custom `Put_Image_T` procedure is automatically called. This is a simplified example of how the `Image` function is implemented:

```
function Image (V : T)
                return String is
   Buffer : Custom_Buffer;
   --       ^ of Root_Buffer_Type'Class
begin
   --  Calling Put_Image procedure
   --  for type T
   Put_Image_T (Buffer, V);

   --  Retrieving the text from the
   --  buffer as a string
   return Buffer.Get;
end Image;
```

In other words, the `Image` attribute basically:

- calls the `Put_Image` procedure specified in the `Put_Image` aspect of type T's declaration and passes a buffer;

and

- retrieves the contents of the buffer as a string and returns it.

If the Put_Image aspect of type T isn't specified, the default version is used. (We've seen the default version of various types *in the previous section* (page 512) about the Image attribute.)

Put_Image and derived types

Types that were derived from untagged types (or null extensions) make use of the Put_Image procedure that was specified for their parent type — either a custom procedure indicated in the Put_Image aspect or the default one. Naturally, if a derived type has the Put_Image aspect, the procedure indicated in the aspect is used instead. For example:

Listing 382: untagged_put_image.ads

```
pragma Ada_2022;

with Ada.Strings.Text_Buffers;

package Untagged_Put_Image is

   use Ada.Strings.Text_Buffers;

   type T is null record
     with Put_Image => Put_Image_T;

   procedure Put_Image_T
     (Buffer : in out Root_Buffer_Type'Class;
      Arg    :        T);

   type T_Derived_1 is new T;

   type T_Derived_2 is new T
     with Put_Image => Put_Image_T_Derived_2;

   procedure Put_Image_T_Derived_2
     (Buffer : in out Root_Buffer_Type'Class;
      Arg    :        T_Derived_2);

end Untagged_Put_Image;
```

Listing 383: untagged_put_image.adb

```
package body Untagged_Put_Image is

   procedure Put_Image_T
     (Buffer : in out Root_Buffer_Type'Class;
      Arg    :        T) is
      pragma Unreferenced (Arg);
   begin
      Buffer.Wide_Wide_Put ("Put_Image_T");
   end Put_Image_T;

   procedure Put_Image_T_Derived_2
     (Buffer : in out Root_Buffer_Type'Class;
      Arg    :        T_Derived_2) is
      pragma Unreferenced (Arg);
   begin
      Buffer.Wide_Wide_Put
        ("Put_Image_T_Derived_2");
   end Put_Image_T_Derived_2;

end Untagged_Put_Image;
```

Listing 384: show_untagged_put_image.adb

```
pragma Ada_2022;

with Ada.Text_IO;        use Ada.Text_IO;

with Untagged_Put_Image; use Untagged_Put_Image;

procedure Show_Untagged_Put_Image is
   Obj_T           : T;
   Obj_T_Derived_1 : T_Derived_1;
   Obj_T_Derived_2 : T_Derived_2;
begin
   Put_Line ("T'Image :           "
             & Obj_T'Image);
   Put_Line ("T_Derived_1'Image : "
             & Obj_T_Derived_1'Image);
   Put_Line ("T_Derived_2'Image : "
             & Obj_T_Derived_2'Image);
end Show_Untagged_Put_Image;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Put_Image.Untagged_Put_Image
MD5: b0a115967ec5f2deaea19967d22266b4
```

Runtime output

```
T'Image :           Put_Image_T
T_Derived_1'Image : Put_Image_T
T_Derived_2'Image : Put_Image_T_Derived_2
```

In this example, we declare the type T and its derived types T_Derived_1 and T_Derived_2. When running this code, we see that:

- T_Derived_1 makes use of the Put_Image_T procedure from its parent.
  - Note that, if we remove the Put_Image aspect from the declaration of T, the default version of the Put_Image procedure is used for both T and T_Derived_1 types.
- T_Derived_2 makes use of the Put_Image_T_Derived_2 procedure, which was indicated in the Put_Image aspect of that type, instead of its parent's procedure.

Put_Image and tagged types

Types that are derived from a tagged type may also inherit the Put_Image aspect. However, there are a couple of small differences in comparison to untagged types, as we can see in the following example:

Listing 385: tagged_put_image.ads

```
pragma Ada_2022;

with Ada.Strings.Text_Buffers;

package Tagged_Put_Image is

   use Ada.Strings.Text_Buffers;

```

(continues on next page)

(continued from previous page)

```
   type T is tagged record
      I : Integer := 0;
   end record
     with Put_Image => Put_Image_T;

   procedure Put_Image_T
     (Buffer : in out Root_Buffer_Type'Class;
      Arg    :        T);

   type T_Child_1 is new T with record
      I1 : Integer;
   end record;

   type T_Child_2 is new T with null record;

   type T_Child_3 is new T with record
      I3 : Integer := 0;
   end record
     with Put_Image => Put_Image_T_Child_3;

   procedure Put_Image_T_Child_3
     (Buffer : in out Root_Buffer_Type'Class;
      Arg    :        T_Child_3);

end Tagged_Put_Image;
```

Listing 386: tagged_put_image.adb

```
package body Tagged_Put_Image is

   procedure Put_Image_T
     (Buffer : in out Root_Buffer_Type'Class;
      Arg    :        T) is
      pragma Unreferenced (Arg);
   begin
      Buffer.Wide_Wide_Put ("Put_Image_T");
   end Put_Image_T;

   procedure Put_Image_T_Child_3
     (Buffer : in out Root_Buffer_Type'Class;
      Arg    :        T_Child_3) is
      pragma Unreferenced (Arg);
   begin
      Buffer.Wide_Wide_Put
        ("Put_Image_T_Child_3");
   end Put_Image_T_Child_3;

end Tagged_Put_Image;
```

Listing 387: show_tagged_put_image.adb

```
pragma Ada_2022;

with Ada.Text_IO;      use Ada.Text_IO;

with Tagged_Put_Image; use Tagged_Put_Image;

procedure Show_Tagged_Put_Image is
   Obj_T         : T;
   Obj_T_Child_1 : T_Child_1;
```

(continues on next page)

(continued from previous page)

```
10    Obj_T_Child_2 : T_Child_2;
11    Obj_T_Child_3 : T_Child_3;
12 begin
13    Put_Line ("T'Image :         "
14              & Obj_T'Image);
15    Put_Line ("--------------------");
16    Put_Line ("T_Child_1'Image : "
17              & Obj_T_Child_1'Image);
18    Put_Line ("--------------------");
19    Put_Line ("T_Child_2'Image : "
20              & Obj_T_Child_2'Image);
21    Put_Line ("--------------------");
22    Put_Line ("T_Child_3'Image : "
23              & Obj_T_Child_3'Image);
24    Put_Line ("--------------------");
25    Put_Line ("T'Class'Image :   "
26              & T'Class (Obj_T_Child_1)'Image);
27 end Show_Tagged_Put_Image;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Put_Image.Tagged_Put_Image
MD5: 74d29ea54f1ad79fea7de2ad7c1dcb31
```

Runtime output

```
T'Image :         Put_Image_T
--------------------
T_Child_1'Image :
(Put_Image_T with I1 =>  1701066593)
--------------------
T_Child_2'Image :
(Put_Image_T)
--------------------
T_Child_3'Image : Put_Image_T_Child_3
--------------------
T'Class'Image :   TAGGED_PUT_IMAGE.T_CHILD_1'
(Put_Image_T with I1 =>  1701066593)
```

In this example, we declare the type T and its derived types `T_Child_1`, `T_Child_2` and `T_Child_3`. When running this code, we see that:

- for both `T_Child_1` and `T_Child_2`, the parent's `Put_Image` aspect (the `Put_Image_T` procedure) is called and its information is combined with the information from the type extension;
  - The information from the parent's `Put_Image_T` procedure is presented in an aggregate syntax — in this case, this results in `(Put_Image_T)`.
  - For the `T_Child_1` type, the `I1` component of the type extension is displayed by calling a default version of the `Put_Image` procedure for that component — `(Put_Image_T with I1 => 0)` is displayed.
  - For the `T_Child_2` type, no additional information is displayed because this type has a null extension.
- for the `T_Child_3` type, the `Put_Image_T_Child_3` procedure, which was indicated in the `Put_Image` aspect of the type, is used.

Finally, class-wide types (such as `T'Class`) include additional information. Here, the tag of the specific derived type is displayed first — in this case, the tag of the `T_Child_1` type — and then the actual information for the derived type is displayed.

25.6.5 Universal text buffer

In the *previous section* (page 519), we've seen that the first parameter of the procedure indicated in the `Put_Image` aspect has the `Root_Buffer_Type'Class` type, which is defined in the `Ada.Strings.Text_Buffers` package. In this section, we talk more about this type and additional procedures associated with this type.

Note: This feature was introduced in Ada 2022.

Overview

We use the `Root_Buffer_Type'Class` type to implement a universal text buffer that is used to store and retrieve information about data types. Because this text buffer isn't associated with specific data types, it is universal — in the sense that we can really use it for any data type, regardless of the characteristics of this type.

In theory, we could use Ada's universal text buffer to implement applications that actually process text in some form — for example, when implementing a text editor. However, in general, Ada programmers are only expected to make use of the `Root_Buffer_Type'Class` type when implementing a procedure for the `Put_Image` aspect. For this reason, we won't discuss any kind of type derivation — or any other kind of usages of this type — in this section. Instead, we'll just focus on additional subprograms from the `Ada.Strings.Text_Buffers` package.

In the Ada Reference Manual

- Universal Text Buffers[102]

Additional procedures

In the previous section, we used the `Put` procedure — and the related `Wide_Put` and `Wide_Wide_Put` procedures — from the `Ada.Strings.Text_Buffers` package. In addition to these procedures, the package also includes:

- the `New_Line` procedure, which writes a new line marker to the text buffer;
- the `Increase_Indent` procedure, which increases the indentation in the text buffer; and
- the `Decrease_Indent` procedure, which decreases the indentation in the text buffer.

The `Ada.Strings.Text_Buffers` package also includes the `Current_Indent` function, which retrieves the current indentation counter.

Let's revisit an example from the previous section and use the procedures mentioned above:

Listing 388: custom_numerics.ads

```
1 pragma Ada_2022;
2
3 with Ada.Strings.Text_Buffers;
4
5 package Custom_Numerics is
6
7    type Float_Integer is record
```

(continues on next page)

[102] http://www.ada-auth.org/standards/22rm/html/RM-A-4-12.html

(continued from previous page)

```
      F : Float;
      I : Integer;
   end record
     with Dynamic_Predicate =>
            Integer (Float_Integer.F) =
              Float_Integer.I,
          Put_Image         => Put_Float_Integer;
   --      ^ Custom version of Put_Image

   use Ada.Strings.Text_Buffers;

   procedure Put_Float_Integer
     (Buffer : in out Root_Buffer_Type'Class;
      Arg    :        Float_Integer);

end Custom_Numerics;
```

Listing 389: custom_numerics.adb

```
package body Custom_Numerics is

   procedure Put_Float_Integer
     (Buffer : in out Root_Buffer_Type'Class;
      Arg    :        Float_Integer) is
   begin
      Buffer.Wide_Wide_Put ("(");
      Buffer.New_Line;

      Buffer.Increase_Indent;

      Buffer.Wide_Wide_Put
        ("F : "
         & Arg.F'Wide_Wide_Image);
      Buffer.New_Line;

      Buffer.Wide_Wide_Put
        ("I : "
        & Arg.I'Wide_Wide_Image);

      Buffer.Decrease_Indent;
      Buffer.New_Line;

      Buffer.Wide_Wide_Put (")");
   end Put_Float_Integer;

end Custom_Numerics;
```

Listing 390: show_put_image.adb

```
pragma Ada_2022;

with Ada.Text_IO;     use Ada.Text_IO;

with Custom_Numerics; use Custom_Numerics;

procedure Show_Put_Image is
   V : Float_Integer;
begin
   V := (F => 100.2,
         I => 100);
```

(continues on next page)

(continued from previous page)

```
12    Put_Line ("V = "
13              & V'Image);
14 end Show_Put_Image;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Strings.Universal_Text_Buffer.Put_Image_
 ↪Custom_Numerics
MD5: af95f9fe4064e8a9d7aebe14d7f561f7
```

Runtime output

```
V = (
   F :  1.00200E+02
   I :  100
)
```

In the body of the `Put_Float_Integer` procedure, we're using the `New_Line`, `Increase_Indent` and `Decrease_Indent` procedures to improve the format of the string returned by the `Float_Integer'Image` attribute. Using these procedures, you can create any kind of output format for your custom type.

25.7 Numerics

25.7.1 Modular Types

In the Introduction to Ada course, we've seen that Ada has two kinds of integer type: *signed* (page 47) and *modular* (page 50) types. For example:

Listing 391: num_types.ads

```
1  package Num_Types is
2
3     type Signed_Integer is range 1 .. 1_000_000;
4     type Modular is mod 2**32;
5
6  end Num_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Modular_Types.Modular_1
MD5: 2dff9fe22c6bbe52f964befccf68debf
```

In this section, we discuss two attributes of modular types: `Modulus` and **`Mod`**. We also discuss operations on modular types.

In the Ada Reference Manual

- 3.5.4 Integer Types[103]

---

[103] http://www.ada-auth.org/standards/22rm/html/RM-3-5-4.html

Modulus Attribute

The Modulus attribute returns the modulus of the modular type as a universal integer value. Let's get the modulus of the 32-bit Modular type that we've declared in the Num_Types package of the previous example:

Listing 392: show_modular.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Num_Types;   use Num_Types;

procedure Show_Modular is
   Modulus_Value : constant := Modular'Modulus;
begin
   Put_Line (Modulus_Value'Image);
end Show_Modular;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Modular_Types.Modular_1
MD5: 336254ebc8c09ee9921633f6919994fe
```

Runtime output

```
 4294967296
```

When we run this example, we get 4294967296, which is equal to 2**32.

Mod Attribute

Note: This section was originally written by Robert A. Duff and published as Gem #26: The Mod Attribute[104].

Operations on signed integers can overflow: if the result is outside the base range, Constraint_Error will be raised. In our previous example, we declared the Signed_Integer type:

```
type Signed_Integer is range 1 .. 1_000_000;
```

The base range of Signed_Integer is the range of Signed_Integer'Base, which is chosen by the compiler, but is likely to be something like -2**31 .. 2**31 - 1. (Note: we discussed the Base attribute *in this section* (page 283).)

Operations on modular integers use modular (wraparound) arithmetic. For example:

Listing 393: show_modular.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Num_Types;   use Num_Types;

procedure Show_Modular is
   X : Modular;
begin
   X := 1;
   Put_Line (X'Image);
```

(continues on next page)

[104] https://www.adacore.com/gems/gem-26

(continued from previous page)

```
10
11    X := -X;
12    Put_Line (X'Image);
13 end Show_Modular;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Modular_Types.Modular_1
MD5: e9ac61d2e43585f002fe2b79544ef9d7
```

Runtime output

```
 1
 4294967295
```

Negating X gives -1, which wraps around to `2**32 - 1`, i.e. all-one-bits.

But what about a type conversion from signed to modular? Is that a signed operation (so it should overflow) or is it a modular operation (so it should wrap around)? The answer in Ada is the former — that is, if you try to convert, say, `Integer'(-1)` to `Modular`, you will get `Constraint_Error`:

Listing 394: show_modular.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  with Num_Types;   use Num_Types;
4
5  procedure Show_Modular is
6     I : Integer := -1;
7     X : Modular := 1;
8  begin
9     X := Modular (I);  --  raises Constraint_Error
10    Put_Line (X'Image);
11 end Show_Modular;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Modular_Types.Modular_1
MD5: e8e1a1924efcbe770c719c29547bb863
```

Build output

```
show_modular.adb:9:09: warning: value not in range of type "Modular" defined at␣
 ↪num_types.ads:4 [enabled by default]
show_modular.adb:9:09: warning: Constraint_Error will be raised at run time␣
 ↪[enabled by default]
```

Runtime output

```

raised CONSTRAINT_ERROR : show_modular.adb:9 range check failed
```

To solve this problem, we can use the **Mod** attribute:

Listing 395: show_modular.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  with Num_Types;   use Num_Types;
4
```

(continues on next page)

(continued from previous page)

```
procedure Show_Modular is
   I : constant Integer := -1;
   X : Modular := 1;
begin
   X := Modular'Mod (I);
   Put_Line (X'Image);
end Show_Modular;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Modular_Types.Modular_1
MD5: 572a753de946b7578c5f1b6a795ede98
```

Runtime output

```
4294967295
```

The **Mod** attribute will correctly convert from any integer type to a given modular type, using wraparound semantics.

Historically

In older versions of Ada — such as Ada 95 —, the only way to do this conversion is to use `Unchecked_Conversion`, which is somewhat uncomfortable. Furthermore, if you're trying to convert to a generic formal modular type, how do you know what size of signed integer type to use? Note that `Unchecked_Conversion` might malfunction if the source and target types are of different sizes.

The **Mod** attribute was added to Ada 2005 to solve this problem. Also, we can now safely use this attribute in generics. For example:

Listing 396: mod_attribute.ads

```
generic
   type Formal_Modular is mod <>;
package Mod_Attribute is
   function F return Formal_Modular;
end Mod_Attribute;
```

Listing 397: mod_attribute.adb

```
package body Mod_Attribute is

   A_Signed_Integer : Integer := -1;

   function F return Formal_Modular is
   begin
      return Formal_Modular'Mod
                (A_Signed_Integer);
   end F;

end Mod_Attribute;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Modular_Types.Mod_Attribute
MD5: b2f227b8d4f14cd36508bf33c403f751
```

In this example, F will return the all-ones bit pattern, for whatever modular type is passed to `Formal_Modular`.

Operations on modular types

Modular types are particularly useful for bit manipulation. For example, we can use the **and**, **or**, **xor** and **not** operators for modular types.

Also, we can perform bit-shifting by multiplying or dividing a modular object with a power of two. For example, if `M` is a variable of modular type, then `M := M * 2 ** 3;` shifts the bits to the left by three bits. Likewise, `M := M / 2 ** 3` shifts the bits to the right. Note that the compiler selects the appropriate shifting operator when translating these operations to machine code — no actual multiplication or division will be performed.

Let's see a simple implementation of the CRC-CCITT (0x1D0F) algorithm:

Listing 398: crc_defs.ads

```
package Crc_Defs is

    type Byte is mod 2 ** 8;
    type Crc  is mod 2 ** 16;

    type Byte_Array is
      array (Positive range <>) of Byte;

    function Crc_CCITT (A : Byte_Array)
                        return Crc;

    procedure Display (Crc_A : Crc);

    procedure Display (A : Byte_Array);

end Crc_Defs;
```

Listing 399: crc_defs.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Crc_Defs is

    package Byte_IO is new Modular_IO (Byte);
    package Crc_IO  is new Modular_IO (Crc);

    function Crc_CCITT (A : Byte_Array)
                        return Crc
    is
       X     : Byte;
       Crc_A : Crc := 16#1d0f#;
    begin
       for I in A'Range loop
          X := Byte (Crc_A / 2 ** 8) xor A (I);
          X := X xor (X / 2 ** 4);
          declare
             Crc_X : constant Crc := Crc (X);
          begin
             Crc_A := Crc_A * 2 ** 8  xor
                      Crc_X * 2 ** 12 xor
                      Crc_X * 2 ** 5  xor
                      Crc_X;
          end;
       end loop;

       return Crc_A;
    end Crc_CCITT;
```

(continues on next page)

(continued from previous page)

```
29
30      procedure Display (Crc_A : Crc) is
31      begin
32         Crc_IO.Put (Crc_A);
33         New_Line;
34      end Display;
35
36      procedure Display (A : Byte_Array) is
37      begin
38         for E of A loop
39            Byte_IO.Put (E);
40            Put (", ");
41         end loop;
42         New_Line;
43      end Display;
44
45   begin
46      Byte_IO.Default_Width := 1;
47      Byte_IO.Default_Base  := 16;
48      Crc_IO.Default_Width  := 1;
49      Crc_IO.Default_Base   := 16;
50   end Crc_Defs;
```

Listing 400: show_crc.adb

```
1   with Ada.Text_IO; use Ada.Text_IO;
2   with Crc_Defs;    use Crc_Defs;
3
4   procedure Show_Crc is
5      AA    : constant Byte_Array :=
6                 (16#0#, 16#20#, 16#30#);
7      Crc_A : Crc;
8   begin
9      Crc_A := Crc_CCITT (AA);
10
11     Put ("Input array: ");
12     Display (AA);
13
14     Put ("CRC-CCITT: ");
15     Display (Crc_A);
16  end Show_Crc;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Modular_Types.Mod_Crc_CCITT_Ada
MD5: 9c66abfadcce92231295cbccad087912
```

Runtime output

```
Input array: 16#0#, 16#20#, 16#30#,
CRC-CCITT: 16#21B9#
```

In this example, the core of the algorithm is implemented in the `Crc_CCITT` function. There, we use bit shifting — for instance, `* 2 ** 8` and `/ 2 ** 8`, which shift left and right, respectively, by eight bits. We also use the **`xor`** operator.

25.7.2 Numeric Literals

Classification

We've already discussed basic characteristics of numeric literals in the Introduction to Ada course — although we haven't used this terminology there. There are two kinds of numeric literals in Ada: integer literals and real literals. They are distinguished by the absence or presence of a radix point. For example:

Listing 401: real_integer_literals.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Real_Integer_Literals is
   Integer_Literal : constant := 365;
   Real_Literal    : constant := 365.2564;
begin
   Put_Line ("Integer Literal: "
             & Integer_Literal'Image);
   Put_Line ("Real Literal:    "
             & Real_Literal'Image);
end Real_Integer_Literals;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Numeric_Literals.Real_Integer_
↪Literals
MD5: ba1cc348cad054f3ab86c05e051b40fa
```

Runtime output

```
Integer Literal:  365
Real Literal:     3.652564000000000000E+02
```

Another classification takes the use of a base indicator into account. (Remember that, when writing a literal such as `2#1011#`, the base is the element before the first # sign.) So here we distinguish between decimal literals and based literals. For example:

Listing 402: decimal_based_literals.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Decimal_Based_Literals is

   package F_IO is new
     Ada.Text_IO.Float_IO (Float);

   --
   --  DECIMAL LITERALS
   --

   Dec_Integer  : constant := 365;

   Dec_Real     : constant := 365.2564;
   Dec_Real_Exp : constant := 0.365_256_4e3;

   --
   --  BASED LITERALS
   --

   Based_Integer     : constant := 16#16D#;
```

(continues on next page)

(continued from previous page)

```
22    Based_Integer_Exp : constant := 5#243#e1;
23
24    Based_Real        : constant :=
25      2#1_0110_1101.0100_0001_1010_0011_0111#;
26    Based_Real_Exp    : constant :=
27      7#1.031_153_643#e3;
28 begin
29    F_IO.Default_Fore := 3;
30    F_IO.Default_Aft  := 4;
31    F_IO.Default_Exp  := 0;
32
33    Put_Line ("Dec_Integer:       "
34              & Dec_Integer'Image);
35
36    Put ("Dec_Real:           ");
37    F_IO.Put (Item => Dec_Real);
38    New_Line;
39
40    Put ("Dec_Real_Exp:       ");
41    F_IO.Put (Item => Dec_Real_Exp);
42    New_Line;
43
44    Put_Line ("Based_Integer:     "
45              & Based_Integer'Image);
46    Put_Line ("Based_Integer_Exp: "
47              & Based_Integer_Exp'Image);
48
49    Put ("Based_Real:         ");
50    F_IO.Put (Item => Based_Real);
51    New_Line;
52
53    Put ("Based_Real_Exp:     ");
54    F_IO.Put (Item => Based_Real_Exp);
55    New_Line;
56 end Decimal_Based_Literals;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Numeric_Literals.Decimal_Based_
 ↪Literals
MD5: bde8f422c3844826819348d18fb48a33
```

Runtime output

```
Dec_Integer:        365
Dec_Real:           365.2564
Dec_Real_Exp:       365.2564
Based_Integer:      365
Based_Integer_Exp:  365
Based_Real:         365.2564
Based_Real_Exp:     365.2564
```

Based literals use the base#number# format. Also, they aren't limited to simple integer literals such as 16#16D#. In fact, we can use a radix point or an exponent in based literals, as well as underscores. In addition, we can use any base from 2 up to 16. We discuss these aspects further in the next section.

Features and Flexibility

Note: This section was originally written by Franco Gasperoni and published as Gem #7: The Beauty of Numeric Literals in Ada[105].

Ada provides a simple and elegant way of expressing numeric literals. One of those simple, yet powerful aspects is the ability to use underscores to separate groups of digits. For example, 3.14159_26535_89793_23846_26433_83279_50288_41971_69399_37510 is more readable and less error prone to type than 3.14159265358979323846264338327950288419716939937510. Here's the complete code:

Listing 403: ada_numeric_literals.adb

```
with Ada.Text_IO;

 procedure Ada_Numeric_Literals is
    Pi   : constant :=
      3.14159_26535_89793_23846_26433_83279_50288_41971_69399_37510;

    Pi2  : constant :=
      3.14159265358979323846264338327950288419716939937510;

    Z    : constant := Pi - Pi2;
    pragma Assert (Z = 0.0);

    use Ada.Text_IO;
 begin
    Put_Line ("Z = " & Float'Image (Z));
 end Ada_Numeric_Literals;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Numeric_Literals.Pi_Literals
MD5: 8f6516730fa98f08234b159488431aaf
```

Runtime output

```
Z =  0.00000E+00
```

Also, when using based literals, Ada allows any base from 2 to 16. Thus, we can write the decimal number 136 in any one of the following notations:

Listing 404: ada_numeric_literals.adb

```
with Ada.Text_IO;

procedure Ada_Numeric_Literals is
   Bin_136 : constant := 2#1000_1000#;
   Oct_136 : constant := 8#210#;
   Dec_136 : constant := 10#136#;
   Hex_136 : constant := 16#88#;
   pragma Assert (Bin_136 = 136);
   pragma Assert (Oct_136 = 136);
   pragma Assert (Dec_136 = 136);
   pragma Assert (Hex_136 = 136);

   use Ada.Text_IO;

```

(continues on next page)

[105] https://www.adacore.com/gems/ada-gem-7

(continued from previous page)

```
begin
   Put_Line ("Bin_136 = "
             & Integer'Image (Bin_136));
   Put_Line ("Oct_136 = "
             & Integer'Image (Oct_136));
   Put_Line ("Dec_136 = "
             & Integer'Image (Dec_136));
   Put_Line ("Hex_136 = "
             & Integer'Image (Hex_136));
end Ada_Numeric_Literals;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Numeric_Literals.Based_Literals
MD5: 0959ec5e4aafcde245c5a15597ac9b7e
```

Runtime output

```
Bin_136 =  136
Oct_136 =  136
Dec_136 =  136
Hex_136 =  136
```

In other languages

The rationale behind the method to specify based literals in the C programming language is strange and unintuitive. Here, you have only three possible bases: 8, 10, and 16 (why no base 2?). Furthermore, requiring that numbers in base 8 be preceded by a zero feels like a bad joke on us programmers. For example, what values do `0210` and `210` represent in C?

When dealing with microcontrollers, we might encounter I/O devices that are memory mapped. Here, we have the ability to write:

```
Lights_On  : constant := 2#1000_1000#;
Lights_Off : constant := 2#0111_0111#;
```

and have the ability to turn on/off the lights as follows:

```
Output_Devices := Output_Devices or  Lights_On;
Output_Devices := Output_Devices and Lights_Off;
```

Here's the complete example:

Listing 405: ada_numeric_literals.adb

```
with Ada.Text_IO;

procedure Ada_Numeric_Literals is
   Lights_On  : constant := 2#1000_1000#;
   Lights_Off : constant := 2#0111_0111#;

   type Byte is mod 256;
   Output_Devices : Byte := 0;

   --  for Output_Devices'Address
   --    use 16#DEAD_BEEF#;
   --  ^^^^^^^^^^^^^^^^^^^^^^^^^
   --  Memory mapped Output

```

(continues on next page)

(continued from previous page)

```
   use Ada.Text_IO;
begin
   Output_Devices := Output_Devices or
                     Lights_On;

   Put_Line ("Output_Devices (lights on ) = "
             & Byte'Image (Output_Devices));

   Output_Devices := Output_Devices and
                     Lights_Off;

   Put_Line ("Output_Devices (lights off) = "
             & Byte'Image (Output_Devices));
end Ada_Numeric_Literals;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Numeric_Literals.Literal_Lights
MD5: c3e72b25366d8d815a1f425f2695ad0b
```

Runtime output

```
Output_Devices (lights on ) =  136
Output_Devices (lights off) =  0
```

Of course, we can also use *records with representation clauses* (page 367) to do the above, which is even more elegant.

The notion of base in Ada allows for exponents, which is particularly pleasant. For instance, we can write:

Listing 406: literal_binaries.ads

```
package Literal_Binaries is
   Kilobyte  : constant := 2#1#e+10;
   Megabyte  : constant := 2#1#e+20;
   Gigabyte  : constant := 2#1#e+30;
   Terabyte  : constant := 2#1#e+40;
   Petabyte  : constant := 2#1#e+50;
   Exabyte   : constant := 2#1#e+60;
   Zettabyte : constant := 2#1#e+70;
   Yottabyte : constant := 2#1#e+80;
end Literal_Binaries;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Numeric_Literals.Literal_Binary
MD5: 98d971e0f170db570069f8868e442d6d
```

In based literals, the exponent — like the base — uses the regular decimal notation and specifies the power of the base that the based literal should be multiplied with to obtain the final value. For instance `2#1#e+10` = 1 x 2^{10} = `1_024` (in base 10), whereas `16#F#e+2` = 15 x 16^2 = 15 x 256 = `3_840` (in base 10).

Based numbers apply equally well to real literals. We can, for instance, write:

```
One_Third : constant := 3#0.1#;
--                      ^^^^^^
--                  same as 1.0/3
```

Whether we write `3#0.1#` or `1.0 / 3`, or even `3#1.0#e-1`, Ada allows us to specify exactly rational numbers for which decimal literals cannot be written.

The last nice feature is that Ada has an open-ended set of integer and real types. As a result, numeric literals in Ada do not carry with them their type as, for example, in C. The actual type of the literal is determined from the context. This is particularly helpful in avoiding overflows, underflows, and loss of precision.

In other languages

In C, a source of confusion can be the distinction between `32l` and `321`. Although both look similar, they're actually very different from each other.

And this is not all: all constant computations done at compile time are done in infinite precision, be they integer or real. This allows us to write constants with whatever size and precision without having to worry about overflow or underflow. We can for instance write:

```
Zero : constant := 1.0 - 3.0 * One_Third;
```

and be guaranteed that constant `Zero` has indeed value zero. This is very different from writing:

```
One_Third_Approx : constant :=
  0.33333333333333333333333333333333;
Zero_Approx      : constant :=
  1.0 - 3.0 * One_Third_Approx;
```

where `Zero_Approx` is really `1.0e-29` — and that will show up in your numerical computations. The above is quite handy when we want to write fractions without any loss of precision. Here's the complete code:

Listing 407: ada_numeric_literals.adb

```
with Ada.Text_IO;

procedure Ada_Numeric_Literals is
   One_Third : constant := 3#1.0#e-1;
   --  same as 1.0/3.0

   Zero      : constant := 1.0 - 3.0 * One_Third;
   pragma Assert (Zero = 0.0);

   One_Third_Approx : constant :=
     0.33333333333333333333333333333333;
   Zero_Approx      : constant :=
     1.0 - 3.0 * One_Third_Approx;

   use Ada.Text_IO;

begin
   Put_Line ("Zero        = "
             & Float'Image (Zero));
   Put_Line ("Zero_Approx = "
             & Float'Image (Zero_Approx));
end Ada_Numeric_Literals;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Numeric_Literals.Literals
MD5: ee604245b34e8cb878a8ebdb21cd564e
```

Runtime output

```
Zero        =  0.00000E+00
Zero_Approx =  1.00000E-29
```

Along these same lines, we can write:

Listing 408: ada_numeric_literals.adb

```
with Ada.Text_IO;

with Literal_Binaries; use Literal_Binaries;

procedure Ada_Numeric_Literals is

   Big_Sum : constant := 1          +
                         Kilobyte   +
                         Megabyte   +
                         Gigabyte   +
                         Terabyte   +
                         Petabyte   +
                         Exabyte    +
                         Zettabyte;

   Result : constant := (Yottabyte - 1) /
                        (Kilobyte - 1);

   Nil    : constant := Result - Big_Sum;
   pragma Assert (Nil = 0);

   use Ada.Text_IO;

begin
   Put_Line ("Nil         = "
             & Integer'Image (Nil));
end Ada_Numeric_Literals;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Numeric_Literals.Literal_Binary
MD5: 7bda6442e68271d12bdb827b63f0d702
```

Runtime output

```
Nil         =  0
```

and be guaranteed that `Nil` is equal to zero.

25.7.3 Floating-Point Types

In this section, we discuss various attributes related to floating-point types.

In the Ada Reference Manual

- 3.5.8 Operations of Floating Point Types[106]
- A.5.3 Attributes of Floating Point Types[107]

[106] http://www.ada-auth.org/standards/22rm/html/RM-3-5-8.html
[107] http://www.ada-auth.org/standards/22rm/html/RM-A-5-3.html

Representation-oriented attributes

In this section, we discuss attributes related to the representation of floating-point types.

Attribute: Machine_Radix

Machine_Radix is an attribute that returns the radix of the hardware representation of a type. For example:

Listing 409: show_machine_radix.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Machine_Radix is
begin
   Put_Line
     ("Float'Machine_Radix:           "
      & Float'Machine_Radix'Image);
   Put_Line
     ("Long_Float'Machine_Radix:      "
      & Long_Float'Machine_Radix'Image);
   Put_Line
     ("Long_Long_Float'Machine_Radix: "
      & Long_Long_Float'Machine_Radix'Image);
end Show_Machine_Radix;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Floating_Point_Types.Machine_
↪Radix
MD5: 88680df680f1db4ff803912850370551
```

Runtime output

```
Float'Machine_Radix:            2
Long_Float'Machine_Radix:       2
Long_Long_Float'Machine_Radix:  2
```

Usually, this value is two, as the radix is based on a binary system.

Attributes: Machine_Mantissa

Machine_Mantissa is an attribute that returns the number of bits reserved for the mantissa of the floating-point type. For example:

Listing 410: show_machine_mantissa.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Machine_Mantissa is
begin
   Put_Line
     ("Float'Machine_Mantissa:           "
      & Float'Machine_Mantissa'Image);
   Put_Line
     ("Long_Float'Machine_Mantissa:      "
      & Long_Float'Machine_Mantissa'Image);
   Put_Line
```

(continues on next page)

(continued from previous page)

```
12      ("Long_Long_Float'Machine_Mantissa: "
13       & Long_Long_Float'Machine_Mantissa'Image);
14 end Show_Machine_Mantissa;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Floating_Point_Types.Machine_
 ↪Mantissa
MD5: da946a90a454c6e8f68cbff1ec54c7d3
```

Runtime output

```
Float'Machine_Mantissa:            24
Long_Float'Machine_Mantissa:       53
Long_Long_Float'Machine_Mantissa:  64
```

On a typical desktop PC, as indicated by `Machine_Mantissa`, we have 24 bits for the floating-point mantissa of the **`Float`** type.

`Machine_Emin` and `Machine_Emax`

The `Machine_Emin` and `Machine_Emax` attributes return the minimum and maximum value, respectively, of the machine exponent the floating-point type. Note that, in all cases, the returned value is a universal integer. For example:

Listing 411: show_machine_emin_emax.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Machine_Emin_Emax is
4  begin
5     Put_Line
6       ("Float'Machine_Emin:              "
7        & Float'Machine_Emin'Image);
8     Put_Line
9       ("Float'Machine_Emax:              "
10       & Float'Machine_Emax'Image);
11    Put_Line
12      ("Long_Float'Machine_Emin:         "
13       & Long_Float'Machine_Emin'Image);
14    Put_Line
15      ("Long_Float'Machine_Emax:         "
16       & Long_Float'Machine_Emax'Image);
17    Put_Line
18      ("Long_Long_Float'Machine_Emin:    "
19       & Long_Long_Float'Machine_Emin'Image);
20    Put_Line
21      ("Long_Long_Float'Machine_Emax:    "
22       & Long_Long_Float'Machine_Emax'Image);
23 end Show_Machine_Emin_Emax;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Floating_Point_Types.Machine_
 ↪Emin_Emax
MD5: 9766e06faaf1fc2ca48dd0bc0461b247
```

Runtime output

```
Float'Machine_Emin:               -125
Float'Machine_Emax:                128
Long_Float'Machine_Emin:          -1021
Long_Float'Machine_Emax:           1024
Long_Long_Float'Machine_Emin:     -16381
Long_Long_Float'Machine_Emax:      16384
```

On a typical desktop PC, the value of `Float'Machine_Emin` and `Float'Machine_Emax` is -125 and 128, respectively.

To get the actual minimum and maximum value of the exponent for a specific type, we need to use the `Machine_Radix` attribute that we've seen previously. Let's calculate the minimum and maximum value of the exponent for the `Float` type on a typical PC:

- Value of minimum exponent: `Float'Machine_Radix ** Float'Machine_Emin`.
  - In our target platform, this is 2^{-125} = 2.35098870164457501594 x 10^{-38}.
- Value of maximum exponent: `Float'Machine_Radix ** Float'Machine_Emax`.
  - In our target platform, this is 2^{128} = 3.40282366920938463463 x 10^{38}.

Attribute: Digits

`Digits` is an attribute that returns the requested decimal precision of a floating-point subtype. Let's see an example:

Listing 412: show_digits.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Digits is
4  begin
5     Put_Line ("Float'Digits:           "
6               & Float'Digits'Image);
7     Put_Line ("Long_Float'Digits:      "
8               & Long_Float'Digits'Image);
9     Put_Line ("Long_Long_Float'Digits: "
10              & Long_Long_Float'Digits'Image);
11 end Show_Digits;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Floating_Point_Types.Digits
MD5: cd1c88054f7d54703760a852d08acb6d
```

Runtime output

```
Float'Digits:            6
Long_Float'Digits:       15
Long_Long_Float'Digits:  18
```

Here, the requested decimal precision of the `Float` type is six digits.

Note that we said that `Digits` is the *requested* level of precision, which is specified as part of declaring a floating point type. We can retrieve the actual decimal precision with `Base'Digits`. For example:

Listing 413: show_base_digits.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Base_Digits is
   type Float_D3 is new Float digits 3;
begin
   Put_Line ("Float_D3'Digits:           "
             & Float_D3'Digits'Image);
   Put_Line ("Float_D3'Base'Digits:      "
             & Float_D3'Base'Digits'Image);
end Show_Base_Digits;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Floating_Point_Types.Base_Digits
MD5: a2deb352f93511ab2a39d41f0b3f9512
```

Runtime output

```
Float_D3'Digits:           3
Float_D3'Base'Digits:      6
```

The requested decimal precision of the `Float_D3` type is three digits, while the actual decimal precision is six digits (on a typical desktop PC).

Attributes: `Denorm`, `Signed_Zeros`, `Machine_Rounds`, `Machine_Overflows`

In this section, we discuss attributes that return **`Boolean`** values indicating whether a feature is available or not in the target architecture:

- `Denorm` is an attribute that indicates whether the target architecture uses denormalized numbers[108].
- `Signed_Zeros` is an attribute that indicates whether the type uses a sign for zero values, so it can represent both -0.0 and 0.0.
- `Machine_Rounds` is an attribute that indicates whether rounding-to-nearest is used, rather than some other choice (such as rounding-toward-zero).
- `Machine_Overflows` is an attribute that indicates whether a `Constraint_Error` exception is (or is not) guaranteed to be raised when an operation with that type produces an overflow or divide-by-zero.

Listing 414: show_boolean_attributes.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Boolean_Attributes is
begin
   Put_Line
     ("Float'Denorm:           "
      & Float'Denorm'Image);
   Put_Line
     ("Long_Float'Denorm:      "
      & Long_Float'Denorm'Image);
   Put_Line
     ("Long_Long_Float'Denorm: "
      & Long_Long_Float'Denorm'Image);
   Put_Line
```

(continues on next page)

[108] https://en.wikipedia.org/wiki/Subnormal_number

(continued from previous page)

```
15      ("Float'Signed_Zeros:           "
16       & Float'Signed_Zeros'Image);
17    Put_Line
18      ("Long_Float'Signed_Zeros:      "
19       & Long_Float'Signed_Zeros'Image);
20    Put_Line
21      ("Long_Long_Float'Signed_Zeros: "
22       & Long_Long_Float'Signed_Zeros'Image);
23    Put_Line
24      ("Float'Machine_Rounds:           "
25       & Float'Machine_Rounds'Image);
26    Put_Line
27      ("Long_Float'Machine_Rounds:      "
28       & Long_Float'Machine_Rounds'Image);
29    Put_Line
30      ("Long_Long_Float'Machine_Rounds: "
31       & Long_Long_Float'Machine_Rounds'Image);
32    Put_Line
33      ("Float'Machine_Overflows:           "
34       & Float'Machine_Overflows'Image);
35    Put_Line
36      ("Long_Float'Machine_Overflows:      "
37       & Long_Long_Float'Machine_Overflows'Image);
38    Put_Line
39      ("Long_Long_Float'Machine_Overflows: "
40       & Long_Long_Float'Machine_Overflows'Image);
41 end Show_Boolean_Attributes;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Floating_Point_Types.Machine_
 ↪Rounds_Overflows
MD5: b3f72c212cf00e697fe144a87eb72339
```

Runtime output

```
Float'Denorm:           TRUE
Long_Float'Denorm:      TRUE
Long_Long_Float'Denorm: TRUE
Float'Signed_Zeros:           TRUE
Long_Float'Signed_Zeros:      TRUE
Long_Long_Float'Signed_Zeros: TRUE
Float'Machine_Rounds:           TRUE
Long_Float'Machine_Rounds:      TRUE
Long_Long_Float'Machine_Rounds: TRUE
Float'Machine_Overflows:           FALSE
Long_Float'Machine_Overflows:      FALSE
Long_Long_Float'Machine_Overflows: FALSE
```

On a typical PC, we have the following information:

- `Denorm` is true (i.e. the architecture uses denormalized numbers);
- `Signed_Zeros` is true (i.e. the standard floating-point types use a sign for zero values);
- `Machine_Rounds` is true (i.e. rounding-to-nearest is used for floating-point types);
- `Machine_Overflows` is false (i.e. there's no guarantee that a `Constraint_Error` exception is raised when an operation with a floating-point type produces an overflow or divide-by-zero).

Primitive function attributes

In this section, we discuss attributes that we can use to manipulate floating-point values.

Attributes: `Fraction`, `Exponent` and `Compose`

The `Exponent` and `Fraction` attributes return "parts" of a floating-point value:

- `Exponent` returns the machine exponent, and
- `Fraction` returns the mantissa part.

`Compose` is used to return a floating-point value based on a fraction (the mantissa part) and the machine exponent.

Let's see some examples:

Listing 415: show_exponent_fraction_compose.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Exponent_Fraction_Compose is
begin
   Put_Line
     ("Float'Fraction (1.0):     "
      & Float'Fraction (1.0)'Image);
   Put_Line
     ("Float'Fraction (0.25):    "
      & Float'Fraction (0.25)'Image);
   Put_Line
     ("Float'Fraction (1.0e-25): "
      & Float'Fraction (1.0e-25)'Image);
   Put_Line
     ("Float'Exponent (1.0):     "
      & Float'Exponent (1.0)'Image);
   Put_Line
     ("Float'Exponent (0.25):    "
      & Float'Exponent (0.25)'Image);
   Put_Line
     ("Float'Exponent (1.0e-25): "
      & Float'Exponent (1.0e-25)'Image);
   Put_Line
     ("Float'Compose (5.00000e-01, 1):   "
      & Float'Compose (5.00000e-01, 1)'Image);
   Put_Line
     ("Float'Compose (5.00000e-01, -1):  "
      & Float'Compose (5.00000e-01, -1)'Image);
   Put_Line
     ("Float'Compose (9.67141E-01, -83): "
      & Float'Compose (9.67141E-01, -83)'Image);
end Show_Exponent_Fraction_Compose;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Floating_Point_Types.Exponent_
↪Fraction
MD5: d2e61b6b9a7a50861145f6b65e9fac39
```

Runtime output

```
Float'Fraction (1.0):      5.00000E-01
Float'Fraction (0.25):     5.00000E-01
```

(continues on next page)

(continued from previous page)

```
Float'Fraction (1.0e-25):  9.67141E-01
Float'Exponent (1.0):      1
Float'Exponent (0.25):    -1
Float'Exponent (1.0e-25): -83
Float'Compose (5.00000e-01, 1):    1.00000E+00
Float'Compose (5.00000e-01, -1):   2.50000E-01
Float'Compose (9.67141E-01, -83):  1.00000E-25
```

To understand this code example, we have to take this formula into account:

$$\text{Value} = \text{Fraction} \times \text{Machine\_Radix}^{\text{Exponent}}$$

Considering that the value of `Float'Machine_Radix` on a typical PC is two, we see that the value 1.0 is composed by a fraction of 0.5 and a machine exponent of one. In other words:

$$0.5 \times 2^{1} = 1.0$$

For the value 0.25, we get a fraction of 0.5 and a machine exponent of -1, which is the result of $0.5 \times 2^{-1} = 0.25$. We can use the `Compose` attribute to perform this calculation. For example, `Float'Compose (0.5, -1) = 0.25`.

Note that `Fraction` is always between 0.5 and 0.999999 (i.e < 1.0), except for denormalized numbers, where it can be < 0.5.

Attribute: `Scaling`

`Scaling` is an attribute that scales a floating-point value based on the machine radix and a machine exponent passed to the function. For example:

Listing 416: show_scaling.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Scaling is
begin
   Put_Line ("Float'Scaling (0.25, 1): "
             & Float'Scaling (0.25, 1)'Image);
   Put_Line ("Float'Scaling (0.25, 2): "
             & Float'Scaling (0.25, 2)'Image);
   Put_Line ("Float'Scaling (0.25, 3): "
             & Float'Scaling (0.25, 3)'Image);
end Show_Scaling;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Floating_Point_Types.Scaling
MD5: 9fa821d32911b74ee4b4fde3f3adafd8
```

Runtime output

```
Float'Scaling (0.25, 1):  5.00000E-01
Float'Scaling (0.25, 2):  1.00000E+00
Float'Scaling (0.25, 3):  2.00000E+00
```

The scaling is calculated with this formula:

$$\text{scaling} = \text{value} \times \text{Machine\_Radix}^{\text{machine exponent}}$$

For example, on a typical PC with a machine radix of two, `Float'Scaling (0.25, 3) = 2.0` corresponds to

$$0.25 \times 2^{3} = 2.0$$

Round-up and round-down attributes

`Floor` and `Ceiling` are attributes that returned the rounded-down or rounded-up value, respectively, of a floating-point value. For example:

Listing 417: show_floor_ceiling.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Floor_Ceiling is
begin
   Put_Line ("Float'Floor (0.25):   "
             & Float'Floor (0.25)'Image);
   Put_Line ("Float'Ceiling (0.25): "
             & Float'Ceiling (0.25)'Image);
end Show_Floor_Ceiling;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Floating_Point_Types.Floor_
 ↪Ceiling
MD5: 1344d54ae86b9fd4831d5f078eb655d4
```

Runtime output

```
Float'Floor (0.25):    0.00000E+00
Float'Ceiling (0.25):  1.00000E+00
```

As we can see in this example, the rounded-down value (floor) of 0.25 is 0.0, while the rounded-up value (ceiling) of 0.25 is 1.0.

Round-to-nearest attributes

In this section, we discuss three attributes used for rounding: `Rounding`, `Unbiased_Rounding`, `Machine_Rounding` In all cases, the rounding attributes return the nearest integer value (as a floating-point value). For example, the rounded value for 4.8 is 5.0 because 5 is the closest integer value.

Let's see a code example:

Listing 418: show_roundings.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Roundings is
begin
   Put_Line
     ("Float'Rounding (0.5):  "
      & Float'Rounding (0.5)'Image);
   Put_Line
     ("Float'Rounding (1.5):  "
      & Float'Rounding (1.5)'Image);
   Put_Line
     ("Float'Rounding (4.5):  "
      & Float'Rounding (4.5)'Image);
   Put_Line
     ("Float'Rounding (-4.5): "
      & Float'Rounding (-4.5)'Image);
   Put_Line
     ("Float'Unbiased_Rounding (0.5): "
```

(continues on next page)

(continued from previous page)

```
      & Float'Unbiased_Rounding (0.5)'Image);
   Put_Line
     ("Float'Unbiased_Rounding (1.5): "
      & Float'Unbiased_Rounding (1.5)'Image);
   Put_Line
     ("Float'Machine_Rounding (0.5): "
      & Float'Machine_Rounding (0.5)'Image);
   Put_Line
     ("Float'Machine_Rounding (1.5): "
      & Float'Machine_Rounding (1.5)'Image);
end Show_Roundings;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Floating_Point_Types.Rounding
MD5: 3f78165f092a163339cb9593ff15a50d
```

Runtime output

```
Float'Rounding (0.5):   1.00000E+00
Float'Rounding (1.5):   2.00000E+00
Float'Rounding (4.5):   5.00000E+00
Float'Rounding (-4.5): -5.00000E+00
Float'Unbiased_Rounding (0.5):  0.00000E+00
Float'Unbiased_Rounding (1.5):  2.00000E+00
Float'Machine_Rounding (0.5):  1.00000E+00
Float'Machine_Rounding (1.5):  2.00000E+00
```

The difference between these attributes is the way they handle the case when a value is exactly in between two integer values. For example, 4.5 could be rounded up to 5.0 or rounded down to 4.0. This is the way each rounding attribute works in this case:

- `Rounding` rounds away from zero. Positive floating-point values are rounded up, while negative floating-point values are rounded down when the value is between two integer values. For example:
  - 4.5 is rounded-up to 5.0, i.e. `Float'Rounding (4.5) = Float'Ceiling (4.5) = 5.0`.
  - -4.5 is rounded-down to -5.0, i.e. `Float'Rounding (-4.5) = Float'Floor (-4.5) = -5.0`.
- `Unbiased_Rounding` rounds toward the even integer. For example,
  - `Float'Unbiased_Rounding (0.5) = 0.0` because zero is the closest even integer, while
  - `Float'Unbiased_Rounding (1.5) = 2.0` because two is the closest even integer.
- `Machine_Rounding` uses the most appropriate rounding instruction available on the target platform. While this rounding attribute can potentially have the best performance, its result may be non-portable. For example, whether the rounding of 4.5 becomes 4.0 or 5.0 depends on the target platform.
  - If an algorithm depends on a specific rounding behavior, it's best to avoid the `Machine_Rounding` attribute. On the other hand, if the rounding behavior won't have a significant impact on the results, we can safely use this attribute.

Attributes: Truncation, Remainder, Adjacent

The Truncation attribute returns the *truncated* value of a floating-point value, i.e. the value corresponding to the integer part of a number rounded toward zero. This corresponds to the number before the radix point. For example, the truncation of 1.55 is 1.0 because the integer part of 1.55 is 1.

The Remainder attribute returns the remainder part of a division. For example, `Float'Remainder (1.25, 0.5) = 0.25`. Let's briefly discuss the details of this operations. The result of the division 1.25 / 0.5 is 2.5. Here, 1.25 is the dividend and 0.5 is the divisor. The quotient and remainder of this division are 2 and 0.25, respectively. (Here, the quotient is an integer number, and the remainder is the floating-point part that remains.)

Note that the relation between quotient and remainder is defined in such a way that we get the original dividend back when we use the formula: "quotient x divisor + remainder = dividend". For the previous example, this means 2 x 0.5 + 0.25 = 1.25.

The Adjacent attribute is the next machine value towards another value. For example, on a typical PC, the adjacent value of a small value — say, 1.0×10^{-83} — towards zero is +0.0, while the adjacent value of this small value towards 1.0 is another small, but greater value — in fact, it's 1.40130×10^{-45}. Note that the first parameter of the Adjacent attribute is the value we want to analyze and the second parameter is the Towards value.

Let's see a code example:

Listing 419: show_truncation_remainder_adjacent.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Truncation_Remainder_Adjacent is
begin
   Put_Line
     ("Float'Truncation (1.55):  "
      & Float'Truncation (1.55)'Image);
   Put_Line
     ("Float'Truncation (-1.55): "
      & Float'Truncation (-1.55)'Image);
   Put_Line
     ("Float'Remainder (1.25, 0.25): "
      & Float'Remainder (1.25, 0.25)'Image);
   Put_Line
     ("Float'Remainder (1.25, 0.5):  "
      & Float'Remainder (1.25, 0.5)'Image);
   Put_Line
     ("Float'Remainder (1.25, 1.0):  "
      & Float'Remainder (1.25, 1.0)'Image);
   Put_Line
     ("Float'Remainder (1.25, 2.0):  "
      & Float'Remainder (1.25, 2.0)'Image);
   Put_Line
     ("Float'Adjacent (1.0e-83, 0.0): "
      & Float'Adjacent (1.0e-83, 0.0)'Image);
   Put_Line
     ("Float'Adjacent (1.0e-83, 1.0): "
      & Float'Adjacent (1.0e-83, 1.0)'Image);
end Show_Truncation_Remainder_Adjacent;
```

Attributes: Copy_Sign and Leading_Part

Copy_Sign is an attribute that returns a value where the sign of the second floating-point argument is multiplied by the magnitude of the first floating-point argument. For example, `Float'Copy_Sign (1.0, -10.0)` is -1.0. Here, the sign of the second argument (-10.0) is multiplied by the magnitude of the first argument (1.0), so the result is -1.0.

Leading_Part is an attribute that returns the *approximated* version of the mantissa of a value based on the specified number of leading bits for the mantissa. Let's see some examples:

- `Float'Leading_Part (3.1416, 1)` is 2.0 because that's the value we can represent with one leading bit.
  - Note that `Float'Fraction (2.0) = 0.5` — which can be represented with one leading bit in the mantissa — and `Float'Exponent (2.0) = 2`.)
- If we increase the number of leading bits of the mantissa to two — by writing `Float'Leading_Part (3.1416, 2)` —, we get 3.0 because that's the value we can represent with two leading bits.
- If we increase again the number of leading bits to five — `Float'Leading_Part (3.1416, 5)` —, we get 3.125.
  - Note that, in this case `Float'Fraction (3.125) = 0.78125` and `Float'Exponent (3.125) = 2`.
  - The binary mantissa is actually `2#110_0100_0000_0000_0000_0000#`, which can be represented with five leading bits as expected: `2#110_01#`.
    * We can get the binary mantissa by calculating `Float'Fraction (3.125) * Float (Float'Machine_Radix) ** (Float'Machine_Mantissa - 1)` and converting the result to binary format. The -1 value in the formula corresponds to the sign bit.

Attention

In this explanation about the Leading_Part attribute, we're talking about leading bits. Strictly speaking, however, this is actually a simplification, and it's only correct if Machine_Radix is equal to two — which is the case for most machines. Therefore, in most cases, the explanation above is perfectly acceptable.

However, if Machine_Radix is *not* equal to two, we cannot use the term "bits" anymore, but rather digits of the Machine_Radix.

Let's see some examples:

Listing 420: show_copy_sign_leading_part_machine.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Copy_Sign_Leading_Part_Machine is
4  begin
5     Put_Line
6       ("Float'Copy_Sign (1.0, -10.0): "
7        & Float'Copy_Sign (1.0, -10.0)'Image);
8     Put_Line
9       ("Float'Copy_Sign (-1.0, -10.0): "
10       & Float'Copy_Sign (-1.0, -10.0)'Image);
11    Put_Line
12      ("Float'Copy_Sign (1.0,  10.0): "
13       & Float'Copy_Sign (1.0,  10.0)'Image);
```

(continues on next page)

(continued from previous page)

```
   Put_Line
     ("Float'Copy_Sign (1.0, -0.0):  "
      & Float'Copy_Sign (1.0, -0.0)'Image);
   Put_Line
     ("Float'Copy_Sign (1.0,  0.0):  "
      & Float'Copy_Sign (1.0,  0.0)'Image);
   Put_Line
     ("Float'Leading_Part (1.75, 1): "
      & Float'Leading_Part (1.75, 1)'Image);
   Put_Line
     ("Float'Leading_Part (1.75, 2): "
      & Float'Leading_Part (1.75, 2)'Image);
   Put_Line
     ("Float'Leading_Part (1.75, 3): "
      & Float'Leading_Part (1.75, 3)'Image);
end Show_Copy_Sign_Leading_Part_Machine;
```

Attribute: Machine

Not every real number is directly representable as a floating-point value on a specific machine. For example, let's take a value such as 1.0 x 10^{15} (or 1,000,000,000,000,000):

Listing 421: show_float_value.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Float_Value is
   package F_IO is new
     Ada.Text_IO.Float_IO (Float);

   V : Float;
begin
   F_IO.Default_Fore := 3;
   F_IO.Default_Aft  := 1;
   F_IO.Default_Exp  := 0;

   V := 1.0E+15;
   Put ("1.0E+15 = ");
   F_IO.Put (Item => V);
   New_Line;

end Show_Float_Value;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Floating_Point_Types.Float_Value
MD5: a7f80f7584ebaf39f2d5f9564c9c7d64
```

Runtime output

```
1.0E+15 = 999999986991000.0
```

If we run this example on a typical PC, we see that the expected value `1_000_000_000_000_000.0` was displayed as `999_999_986_991_000.0`. This is because 1.0 x 10^{15} isn't directly representable on this machine, so it has to be modified to a value that is actually representable (on the machine).

This *automatic* modification we've just described is actually hidden, so to say, in the assignment. However, we can make it more visible by using the `Machine (X)` attribute,

which returns a version of X that is representable on the target machine. The `Machine (X)` attribute rounds (or truncates) X to either one of the adjacent machine numbers for the specific floating-point type of X. (Of course, if the real value of X is directly representable on the target machine, no modification is performed.)

In fact, we could rewrite the `V := 1.0E+15` assignment of the code example as `V := Float'Machine (1.0E+15)`, as we're never assigning a real value directly to a floating-pointing variable — instead, we're first converting it to a version of the real value that is representable on the target machine. In this case, 999999986991000.0 is a representable version of the real value 1.0×10^{15}. Of course, writing `V := 1.0E+15` or `V := Float'Machine (1.0E+15)` doesn't make any difference to the actual value that is assigned to V (in the case of this specific target architecture), as the conversion to a representable value happens automatically during the assignment to V.

There are, however, instances where using the `Machine` attribute does make a difference in the result. For example, let's say we want to calculate the difference between the original real value in our example (1.0×10^{15}) and the actual value that is assigned to V. We can do this by using the `Machine` attribute in the calculation:

Listing 422: show_machine_attribute.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Machine_Attribute is
   package F_IO is new
     Ada.Text_IO.Float_IO (Float);

   V : Float;
begin
   F_IO.Default_Fore := 3;
   F_IO.Default_Aft  := 1;
   F_IO.Default_Exp  := 0;

   Put_Line
     ("Original value: 1_000_000_000_000_000.0");

   V := 1.0E+15;
   Put ("Machine value:  ");
   F_IO.Put (Item => V);
   New_Line;

   V := 1.0E+15 - Float'Machine (1.0E+15);
   Put ("Difference:     ");
   F_IO.Put (Item => V);
   New_Line;

end Show_Machine_Attribute;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Floating_Point_Types.Machine_
 ↪Attribute
MD5: c2db2cca028dc5811068f9b7f1bc209d
```

Runtime output

```
Original value: 1_000_000_000_000_000.0
Machine value:  999999986991000.0
Difference:     13008896.0
```

When we run this example on a typical PC, we see that the difference is roughly 1.3009×10^7. (Actually, the value that we might see is 1.3008896×10^7, which is a version of 1.3009×10^7 that is representable on the target machine.)

When we write `1.0E+15 - Float'Machine (1.0E+15)`:

- the first value in the operation is the universal real value 1.0 x 10^{15}, while
- the second value in the operation is a version of the universal real value 1.0 x 10^{15} that is representable on the target machine.

This also means that, in the assignment to V, we're actually writing `V := Float'Machine (1.0E+15 - Float'Machine (1.0E+15))`, so that:

1. we first get the intermediate real value that represents the difference between these values; and then
2. we get a version of this intermediate real value that is representable on the target machine.

This is the reason why we see 1.3008896 x 10^{7} instead of 1.3009 x 10^{7} when we run this application.

25.7.4 Fixed-Point Types

In this section, we discuss various attributes and operations related to fixed-point types.

In the Ada Reference Manual

- 3.5.10 Operations of Fixed Point Types[109]
- A.5.4 Attributes of Fixed Point Types[110]

Attributes of fixed-point types

Attribute: Machine_Radix

Machine_Radix is an attribute that returns the radix of the hardware representation of a type. For example:

Listing 423: show_fixed_machine_radix.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Fixed_Machine_Radix is
   type T3_D3 is delta 10.0 ** (-3) digits 3;

   D : constant := 2.0 ** (-31);
   type TQ31 is delta D range -1.0 .. 1.0 - D;
begin
   Put_Line ("T3_D3'Machine_Radix: "
             & T3_D3'Machine_Radix'Image);
   Put_Line ("TQ31'Machine_Radix:  "
             & TQ31'Machine_Radix'Image);
end Show_Fixed_Machine_Radix;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Fixed_Point_Types.Fixed_Machine_
 ↪Radix
MD5: a09d060a58f76550e948a8245ffb5fde
```

[109] http://www.ada-auth.org/standards/22rm/html/RM-3-5-10.html
[110] http://www.ada-auth.org/standards/22rm/html/RM-A-5-4.html

Runtime output

```
T3_D3'Machine_Radix:  2
TQ31'Machine_Radix:   2
```

Usually, this value is two, as the radix is based on a binary system.

Attribute: `Machine_Rounds` and `Machine_Overflows`

In this section, we discuss attributes that return **`Boolean`** values indicating whether a feature is available or not in the target architecture:

- `Machine_Rounds` is an attribute that indicates what happens when the result of a fixed-point operation is inexact:
  - `T'Machine_Rounds = True`: inexact result is rounded;
  - `T'Machine_Rounds = False`: inexact result is truncated.
- `Machine_Overflows` is an attribute that indicates whether a `Constraint_Error` is guaranteed to be raised when a fixed-point operation with that type produces an overflow or divide-by-zero.

Listing 424: show_boolean_attributes.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Boolean_Attributes is
   type T3_D3 is delta 10.0 ** (-3) digits 3;

   D : constant := 2.0 ** (-31);
   type TQ31 is delta D range -1.0 .. 1.0 - D;
begin
   Put_Line ("T3_D3'Machine_Rounds:    "
             & T3_D3'Machine_Rounds'Image);
   Put_Line ("TQ31'Machine_Rounds:     "
             & TQ31'Machine_Rounds'Image);
   Put_Line ("T3_D3'Machine_Overflows: "
             & T3_D3'Machine_Overflows'Image);
   Put_Line ("TQ31'Machine_Overflows:  "
             & TQ31'Machine_Overflows'Image);
end Show_Boolean_Attributes;
```

Attribute: `Small` and `Delta`

The `Small` and **`Delta`** attributes return numbers that indicate the numeric precision of a fixed-point type. In many cases, the `Small` of a type T is equal to the **`Delta`** of that type — i.e. `T'Small = T'Delta`. Let's discuss each attribute and how they distinguish from each other.

The **`Delta`** attribute returns the value of the **`delta`** that was used in the type definition. For example, if we declare **`type T3_D3 is delta`** `10.0 ** (-3)` **`digits`** `D`, then the value of `T3_D3'Delta` is the `10.0 ** (-3)` that we used in the type definition.

The `Small` attribute returns the "small" of a type, i.e. the smallest value used in the machine representation of the type. The *small* must be at least equal to or smaller than the *delta* — in other words, it must conform to the `T'Small <= T'Delta` rule.

For further reading...

The `Small` and the **`Delta`** need not actually be small numbers. They can be arbitrarily large. For instance, they could be 1.0, or 1000.0. Consider the following example:

Listing 425: fixed_point_defs.ads

```
package Fixed_Point_Defs is
   S     : constant := 32;
   Exp   : constant := 128;
   D     : constant := 2.0 ** (-S + Exp + 1);

   type Fixed is delta D
     range -1.0 * 2.0 ** Exp ..
           1.0 * 2.0 ** Exp - D;

   pragma Assert (Fixed'Size = S);
end Fixed_Point_Defs;
```

Listing 426: show_fixed_type_info.adb

```
with Fixed_Point_Defs; use Fixed_Point_Defs;
with Ada.Text_IO;      use Ada.Text_IO;

procedure Show_Fixed_Type_Info is
begin
   Put_Line ("Size : "
             & Fixed'Size'Image);
   Put_Line ("Small : "
             & Fixed'Small'Image);
   Put_Line ("Delta : "
             & Fixed'Delta'Image);
   Put_Line ("First : "
             & Fixed'First'Image);
   Put_Line ("Last : "
             & Fixed'Last'Image);
end Show_Fixed_Type_Info;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Fixed_Point_Types.Large_Small_
↪Attribute
MD5: 89672950b355060d250e0f5d7e2d40cb
```

Runtime output

```
Size :  32
Small :  1.58456325028528675E+29
Delta :  1.58456325028528675E+29
First : -340282366920938463463374607431768211456.0
Last :  340282366762482138434845932244680310784.0
```

In this example, the *small* of the Fixed type is actually quite large: 1.58456325028528675^{29}. (Also, the first and the last values are large: -340,282,366,920,938,463,463,374,607,431,768,211,456.0 and 340,282,366,762,482,138,434,845,932,244,680,310,784.0, or approximately -3.4028^{38} and 3.4028^{38}.)

In this case, if we assign 1 or 1,000 to a variable F of this type, the actual value stored in F is zero. Feel free to try this out!

When we declare an ordinary fixed-point data type, we must specify the *delta*. Specifying the *small*, however, is optional:

- If the *small* isn't specified, it is automatically selected by the compiler. In this case, the actual value of the *small* is an implementation-defined power of two — always following the rule that says: T'Small <= T'Delta.
- If we want, however, to specify the *small*, we can do that by using the Small aspect. In this case, it doesn't need to be a power of two.

For decimal fixed-point types, we cannot specify the *small*. In this case, it's automatically selected by the compiler, and it's always equal to the *delta*.

Let's see an example:

Listing 427: fixed_small_delta.ads

```
package Fixed_Small_Delta is
   D3 : constant := 10.0 ** (-3);

   type T3_D3 is delta D3 digits 3;

   type TD3   is delta D3 range -1.0 .. 1.0 - D3;

   D31 : constant := 2.0 ** (-31);
   D15 : constant := 2.0 ** (-15);

   type TQ31 is delta D31 range -1.0 .. 1.0 - D31;

   type TQ15 is delta D15 range -1.0 .. 1.0 - D15
     with Small => D31;
end Fixed_Small_Delta;
```

Listing 428: show_fixed_small_delta.adb

```
with Ada.Text_IO;       use Ada.Text_IO;

with Fixed_Small_Delta; use Fixed_Small_Delta;

procedure Show_Fixed_Small_Delta is
begin
   Put_Line ("T3_D3'Small: "
             & T3_D3'Small'Image);
   Put_Line ("T3_D3'Delta: "
             & T3_D3'Delta'Image);
   Put_Line ("T3_D3'Size: "
             & T3_D3'Size'Image);
   Put_Line ("--------------------");

   Put_Line ("TD3'Small: "
             & TD3'Small'Image);
   Put_Line ("TD3'Delta: "
             & TD3'Delta'Image);
   Put_Line ("TD3'Size: "
             & TD3'Size'Image);
   Put_Line ("--------------------");

   Put_Line ("TQ31'Small: "
             & TQ31'Small'Image);
   Put_Line ("TQ31'Delta: "
             & TQ31'Delta'Image);
   Put_Line ("TQ32'Size: "
             & TQ31'Size'Image);
   Put_Line ("--------------------");

   Put_Line ("TQ15'Small: "
```

(continues on next page)

(continued from previous page)

```
32              & TQ15'Small'Image);
33    Put_Line ("TQ15'Delta: "
34              & TQ15'Delta'Image);
35    Put_Line ("TQ15'Size: "
36              & TQ15'Size'Image);
37 end Show_Fixed_Small_Delta;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Fixed_Point_Types.Fixed_Small_
↪Delta
MD5: 0e811c7c0b92f05483b0ac7c3489dc3d
```

Runtime output

```
T3_D3'Small:  1.00000000000000000E-03
T3_D3'Delta:  1.00000000000000000E-03
T3_D3'Size:  11
--------------------
TD3'Small:  9.76562500000000000E-04
TD3'Delta:  1.00000000000000000E-03
TD3'Size:  11
--------------------
TQ31'Small:  4.65661287307739258E-10
TQ31'Delta:  4.65661287307739258E-10
TQ32'Size:  32
--------------------
TQ15'Small:  4.65661287307739258E-10
TQ15'Delta:  3.05175781250000000E-05
TQ15'Size:  32
```

As we can see in the output of the code example, the **Delta** attribute returns the value we used for **delta** in the type definition of the T3_D3, TD3, TQ31 and TQ15 types.

The TD3 type is an ordinary fixed-point type with the the same delta as the decimal T3_D3 type. In this case, however, TD3'Small is not the same as the TD3'Delta. On a typical desktop PC, TD3'Small is 2^{-10}, while the delta is 10^{-3}. (Remember that, for ordinary fixed-point types, if we don't specify the *small*, it's automatically selected by the compiler as a power of two smaller than or equal to the *delta*.)

In the case of the TQ15 type, we're specifying the *small* by using the Small aspect. In this case, the underlying size of the TQ15 type is 32 bits, while the precision we get when operating with this type is 16 bits. Let's see a specific example for this type:

Listing 429: show_fixed_small_delta.adb

```
1  with Ada.Text_IO;       use Ada.Text_IO;
2
3  with Fixed_Small_Delta; use Fixed_Small_Delta;
4
5  procedure Show_Fixed_Small_Delta is
6     V : TQ15;
7  begin
8     Put_Line ("V'Size: " & V'Size'Image);
9
10    V := TQ15'Small;
11    Put_Line ("V: " & V'Image);
12
13    V := TQ15'Delta;
14    Put_Line ("V: " & V'Image);
15 end Show_Fixed_Small_Delta;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Fixed_Point_Types.Fixed_Small_
 ↪Delta
MD5: f2a71db911913d6fbf5343671599c0ae
```

Runtime output

```
V'Size:  32
V:  0.00000
V:  0.00003
```

In the first assignment, we assign TQ15'Small (2^{-31}) to V. This value is smaller than the type's *delta* (2^{-15}). Even though V'Size is 32 bits, V'Delta indicates 16-bit precision, and TQ15'Small requires 32-bit precision to be represented correctly. As a result, V has a value of zero after this assignment.

In contrast, after the second assignment — where we assign TQ15'Delta (2^{-15}) to V — we see, as expected, that V has the same value as the *delta*.

Attributes: Fore and Aft

The Fore and Aft attributes indicate the number of characters or digits needed for displaying a value in decimal representation. To be more precise:

- The Fore attribute refers to the digits before the decimal point and it returns the number of digits plus one for the sign indicator (which is either - or space), and it's always at least two.
- The Aft attribute returns the number of decimal digits that is needed to represent the delta after the decimal point.

Let's see an example:

Listing 430: show_fixed_fore_aft.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Fixed_Fore_Aft is
   type T3_D3 is delta 10.0 ** (-3) digits 3;

   D : constant := 2.0 ** (-31);
   type TQ31 is delta D range -1.0 .. 1.0 - D;

   Dec : constant T3_D3 := -0.123;
   Fix : constant TQ31  := -TQ31'Delta;
begin
   Put_Line ("T3_D3'Fore: "
             & T3_D3'Fore'Image);
   Put_Line ("T3_D3'Aft:  "
             & T3_D3'Aft'Image);

   Put_Line ("TQ31'Fore: "
             & TQ31'Fore'Image);
   Put_Line ("TQ31'Aft:  "
             & TQ31'Aft'Image);
   Put_Line ("----");
   Put_Line ("Dec: "
             & Dec'Image);
   Put_Line ("Fix: "
             & Fix'Image);
end Show_Fixed_Fore_Aft;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Fixed_Point_Types.Fixed_Fore_Aft
MD5: d031f74d967a96dee1c6a83ff4bd14cf
```

Runtime output

```
T3_D3'Fore:  2
T3_D3'Aft:   3
TQ31'Fore:  2
TQ31'Aft:   10
----
Dec: -0.123
Fix: -0.0000000005
```

As we can see in the output of the `Dec` and `Fix` variables at the bottom, the value of `Fore` is two for both `T3_D3` and `TQ31`. This value corresponds to the length of the string "-0" displayed in the output for these variables (the first two characters of "-0.123" and "-0.0000000005").

The value of `Dec'Aft` is three, which matches the number of digits after the decimal point in "-0.123". Similarly, the value of `Fix'Aft` is 10, which matches the number of digits after the decimal point in "-0.0000000005".

Attributes of decimal fixed-point types

The attributes presented in this subsection are only available for decimal fixed-point types.

Attribute: `Digits`

`Digits` is an attribute that returns the number of significant decimal digits of a decimal fixed-point subtype. This corresponds to the value that we use for the **`digits`** in the definition of a decimal fixed-point type.

Let's see an example:

Listing 431: show_decimal_digits.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Decimal_Digits is
4     type T3_D6 is delta 10.0 ** (-3) digits 6;
5     subtype T3_D2 is T3_D6 digits 2;
6  begin
7     Put_Line ("T3_D6'Digits: "
8               & T3_D6'Digits'Image);
9     Put_Line ("T3_D2'Digits: "
10              & T3_D2'Digits'Image);
11 end Show_Decimal_Digits;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Fixed_Point_Types.Decimal_Digits
MD5: d46e67bd0f8b369918e7ab9ab4413ae7
```

Runtime output

```
T3_D6'Digits:  6
T3_D2'Digits:  2
```

In this example, T3_D6'Digits is six, which matches the value that we used for **digits** in the type definition of T3_D6. The same logic applies for subtypes, as we can see in the value of T3_D2'Digits. Here, the value is two, which was used in the declaration of the T3_D2 subtype.

Attribute: Scale

According to the Ada Reference Manual, the Scale attribute "indicates the position of the point relative to the rightmost significant digits of values" of a decimal type. For example:

- If the value of Scale is two, then there are two decimal digits after the decimal point.
- If the value of Scale is negative, that implies that the **Delta** is a power of 10 greater than 1, and it would be the number of zero digits that every value would end in.

The Scale corresponds to the N used in the **delta** 10.0 ** (-N) expression of the type declaration. For example, if we write **delta** 10.0 ** (-3) in the declaration of a type T, then the value of T'Scale is three.

Let's look at this complete example:

Listing 432: show_decimal_scale.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Decimal_Scale is
   type TM3_D6 is delta 10.0 **   3  digits 6;
   type T3_D6  is delta 10.0 ** (-3) digits 6;
   type T9_D12 is delta 10.0 ** (-9) digits 12;
begin
   Put_Line ("TM3_D6'Scale: "
             & TM3_D6'Scale'Image);
   Put_Line ("T3_D6'Scale: "
             & T3_D6'Scale'Image);
   Put_Line ("T9_D12'Scale: "
             & T9_D12'Scale'Image);
end Show_Decimal_Scale;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Fixed_Point_Types.Decimal_Scale
MD5: 56a99848cf31a9c69fe6d91ead73375a
```

Runtime output

```
TM3_D6'Scale: -3
T3_D6'Scale:  3
T9_D12'Scale:  9
```

In this example, we get the following values for the scales:

- TM3_D6'Scale = -3,
- T3_D6'Scale = 3,
- T9_D12 = 9.

As you can see, the value of Scale is directly related to the *delta* of the corresponding type declaration.

Attribute: Round

The Round attribute rounds a value of any real type to the nearest value that is a multiple of the *delta* of the decimal fixed-point type, rounding away from zero if exactly between two such multiples.

For example, if we have a type T with three digits, and we use a value with 10 digits after the decimal point in a call to T'Round, the resulting value will have three digits after the decimal point.

Note that the X input of an S'Round (X) call is a universal real value, while the returned value is of S'Base type.

Let's look at this example:

Listing 433: show_decimal_round.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Decimal_Round is
   type T3_D3 is delta 10.0 ** (-3) digits 3;
begin
   Put_Line ("T3_D3'Round (0.2774): "
             & T3_D3'Round (0.2774)'Image);
   Put_Line ("T3_D3'Round (0.2777): "
             & T3_D3'Round (0.2777)'Image);
end Show_Decimal_Round;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Fixed_Point_Types.Decimal_Round
MD5: 153d9dae52fee750da30dd9152a03c37
```

Runtime output

```
T3_D3'Round (0.2774):  0.277
T3_D3'Round (0.2777):  0.278
```

Here, the T3_D3 has a precision of three digits. Therefore, to fit this precision, 0.2774 is rounded to 0.277, and 0.2777 is rounded to 0.278.

25.7.5 Big Numbers

As we've seen before, we can define numeric types in Ada with a high degree of precision. However, these normal numeric types in Ada are limited to what the underlying hardware actually supports. For example, any signed integer type — whether defined by the language or the user — cannot have a range greater than that of System.Min_Int .. System.Max_Int because those constants reflect the actual hardware's signed integer types. In certain applications, that precision might not be enough, so we have to rely on arbitrary-precision arithmetic[111]. These so-called "big numbers" are limited conceptually only by available memory, in contrast to the underlying hardware-defined numeric types.

Ada supports two categories of big numbers: big integers and big reals — both are specified in child packages of the Ada.Numerics.Big_Numbers package:

Category	Package
Big Integers	Ada.Numerics.Big_Numbers.Big_Integers
Big Reals	Ada.Numerics.Big_Numbers.Big_Real

[111] https://en.wikipedia.org/wiki/arbitrary-precision_arithmetic

In the Ada Reference Manual

- Big Numbers[112]
- Big Integers[113]
- Big Reals[114]

Overview

Let's start with a simple declaration of big numbers:

Listing 434: show_simple_big_numbers.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

with Ada.Numerics.Big_Numbers.Big_Integers;
use  Ada.Numerics.Big_Numbers.Big_Integers;

with Ada.Numerics.Big_Numbers.Big_Reals;
use  Ada.Numerics.Big_Numbers.Big_Reals;

procedure Show_Simple_Big_Numbers is
   BI : Big_Integer;
   BR : Big_Real;
begin
   BI := 12345678901234567890;
   BR := 2.0 ** 1234;

   Put_Line ("BI: " & BI'Image);
   Put_Line ("BR: " & BR'Image);

   BI := BI + 1;
   BR := BR + 1.0;

   Put_Line ("BI: " & BI'Image);
   Put_Line ("BR: " & BR'Image);
end Show_Simple_Big_Numbers;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Big_Numbers.Simple_Big_Numbers
MD5: d25e0c73ef04b6c950f2ab63fc96a353
```

Runtime output

```

```

[112] http://www.ada-auth.org/standards/22rm/html/RM-A-5-5.html
[113] http://www.ada-auth.org/standards/22rm/html/RM-A-5-6.html
[114] http://www.ada-auth.org/standards/22rm/html/RM-A-5-7.html

In this example, we're declaring the big integer BI and the big real BR, and we're incrementing them by one.

Naturally, we're not limited to using the + operator (such as in this example). We can use the same operators on big numbers that we can use with normal numeric types. In fact, the common unary operators (+, -, **abs**) and binary operators (+, -, *, /, **, Min and Max) are available to us. For example:

Listing 435: show_simple_big_numbers_operators.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

with Ada.Numerics.Big_Numbers.Big_Integers;
use  Ada.Numerics.Big_Numbers.Big_Integers;

procedure Show_Simple_Big_Numbers_Operators is
   BI : Big_Integer;
begin
   BI := 12345678901234567890;

   Put_Line ("BI: " & BI'Image);

   BI := -BI + BI / 2;
   BI :=  BI - BI * 2;

   Put_Line ("BI: " & BI'Image);
end Show_Simple_Big_Numbers_Operators;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Big_Numbers.Simple_Big_Numbers_
 ↪Operators
MD5: c4f405e3ea916bc8a3f309acdeb0606a
```

Runtime output

```
BI:  12345678901234567890
BI:  6172839450617283945
```

In this example, we're applying the four basic operators (+, -, *, /) on big integers.

Factorial

A typical example is the factorial[115]: a sequence of the factorial of consecutive small numbers can quickly lead to big numbers. Let's take this implementation as an example:

Listing 436: factorial.ads

```
function Factorial (N : Integer)
                    return Long_Long_Integer;
```

Listing 437: factorial.adb

```
function Factorial (N : Integer)
                    return Long_Long_Integer is
   Fact : Long_Long_Integer := 1;
begin
```

(continues on next page)

[115] https://en.wikipedia.org/wiki/Factorial

(continued from previous page)

```
   for I in 2 .. N loop
      Fact := Fact * Long_Long_Integer (I);
   end loop;

   return Fact;
end Factorial;
```

Listing 438: show_factorial.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Factorial;

procedure Show_Factorial is
begin
   for I in 1 .. 50 loop
      Put_Line (I'Image & "! = "
                & Factorial (I)'Image);
   end loop;
end Show_Factorial;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Big_Numbers.Factorial_Integer

raised CONSTRAINT_ERROR : factorial.adb:6 overflow check failed
```

Here, we're using **Long_Long_Integer** for the computation and return type of the `Factorial` function. (We're using **Long_Long_Integer** because its range is probably the biggest possible on the machine, although that is not necessarily so.) The last number we're able to calculate before getting an exception is *20!*, which basically shows the limitation of standard integers for this kind of algorithm. If we use big integers instead, we can easily display all numbers up to *50!* (and more!):

Listing 439: factorial.ads

```
pragma Ada_2022;

with Ada.Numerics.Big_Numbers.Big_Integers;
use  Ada.Numerics.Big_Numbers.Big_Integers;

function Factorial (N : Integer)

```

As we can see in this example, replacing the **Long_Long_Integer** type by the Big_Integer type fixes the problem (the runtime exception) that we had in the previous version. (Note that we're using the To_Big_Integer function to convert from **Integer** to Big_Integer: we discuss these conversions next.)

Note that there is a limit to the upper bounds for big integers. However, this limit isn't dependent on the hardware types — as it's the case for normal numeric types —, but rather compiler specific. In other words, the compiler can decide how much memory it wants to use to represent big integers.

Conversions

Most probably, we want to mix big numbers and *standard* numbers (i.e. integer and real numbers) in our application. In this section, we talk about the conversion between big numbers and standard types.

Validity

The package specifications of big numbers include subtypes that *ensure* that a actual value of a big number is valid:

Type	Subtype for valid values
Big Integers	`Valid_Big_Integer`
Big Reals	`Valid_Big_Real`

These subtypes include a contract for this check. For example, this is the definition of the `Valid_Big_Integer` subtype:

```
subtype Valid_Big_Integer is Big_Integer
  with Dynamic_Predicate =>
           Is_Valid (Valid_Big_Integer),
       Predicate_Failure =>
           (raise Program_Error);
```

Any operation on big numbers is actually performing this validity check (via a call to the `Is_Valid` function). For example, this is the addition operator for big integers:

```
function "+" (L, R : Valid_Big_Integer)
              return Valid_Big_Integer;
```

As we can see, both the input values to the operator as well as the return value are expected to be valid — the `Valid_Big_Integer` subtype triggers this check, so to say. This approach ensures that an algorithm operating on big numbers won't be using invalid values.

Conversion functions

These are the most important functions to convert between big number and *standard* types:

Category	To big number	From big number
Big Integers	• `To_Big_Integer`	• `To_Integer` (**`Integer`**) • `From_Big_Integer` (other integer types)
Big Reals	• `To_Big_Real` (floating-point types or fixed-point types)	• `From_Big_Real`
	• `To_Big_Real` (`Valid_Big_Integer`) • `To_Real` (**`Integer`**)	• `Numerator`, `Denominator` (**`Integer`**)

In the following sections, we discuss these functions in more detail.

Big integer to integer

We use the To_Big_Integer and To_Integer functions to convert back and forth between Big_Integer and **Integer** types:

Listing 442: show_simple_big_integer_conversion.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

with Ada.Numerics.Big_Numbers.Big_Integers;
use  Ada.Numerics.Big_Numbers.Big_Integers;

procedure Show_Simple_Big_Integer_Conversion is
   BI : Big_Integer;
   I  : Integer := 10000;
begin
   BI := To_Big_Integer (I);
   Put_Line ("BI: " & BI'Image);

   I := To_Integer (BI + 1);
   Put_Line ("I:  " & I'Image);
end Show_Simple_Big_Integer_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Big_Numbers.Simple_Big_Integer_
↪Conversion
MD5: 84f55568b26bf6c1c6f0b06391e8ac0f
```

Runtime output

```
BI:  10000
I:   10001
```

In addition, we can use the generic Signed_Conversions and Unsigned_Conversions packages to convert between Big_Integer and any signed or unsigned integer types:

Listing 443: show_arbitrary_big_integer_conversion.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

with Ada.Numerics.Big_Numbers.Big_Integers;
use  Ada.Numerics.Big_Numbers.Big_Integers;

procedure Show_Arbitrary_Big_Integer_Conversion is

   type Mod_32_Bit is mod 2 ** 32;

   package Long_Long_Integer_Conversions is new
     Signed_Conversions (Long_Long_Integer);
   use Long_Long_Integer_Conversions;

   package Mod_32_Bit_Conversions is new
     Unsigned_Conversions (Mod_32_Bit);
   use Mod_32_Bit_Conversions;
```

(continues on next page)

(continued from previous page)

```
19
20    BI   : Big_Integer;
21    LLI  : Long_Long_Integer := 10000;
22    U_32 : Mod_32_Bit        := 2 ** 32 + 1;
23
24 begin
25    BI := To_Big_Integer (LLI);
26    Put_Line ("BI:   " & BI'Image);
27
28    LLI := From_Big_Integer (BI + 1);
29    Put_Line ("LLI:  " & LLI'Image);
30
31    BI := To_Big_Integer (U_32);
32    Put_Line ("BI:   " & BI'Image);
33
34    U_32 := From_Big_Integer (BI + 1);
35    Put_Line ("U_32: " & U_32'Image);
36
37 end Show_Arbitrary_Big_Integer_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Big_Numbers.Arbitrary_Big_
 ↪Integer_Conversion
MD5: 21466010594cf09f37776bc8cb61ee9c
```

Runtime output

```
BI:    10000
LLI:   10001
BI:    1
U_32:  2
```

In this examples, we declare the `Long_Long_Integer_Conversions` and the `Mod_32_Bit_Conversions` to be able to convert between big integers and the **`Long_Long_Integer`** and the `Mod_32_Bit` types, respectively.

Note that, when converting from big integer to integer, we used the `To_Integer` function, while, when using the instances of the generic packages, the function is named `From_Big_Integer`.

Big real to floating-point types

When converting between big real and floating-point types, we have to instantiate the generic `Float_Conversions` package:

Listing 444: show_big_real_floating_point_conversion.adb

```
1  pragma Ada_2022;
2
3  with Ada.Text_IO; use Ada.Text_IO;
4
5  with Ada.Numerics.Big_Numbers.Big_Reals;
6  use  Ada.Numerics.Big_Numbers.Big_Reals;
7
8  procedure Show_Big_Real_Floating_Point_Conversion
9  is
10    type D10 is digits 10;
11
```

(continues on next page)

(continued from previous page)

```
12    package D10_Conversions is new
13      Float_Conversions (D10);
14    use D10_Conversions;
15
16    package Long_Float_Conversions is new
17      Float_Conversions (Long_Float);
18    use Long_Float_Conversions;
19
20    BR  : Big_Real;
21    LF  : Long_Float := 2.0;
22    F10 : D10        := 1.999;
23
24 begin
25    BR := To_Big_Real (LF);
26    Put_Line ("BR:   " & BR'Image);
27
28    LF := From_Big_Real (BR + 1.0);
29    Put_Line ("LF:   " & LF'Image);
30
31    BR := To_Big_Real (F10);
32    Put_Line ("BR:   " & BR'Image);
33
34    F10 := From_Big_Real (BR + 0.1);
35    Put_Line ("F10:  " & F10'Image);
36
37 end Show_Big_Real_Floating_Point_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Big_Numbers.Big_Real_Floating_
↪Point_Conversion
MD5: 531c59a06b46c2074bc5378b5dcddd35
```

Runtime output

```
BR:    2.000
LF:    3.00000000000000E+00
BR:    1.999
F10:   2.099000000E+00
```

In this example, we declare the `D10_Conversions` and the `Long_Float_Conversions` to be able to convert between big reals and the custom floating-point type `D10` and the **`Long_Float`** type, respectively. To do that, we use the `To_Big_Real` and the `From_Big_Real` functions.

Big real to fixed-point types

When converting between big real and ordinary fixed-point types, we have to instantiate the generic `Fixed_Conversions` package:

Listing 445: show_big_real_fixed_point_conversion.adb

```
1  pragma Ada_2022;
2
3  with Ada.Text_IO; use Ada.Text_IO;
4
5  with Ada.Numerics.Big_Numbers.Big_Reals;
6  use  Ada.Numerics.Big_Numbers.Big_Reals;
7
```

(continues on next page)

(continued from previous page)

```
8  procedure Show_Big_Real_Fixed_Point_Conversion
9  is
10    D : constant := 2.0 ** (-31);
11    type TQ31 is delta D range -1.0 .. 1.0 - D;
12
13    package TQ31_Conversions is new
14      Fixed_Conversions (TQ31);
15    use TQ31_Conversions;
16
17    BR   : Big_Real;
18    FQ31 : TQ31 := 0.25;
19
20 begin
21    BR := To_Big_Real (FQ31);
22    Put_Line ("BR:   " & BR'Image);
23
24    FQ31 := From_Big_Real (BR * 2.0);
25    Put_Line ("FQ31: " & FQ31'Image);
26
27 end Show_Big_Real_Fixed_Point_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Big_Numbers.Big_Real_Fixed_Point_
 ↪Conversion
MD5: 94a87bfc6ffad70f757cfc8b6ae32530
```

Runtime output

```
BR:    0.250
FQ31:  0.5000000000
```

In this example, we declare the `TQ31_Conversions` to be able to convert between big reals and the custom fixed-point type `TQ31` type. Again, we use the `To_Big_Real` and the `From_Big_Real` functions for the conversions.

Note that there's no direct way to convert between decimal fixed-point types and big real types. (Of course, you could perform this conversion indirectly by using a floating-point or an ordinary fixed-point type in between.)

Big reals to (big) integers

We can also convert between big reals and big integers (or standard integers):

Listing 446: show_big_real_big_integer_conversion.adb

```
1  pragma Ada_2022;
2
3  with Ada.Text_IO; use Ada.Text_IO;
4
5  with Ada.Numerics.Big_Numbers.Big_Integers;
6  use  Ada.Numerics.Big_Numbers.Big_Integers;
7
8  with Ada.Numerics.Big_Numbers.Big_Reals;
9  use  Ada.Numerics.Big_Numbers.Big_Reals;
10
11 procedure Show_Big_Real_Big_Integer_Conversion
12 is
13    I  : Integer;
```

(continues on next page)

(continued from previous page)

```
   BI : Big_Integer;
   BR : Big_Real;

begin
   I  := 12345;
   BR := To_Real (I);
   Put_Line ("BR (from I):  " & BR'Image);

   BI := 123456;
   BR := To_Big_Real (BI);
   Put_Line ("BR (from BI): " & BR'Image);

end Show_Big_Real_Big_Integer_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Big_Numbers.Big_Real_Big_Integer_
↪Conversion
MD5: 9a217c0551bc80269596d7217d2be879
```

Runtime output

```
BR (from I):  12345.000
BR (from BI): 123456.000
```

Here, we use the `To_Real` and the `To_Big_Real` and functions for the conversions.

String conversions

In addition to that, we can use string conversions:

Listing 447: show_big_number_string_conversion.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

with Ada.Numerics.Big_Numbers.Big_Integers;
use  Ada.Numerics.Big_Numbers.Big_Integers;

with Ada.Numerics.Big_Numbers.Big_Reals;
use  Ada.Numerics.Big_Numbers.Big_Reals;

procedure Show_Big_Number_String_Conversion
is
   BI : Big_Integer;
   BR : Big_Real;
begin
   BI := From_String ("12345678901234567890");
   BR := From_String ("12345678901234567890.0");

   Put_Line ("BI: "
             & To_String (Arg   => BI,
                          Width => 5,
                          Base => 2));
   Put_Line ("BR: "
             & To_String (Arg   => BR,
                          Fore  => 2,
                          Aft   => 6,
```

(continues on next page)

(continued from previous page)

```
27                            Exp   => 18));
28 end Show_Big_Number_String_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Big_Numbers.Big_Number_String_
 ↪Conversion
MD5: 3819df198ec140b457fa56a65d8876f9
```

Runtime output

```
BI:  2#10101011010101001010100110001100111010110001111100001010110100 10#
BR: 12.345678E+18
```

In this example, we use the `From_String` to convert a string to a big number. Note that the `From_String` function is actually called when converting a literal — because of the corresponding aspect for user-defined literals in the definitions of the `Big_Integer` and the `Big_Real` types.

For further reading...

Big numbers are implemented using *user-defined literals* (page 339), which we discussed previously. In fact, these are the corresponding type declarations:

```
--  Declaration from
--  Ada.Numerics.Big_Numbers.Big_Integers;

type Big_Integer is private
  with Integer_Literal => From_Universal_Image,
       Put_Image       => Put_Image;

function From_Universal_Image
  (Arg : String)
  return Valid_Big_Integer
    renames From_String;

--  Declaration from
--  Ada.Numerics.Big_Numbers.Big_Reals;

type Big_Real is private
  with Real_Literal => From_Universal_Image,
       Put_Image    => Put_Image;

function From_Universal_Image
  (Arg : String)
   return Valid_Big_Real
     renames From_String;
```

As we can see in these declarations, the `From_String` function renames the `From_Universal_Image` function, which is being used for the user-defined literals.

Also, we call the `To_String` function to get a string for the big numbers. Naturally, using the `To_String` function instead of the `Image` attribute — as we did in previous examples — allows us to customize the format of the string that we display in the user message.

Other features of big integers

Now, let's look at two additional features of big integers:

- the natural and positive subtypes, and
- other available operators and functions.

Big positive and natural subtypes

Similar to integer types, big integers have the `Big_Natural` and `Big_Positive` subtypes to indicate natural and positive numbers. However, in contrast to the **`Natural`** and **`Positive`** subtypes, the `Big_Natural` and `Big_Positive` subtypes are defined via predicates rather than the simple ranges of normal (ordinary) numeric types:

```
subtype Natural  is
  Integer range 0 .. Integer'Last;

subtype Positive is
  Integer range 1 .. Integer'Last;

subtype Big_Natural is Big_Integer
  with Dynamic_Predicate =>
         (if Is_Valid (Big_Natural)
            then Big_Natural >= 0),
       Predicate_Failure =>
         (raise Constraint_Error);

subtype Big_Positive is Big_Integer
  with Dynamic_Predicate =>
         (if Is_Valid (Big_Positive)
            then Big_Positive > 0),
       Predicate_Failure =>
         (raise Constraint_Error);
```

Therefore, we cannot simply use attributes such as `Big_Natural'First`. However, we can use the subtypes to ensure that a big integer is in the expected (natural or positive) range:

Listing 448: show_big_positive_natural.adb

```
1  pragma Ada_2022;
2
3  with Ada.Text_IO; use Ada.Text_IO;
4
5  with Ada.Numerics.Big_Numbers.Big_Integers;
6  use  Ada.Numerics.Big_Numbers.Big_Integers;
7
8  procedure Show_Big_Positive_Natural is
9     BI, D, N : Big_Integer;
10 begin
11    D  := 3;
12    N  := 2;
13    BI := Big_Natural (D / Big_Positive (N));
14
15    Put_Line ("BI: " & BI'Image);
16 end Show_Big_Positive_Natural;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Big_Numbers.Big_Positive_Natural
MD5: 6debfb86e11c7bfa3dbaf2d81eb24360
```

Runtime output

```
BI:  1
```

By using the `Big_Natural` and `Big_Positive` subtypes in the calculation above (in the assignment to `BI`), we ensure that we don't perform a division by zero, and that the result of the calculation is a natural number.

Other operators for big integers

We can use the **mod** and **rem** operators with big integers:

Listing 449: show_big_integer_rem_mod.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

with Ada.Numerics.Big_Numbers.Big_Integers;
use  Ada.Numerics.Big_Numbers.Big_Integers;

procedure Show_Big_Integer_Rem_Mod is
   BI : Big_Integer;
begin
   BI := 145 mod (-4);
   Put_Line ("BI (mod): " & BI'Image);

   BI := 145 rem (-4);
   Put_Line ("BI (rem): " & BI'Image);
end Show_Big_Integer_Rem_Mod;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Big_Numbers.Big_Integer_Rem_Mod
MD5: 079f2f88f98f52e81ae7719d4629ca08
```

Runtime output

```
BI (mod): -5
BI (rem):  1
```

In this example, we use the **mod** and **rem** operators in the assignments to `BI`.

Moreover, there's a `Greatest_Common_Divisor` function for big integers which, as the name suggests, calculates the greatest common divisor of two big integer values:

Listing 450: show_big_integer_greatest_common_divisor.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

with Ada.Numerics.Big_Numbers.Big_Integers;
use  Ada.Numerics.Big_Numbers.Big_Integers;

procedure Show_Big_Integer_Greatest_Common_Divisor
is
   BI : Big_Integer;
begin
   BI := Greatest_Common_Divisor (145, 25);
   Put_Line ("BI: " & BI'Image);
```

(continues on next page)

(continued from previous page)

```
14
15 end Show_Big_Integer_Greatest_Common_Divisor;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Big_Numbers.Big_Integer_Greatest_
 ↪Common_Divisor
MD5: b2d0098fcca6f949f228276b4d862b56
```

Runtime output

```
BI:  5
```

In this example, we retrieve the greatest common divisor of 145 and 25 (i.e.: 5).

Big real and quotients

An interesting feature of big reals is that they support quotients. In fact, we can simply assign *2/3* to a big real variable. (Note that we're able to omit the decimal points, as we write `2/3` instead of `2.0 / 3.0`.) For example:

Listing 451: show_big_real_quotient_conversion.adb

```
1  pragma Ada_2022;
2
3  with Ada.Text_IO; use Ada.Text_IO;
4
5  with Ada.Numerics.Big_Numbers.Big_Reals;
6  use  Ada.Numerics.Big_Numbers.Big_Reals;
7
8  procedure Show_Big_Real_Quotient_Conversion
9  is
10    BR   : Big_Real;
11 begin
12    BR := 2 / 3;
13    --  Same as:
14    --  BR := From_Quotient_String ("2 / 3");
15
16    Put_Line ("BR:   " & BR'Image);
17
18    Put_Line ("Q:    "
19              & To_Quotient_String (BR));
20
21    Put_Line ("Q numerator:    "
22              & Numerator (BR)'Image);
23    Put_Line ("Q denominator:  "
24              & Denominator (BR)'Image);
25 end Show_Big_Real_Quotient_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Big_Numbers.Big_Real_Quotient_
 ↪Conversion
MD5: 4ef8355332e73a1f7da036b8e1e4b898
```

Runtime output

```
BR:    0.666
Q:     2 /  3
```

(continues on next page)

(continued from previous page)

```
Q numerator:     2
Q denominator:   3
```

In this example, we assign `2 / 3` to BR — we could have used the `From_Quotient_String` function as well. Also, we use the `To_Quotient_String` to get a string that represents the quotient. Finally, we use the `Numerator` and `Denominator` functions to retrieve the values, respectively, of the numerator and denominator of the quotient (as big integers) of the big real variable.

Range checks

Previously, we've talked about the `Big_Natural` and `Big_Positive` subtypes. In addition to those subtypes, we have the `In_Range` function for big numbers:

Listing 452: show_big_numbers_in_range.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

with Ada.Numerics.Big_Numbers.Big_Integers;
use  Ada.Numerics.Big_Numbers.Big_Integers;

with Ada.Numerics.Big_Numbers.Big_Reals;
use  Ada.Numerics.Big_Numbers.Big_Reals;

procedure Show_Big_Numbers_In_Range is

   BI : Big_Integer;
   BR : Big_Real;

   BI_From : constant Big_Integer := 0;
   BI_To   : constant Big_Integer := 1024;

   BR_From : constant Big_Real := 0.0;
   BR_To   : constant Big_Real := 1024.0;

begin
   BI := 1023;
   BR := 1023.9;

   if In_Range (BI, BI_From, BI_To) then
      Put_Line ("BI ("
                & BI'Image
                & ") is in the "
                & BI_From'Image
                & " .. "
                & BI_To'Image
                & " range");
   end if;

   if In_Range (BR, BR_From, BR_To) then
      Put_Line ("BR ("
                & BR'Image
                & ") is in the "
                & BR_From'Image
                & " .. "
                & BR_To'Image
                & " range");
```

(continues on next page)

(continued from previous page)

```
44    end if;
45
46 end Show_Big_Numbers_In_Range;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Data_Types.Numerics.Big_Numbers.Big_Numbers_In_Range
MD5: 9c85e8374db1095142260f45c4c4e7e1
```

Runtime output

```
BI ( 1023) is in the  0 ..  1024 range
BR (1023.900) is in the  0.000 .. 1024.000 range
```

In this example, we call the In_Range function to check whether the big integer number (BI) and the big real number (BR) are in the range between 0 and 1024.

CHAPTER

TWENTYSIX

CONTROL FLOW

26.1 Expressions

26.1.1 Expressions: Definition

According to the Ada Reference Manual, an expression "is a formula that defines the computation or retrieval of a value." Also, when an expression is evaluated, the computed or retrieved value always has an associated type known at compile-time.

Even though the definition above is very simple, Ada expressions are actually very flexible — and they can also be very complex. In fact, if you read the corresponding section[116] of the Ada Reference Manual, you'll quickly discover that they include elements such as relations, membership choices, terms and primaries. Some of these are classic elements of expressions in programming languages, although some of their forms are unique to Ada. In this section, we present examples of just some of these elements. For a complete overview, please refer to the Reference Manual.

In the Ada Reference Manual

- 4.4 Expressions[117]

Relations and simple expressions

Expressions usually consist of relations, which in turn consist of simple expressions. (There are more details to this, but we'll keep it simple for the moment.) Let's see a code example with a few expressions, which we dissect into the corresponding grammatical elements (we're going to discuss them later):

Listing 1: show_expression_elements.adb

```
1  procedure Show_Expression_Elements is
2     type Mode is (Off, A, B, C, D);
3
4     pragma Unreferenced (B, C, D);
5
6     subtype Active_Mode is Mode
7       range Mode'Succ (Off) .. Mode'Last;
8
9     M1, M2 : Mode;
10    Dummy  : Boolean;
11 begin
```

(continues on next page)

[116] http://www.ada-auth.org/standards/22rm/html/RM-4-4.html
[117] http://www.ada-auth.org/standards/22rm/html/RM-4-4.html

(continued from previous page)

```
12      M1 := A;
13
14      Dummy :=
15          M1 in Active_Mode
16                   and then M2 in Off | A;
17      --
18      --    ^^^^^^^^^^^^^^^^^ relation
19      --
20      --                       ^^^^^^^^^^^^^^ relation
21      --    ^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^
22      --                                    expression
23
24      Dummy :=
25          M1 in Active_Mode;
26      --  ^^ name
27      --  ^^ primary
28      --  ^^ factor
29      --  ^^ term
30      --  ^^ simple expression
31      --
32      --         ^^^^^^^^^^^ membership choice
33      --         ^^^^^^^^^^^ membership choice list
34      --
35      --  ^^^^^^^^^^^^^^^^^ relation
36      --  ^^^^^^^^^^^^^^^^^ expression
37
38      Dummy :=
39          M2 in Off | A;
40      --  ^^ name
41      --  ^^ primary
42      --  ^^ factor
43      --  ^^ term
44      --  ^^ simple expression
45      --
46      --         ^^^ membership choice
47      --               ^ membership choice
48      --         ^^^^^^^ membership choice list
49      --
50      --  ^^^^^^^^^^^^^ relation
51      --  ^^^^^^^^^^^^^ expression
52
53  end Show_Expression_Elements;
```

Code block metadata

 ↪Expression_Elements
MD5: a22e6f2d2bc181ce77097a1de204eb62
```

Build output

```
show_expression_elements.adb:9:08: warning: variable "M2" is read but never␣
 ↪assigned [-gnatwv]
```

In this code example, we see three expressions. As we mentioned earlier, every expression has a type; here, the type of each expression is **Boolean**.

The first expression (`M1 in Active_Mode and then M2 in Off | A`) consists of two relations: `M1 in Active_Mode` and `M2 in Off | A`. Let's discuss some of the details.

The `M1 in Active_Mode` relation consists of the simple expression `M1` and the membership choice list `Active_Mode`. (Here, the **in** keyword is part of the relation definition.) Also, as

we see in the comments of the source code, the simple expression `M1` is, at the same time, a term, a factor, a primary and a name.

Let's briefly talk about this chain of syntactic elements for simple expressions. Very roughly said, this is how we can break up simple expressions:

- a simple expression consists of terms;
- a term consists of factors;
- a factor consists of primaries;
- a primary can be one of those:
  - a numeric literal;
  - **`null`**;
  - a string literal;
  - *an aggregate* (page 435);
  - a name;
  - an allocator (like **`new Integer`**);
  - *a parenthesized expression* (page 585);
  - *a conditional expression* (page 588);
  - *a quantified expression* (page 590);
  - *a declare expression* (page 594).

For further reading...

The definition of simple expressions we've just seen is very simplified. In actuality, these are the grammatical elements specified in the Ada Reference Manual:

```
simple_expression ::=
  [unary_adding_operator] term {binary_adding_operator term}

term ::= factor {multiplying_operator factor}

factor ::= primary [** primary] | abs primary | not primary

primary ::=
  numeric_literal | null | string_literal | aggregate
| name | allocator | (expression)
| (conditional_expression) | (quantified_expression)
| (declare_expression)
```

Later on in this chapter, we discuss *conditional expressions* (page 588), *quantified expressions* (page 590) and *declare expressions* (page 594) in more details.

In the relation `M2 in Off | A` from the code example, `Off | A` is a membership choice list, and `Off` and `A` are membership choices.

For further reading...

Relations can actually be much more complicated than the one we just saw. In fact, this is the definition from the Ada Reference Manual:

```
expression ::=
     relation {and relation}
   | relation {and then relation}
```

(continues on next page)

(continued from previous page)

```
   | relation {or relation}
   | relation {or else relation}
   | relation {xor relation}

relation ::=
     simple_expression
       [relational_operator simple_expression]
   | simple_expression [not] in
       membership_choice_list
   | raise_expression
```

Again, for more details, please refer to the section on expressions[118] of the Ada Reference Manual.

In the Ada Reference Manual

- 4.4 Expressions[119]
- 4.5.2 Relational Operators and Membership Tests[120]

Numeric expressions

The expressions we've seen so far had the **Boolean** type. Although much of the grammar described in the Manual exists exclusively for Boolean operations, we can also write numeric expressions such as the following one:

Listing 2: show_numeric_expressions.adb

```
procedure Show_Numeric_Expressions is
   C1    : constant Integer := 5;
   Dummy :          Integer;
begin
   Dummy :=
       -2 ** 4 + 3 * C1 ** 8;
   --                      ^ numeric literal
   --                      ^ primary
   --                ^^      name
   --                ^^      primary
   --                ^^^^^^^ factor
   --              ^ multiplying operator
   --            ^           numeric literal
   --            ^           primary
   --            ^           factor
   --            ^^^^^^^^^^^ term
   --
   --        ^ numeric literal
   --        ^ primary
   --    ^ numeric literal
   --    ^ primary
   --    ^^^^^^              factor
   --    ^^^^^^              term
   --          ^ binary adding operator
   --  ^ unary adding operator
```

(continues on next page)

↪Numeric_Expressions
MD5: a3c902c7aa5b0afe30ae220256c3306a
```

In this code example, the expression `- 2 ** 4 + 3 * C1 ** 8` consists of just a single simple expression. (Note that simple expressions do not have to be "simple".) This simple expression consists of two terms: `2 ** 4` and `3 * C1 ** 8`. While the `2 ** 4` term is also a single factor, the `3 * C1 ** 8` term consists of two factors: `3` and `C1 ** 8`. Both the `2 ** 4` and the `C1 ** 8` factors consists of two primaries each:

- the `2 ** 4` factor has the primaries `2` and `4`,
- the `C1 ** 8` factor has the primaries `C1` and `8`.

In the Ada Reference Manual

- 4.4 Expressions[121]

Other expressions

Expressions aren't limited to the **Boolean** type or to numeric types. Indeed, expressions can be of any type, and the definition of primaries we've seen earlier on already hints in this direction — as it includes elements such as allocators. Because expressions are very flexible, covering all possible variations and combinations in this section is out of scope. Again, please refer to the section on expressions[122] of the Ada Reference Manual for further details.

Parenthesized expression

An interesting aspect of primaries is that, by using parentheses, we can embed an expression inside another expression. As an example, let's discuss the following expression and its elements:

Listing 3: show_parenthesized_expressions.adb

```
procedure Show_Parenthesized_Expressions is
   C1 : constant Integer := 4;
   C2 : constant Integer := 5;

   Dummy : Integer;
begin
   Dummy :=
       (2 + C1) * C2;
   --      ^^       name
   --      ^^       primary
```

(continues on next page)

[121] http://www.ada-auth.org/standards/22rm/html/RM-4-4.html
[122] http://www.ada-auth.org/standards/22rm/html/RM-4-4.html

(continued from previous page)

```
   --        ^^        factor
   --        ^^        term
   --
   --     ^            numeric literal
   --     ^            primary
   --     ^            factor
   --     ^            term
   --
   --       ^          binary adding operator
   --   ^^^^^^^^       simple expression
   --
   --   ^^^^^^^^       expression
   --   ^^^^^^^^       primary
   --   ^^^^^^^^       factor
   --
   --               ^^ factor
   --   ^^^^^^^^^^^^^^ term
   --
   --   ^^^^^^^^^^^^^^ simple expression
   --
   --   ^^^^^^^^^^^^^^ expression
end Show_Parenthesized_Expressions;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Expressions_Definition.
 ↪Parenthesized_Expressions
MD5: 5871d2b0cd33e4f562b96381e0f0d293
```

In this example, we first start with the single expression `(2 + C1) * C2`, which is also a simple expression consisting of just one term, which consists of two factors: `(2 + C1)` and `C2`. The `(2 + C1)` factor is also a primary. Now, because of the parentheses, we identify that the primary `(2 + C1)` is an expression that is embedded in another expression.

Important

To be fair, the existence of parentheses in a primary could also indicate other kinds of expressions, such as conditional or quantified expressions. However, differentiating between them is straightforward, as we'll see later on in this chapter.

We then proceed to parse the `(2 + C1)` expression, which consists of the terms `2` and `C1`. As we've seen in the comments of the code example, each of these terms consists of one factor, which consists of one primary. In the end, after parsing the primaries, we identify that `2` is a numeric literal and `C1` is a name.

Note that the usage of parentheses might lead to situations where we have expressions in potentially unsuspected places. For example, consider the following code example:

Listing 4: show_name_in_expression.adb

```
procedure Show_Name_In_Expression is
   type Mode is (Off, A, B, C, D);

   M1 : Mode;
begin
   M1 := A;

   case M1 is
     when Off | D   =>
```

(continues on next page)

(continued from previous page)

```
      null;
   when A | B | C =>
      M1 := D;
end case;

end Show_Name_In_Expression;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Expressions_Definition.Name_
↪In_Expression
MD5: ec8fcbc511e6a372da4f0ad99d2619a5
```

Here, the case statement expects a selecting expression. In this case, M1 is identified as a name — after being identified as a relation, a simple expression, a term, a factor and a primary.

However, if we replace `case M1 is` by `case (M1) is`, (M1) is identified as a parenthesized expression, not as a name! This parenthesized expression is first parsed and evaluated, which might have implications in case statements, as we'll see *in another chapter* (page 612).

Let's look at another example, this time with a subprogram call:

Listing 5: increment_by_one.ads

```
procedure Increment_By_One (I : in out Integer);
```

Listing 6: increment_by_one.adb

```
procedure Increment_By_One (I : in out Integer) is
begin
   I := I + 1;
end Increment_By_One;
```

Listing 7: show_name_in_expression.adb

```
with Increment_By_One;

procedure Show_Name_In_Expression is
   V : Integer := 0;
begin
   Increment_By_One ((V));
end Show_Name_In_Expression;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Expressions_Definition.Name_
↪In_Expression
MD5: 4805df49dc702e5cb365252e58742dd2
```

Build output

```
show_name_in_expression.adb:6:23: error: actual for "I" must be a variable
gprbuild: *** compilation phase failed
```

The `Increment_By_One` procedure from this example expects a variable as an actual parameter because the parameter mode is `in out`. However, the `(V)` in the call to the procedure is interpreted as an expression, so we end up providing a value — the result of the expression — as the actual parameter instead of the `V` variable. Naturally, this is a compilation error. (Of course, writing `Increment_By_One (V)` fixes the error.)

26.1.2 Conditional Expressions

As we've seen before, we can write simple expressions such as `I = 0` or `D.Valid`. A conditional expression, as the name implies, is an expression that contains a condition. This might be an "if-expression" (in the **`if ... then ... else`** form) or a "case-expression" (in the **`case ... is when`** => form).

The `Max` function in the following code example is an expression function implemented with a conditional expression — an if-expression, to be more precise:

Listing 8: expr_func.ads

```
package Expr_Func is

   function Max (A, B : Integer) return Integer is
     (if A >= B then A else B);

end Expr_Func;
```

Let's say we have a system with four states `Off`, `On`, `Waiting`, and `Invalid`. For this system, we want to implement a function named `Toggled` that returns the *toggled* value of a state `S`. If the current value of `S` is either `Off` or `On`, the function toggles from `Off` to `On` (or from `On` to `Off`). For other values, the state remains unchanged — i.e. the returned value is the same as the input value. This is the implementation using a conditional expression:

Listing 9: expr_func.ads

```
package Expr_Func is

   type State is (Off, On, Waiting, Invalid);

   function Toggled (S : State) return State is
     (if S = Off
       then On
       elsif S = On
         then Off
         else S);

end Expr_Func;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Conditional_Expressions.
 ↪Conditional_If_Expressions_1
MD5: 7a99711afecc0b481557f9874dfbf4de
```

As you can see, if-expressions may contain an **`elsif`** branch (and therefore be more complicated).

The code above corresponds to this more verbose version:

Listing 10: expr_func.ads

```
package Expr_Func is

   type State is (Off, On, Waiting, Invalid);

   function Toggled (S : State) return State;

end Expr_Func;
```

Listing 11: expr_func.adb

```
package body Expr_Func is

   function Toggled (S : State) return State is
   begin
      if S = Off then
         return On;
      elsif S = On then
         return Off;
      else
         return S;
      end if;
   end Toggled;

end Expr_Func;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Conditional_Expressions.
 ↪Conditional_If_Expressions_2
MD5: 9e6cdf53c9c934f37e5717e1d230615a
```

If we compare the if-block of this code example to the if-expression of the previous example, we notice that the if-expression is just a simplified version without the **return** keyword and the **end if;**. In fact, converting an if-block to an if-expression is quite straightforward.

We could also replace the if-expression used in the Toggled function above with a case-expression. For example:

Listing 12: expr_func.ads

```
package Expr_Func is

   type State is (Off, On, Waiting, Invalid);

   function Toggled (S : State) return State is
     (case S is
       when Off    => On,
       when On     => Off,
       when others => S);

end Expr_Func;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Conditional_Expressions.
 ↪Conditional_Case_Expressions_1
MD5: 0dd3a86f0872d1e8c3a81f7a17c44bd5
```

Note that we use commas in case-expressions to separate the alternatives (the **when** expressions). The code above corresponds to this more verbose version:

Listing 13: expr_func.ads

```
package Expr_Func is

   type State is (Off, On, Waiting, Invalid);

   function Toggled (S : State) return State;

end Expr_Func;
```

Listing 14: expr_func.adb

```
package body Expr_Func is

   function Toggled (S : State) return State is
   begin
      case S is
         when Off    => return On;
         when On     => return Off;
         when others => return S;
      end case;
   end Toggled;

end Expr_Func;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Conditional_Expressions.
 ↪Conditional_Case_Expressions_2
MD5: db6a0737e3931c83c31f53e4da3d8a2b
```

If we compare the case block of this code example to the case-expression of the previous example, we notice that the case-expression is just a simplified version of the case block without the **return** keyword and the **end case;**, and with alternatives separated by commas instead of semicolons.

In the Ada Reference Manual

- 4.5.7 Conditional Expressions[123]

26.1.3 Quantified Expressions

Quantified expressions are **for** expressions using a quantifier — which can be either **all** or **some** — and a predicate. This kind of expressions let us formalize statements such as:

- "all values of array A must be zero" into `for all I in A'Range => A (I) = 0`, and
- "at least one value of array A must be zero" into `for some I in A'Range => A (I) = 0`.

In the quantified expression `for all I in A'Range => A (I) = 0`, the quantifier is **all** and the predicate is `A (I) = 0`. In the second expression, the quantifier is **some**. The result of a quantified expression is always a Boolean value.

For example, we could use the quantified expressions above and implement these two functions:

- `Is_Zero`, which checks whether all components of an array A are zero, and
- `Has_Zero`, which checks whether array A has at least one component of the array A is zero.

This is the complete code:

[123] http://www.ada-auth.org/standards/22rm/html/RM-4-5-7.html

Listing 15: int_arrays.ads

```
package Int_Arrays is

   type Integer_Arr is
     array (Positive range <>) of Integer;

   function Is_Zero (A : Integer_Arr)
                     return Boolean is
      (for all I in A'Range => A (I) = 0);

   function Has_Zero (A : Integer_Arr)
                      return Boolean is
      (for some I in A'Range => A (I) = 0);

   procedure Display_Array (A    : Integer_Arr;
                            Name : String);

end Int_Arrays;
```

Listing 16: int_arrays.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Int_Arrays is

   procedure Display_Array (A    : Integer_Arr;
                            Name : String) is
   begin
      Put (Name & ": ");
      for E of A loop
         Put (E'Image & " ");
      end loop;
      New_Line;
   end Display_Array;

end Int_Arrays;
```

Listing 17: test_int_arrays.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Int_Arrays;  use Int_Arrays;

procedure Test_Int_Arrays is
   A : Integer_Arr := (0, 0, 1);
begin
   Display_Array (A, "A");
   Put_Line ("Is_Zero: "
             & Boolean'Image (Is_Zero (A)));
   Put_Line ("Has_Zero: "
             & Boolean'Image (Has_Zero (A)));

   A := (0, 0, 0);

   Display_Array (A, "A");
   Put_Line ("Is_Zero: "
             & Boolean'Image (Is_Zero (A)));
   Put_Line ("Has_Zero: "
             & Boolean'Image (Has_Zero (A)));
end Test_Int_Arrays;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Quantified_Expression.
 ↪Quantified_Expression_1
MD5: 4bbda8a3830272748500f797f23f76fc
```

Runtime output

```
A:  0  0  1
Is_Zero: FALSE
Has_Zero: TRUE
A:  0  0  0
Is_Zero: TRUE
Has_Zero: TRUE
```

As you might have expected, we can rewrite a quantified expression as a loop in the `for I in A'Range loop if ... return ...` form. In the code below, we're implementing `Is_Zero` and `Has_Zero` using loops and conditions instead of quantified expressions:

Listing 18: int_arrays.ads

```
1  package Int_Arrays is
2
3     type Integer_Arr is
4       array (Positive range <>) of Integer;
5
6     function Is_Zero (A : Integer_Arr)
7                       return Boolean;
8
9     function Has_Zero (A : Integer_Arr)
10                       return Boolean;
11
12    procedure Display_Array (A    : Integer_Arr;
13                             Name : String);
14
15 end Int_Arrays;
```

Listing 19: int_arrays.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Int_Arrays is
4
5     function Is_Zero (A : Integer_Arr)
6                       return Boolean is
7     begin
8        for I in A'Range loop
9           if A (I) /= 0 then
10             return False;
11          end if;
12       end loop;
13
14       return True;
15    end Is_Zero;
16
17    function Has_Zero (A : Integer_Arr)
18                       return Boolean is
19    begin
20       for I in A'Range loop
21         if A (I) = 0 then
22            return True;
23         end if;
```

(continues on next page)

(continued from previous page)

```
      end loop;

      return False;
   end Has_Zero;

   procedure Display_Array (A    : Integer_Arr;
                            Name : String) is
   begin
      Put (Name & ": ");
      for E of A loop
         Put (E'Image & " ");
      end loop;
      New_Line;
   end Display_Array;

end Int_Arrays;
```

Listing 20: test_int_arrays.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Int_Arrays;  use Int_Arrays;

procedure Test_Int_Arrays is
   A : Integer_Arr := (0, 0, 1);
begin
   Display_Array (A, "A");
   Put_Line ("Is_Zero: "
             & Boolean'Image (Is_Zero (A)));
   Put_Line ("Has_Zero: "
             & Boolean'Image (Has_Zero (A)));

   A := (0, 0, 0);

   Display_Array (A, "A");
   Put_Line ("Is_Zero: "
             & Boolean'Image (Is_Zero (A)));
   Put_Line ("Has_Zero: "
             & Boolean'Image (Has_Zero (A)));
end Test_Int_Arrays;
```

Code block metadata

Is_Zero: FALSE
Has_Zero: TRUE
A:  0  0  0
Is_Zero: TRUE
Has_Zero: TRUE
```

So far, we've seen quantified expressions using indices — e.g. `for all I in A'Range => ...`. We could avoid indices in quantified expressions by simply using the `E of A` form. In this case, we can just write `for all E of A => ...`. Let's adapt the implementation of `Is_Zero` and `Has_Zero` using this form:

Listing 21: int_arrays.ads

```
package Int_Arrays is

   type Integer_Arr is
     array (Positive range <>) of Integer;

   function Is_Zero (A : Integer_Arr)
                     return Boolean is
      (for all E of A => E = 0);

   function Has_Zero (A : Integer_Arr)
                      return Boolean is
      (for some E of A => E = 0);

end Int_Arrays;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Quantified_Expression.
 ↪Quantified_Expression_3
MD5: 059d12a6529483ebcc5db23dc6262896
```

Here, we're checking the components E of the array A and comparing them against zero.

In the Ada Reference Manual

- 4.5.8 Quantified Expressions[124]

26.1.4 Declare Expressions

So far, we've seen expressions that make use of existing objects declared outside of the expression. Sometimes, we might want to declare constant objects inside the expression, so we can use them locally in the expression. Similarly, we might want to rename an object and use the renamed object in an expression. In those cases, we can use a declare expression.

A declare expression allows for declaring or renaming objects within an expression:

Listing 22: p.ads

```
pragma Ada_2022;

package P is

   function Max (A, B : Integer) return Integer is
     (declare
         Bigger_A : constant Boolean := (A >= B);
      begin
         (if Bigger_A then A else B));

end P;
```

Code block metadata

[124] http://www.ada-auth.org/standards/22rm/html/RM-4-5-8.html

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Declare_Expressions.Simple_
 ↪Declare_Expression
MD5: 5da80e76393645d6eb1cb8cfe88e190a
```

The declare expression starts with the **declare** keyword and the usual object declarations, and it's followed by the **begin** keyword and the body. In this example, the body of the declare expression is a conditional expression.

Of course, the code above isn't really useful, so let's look at a more complete example:

Listing 23: integer_arrays.ads

```
pragma Ada_2022;

package Integer_Arrays is

   type Integer_Array is
     array (Positive range <>) of Integer;

   function Sum (Arr : Integer_Array)
                 return Integer;

   --
   --  Expression function using
   --  declare expression:
   --
   function Avg (Arr : Integer_Array)
                 return Float is
     (declare
         A :          Integer_Array renames Arr;
         S : constant Float := Float (Sum (A));
         L : constant Float := Float (A'Length);
      begin
         S / L);

end Integer_Arrays;
```

Listing 24: integer_arrays.adb

```
package body Integer_Arrays is

   function Sum (Arr : Integer_Array)
                 return Integer is
   begin
      return Acc : Integer := 0 do
         for V of Arr loop
            Acc := Acc + V;
         end loop;
      end return;
   end Sum;

end Integer_Arrays;
```

Listing 25: show_integer_arrays.adb

```
pragma Ada_2022;

with Ada.Text_IO;    use Ada.Text_IO;

with Integer_Arrays; use Integer_Arrays;

```

(continues on next page)

(continued from previous page)

```
procedure Show_Integer_Arrays is
   Arr : constant Integer_Array := [1, 2, 3];
begin
   Put_Line ("Sum: "
             & Sum (Arr)'Image);
   Put_Line ("Avg: "
             & Avg (Arr)'Image);
end Show_Integer_Arrays;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Declare_Expressions.Integer_
↪Arrays
MD5: 8e96d49b1676f0aaf95437e271069690
```

Runtime output

```
Sum:  6
Avg:  2.00000E+00
```

In this example, the Avg function is implemented using a declare expression. In this expression, A renames the `Arr` array, and S is a constant initialized with the value returned by the `Sum` function.

In the Ada Reference Manual

- 4.5.9 Declare Expressions[125]

Restrictions in the declarative part

The declarative part of a declare expression is more restricted than the declarative part of a subprogram or declare block. In fact, we cannot:

- declare variables;
- declare constants of limited types;
- rename an object of limited type that is constructed within the declarative part;
- declare aliased constants;
- declare constants that make use of the **`Access`** or `Unchecked_Access` attributes in the initialization;
- declare constants of anonymous access type.

Let's see some examples of erroneous declarations:

Listing 26: integer_arrays.ads

```
pragma Ada_2022;

package Integer_Arrays is

   type Integer_Array is
     array (Positive range <>) of Integer;

   type Integer_Sum is limited private;
```

(continues on next page)

[125] http://www.ada-auth.org/standards/22rm/html/RM-4-5-9.html

(continued from previous page)

```
9
10    type Const_Integer_Access is
11      access constant Integer;
12
13    function Sum (Arr : Integer_Array)
14                  return Integer;
15
16    function Sum (Arr : Integer_Array)
17                  return Integer_Sum;
18
19    --
20    --  Expression function using
21    --  declare expression:
22    --
23    function Avg (Arr : Integer_Array)
24                  return Float is
25      (declare
26          A  : Integer_Array renames Arr;
27
28          S1 : aliased constant Integer := Sum (A);
29          --  ERROR: aliased constant
30
31          S : Float := Float (S1);
32          L : Float := Float (A'Length);
33          --  ERROR: declaring variables
34
35          S2 : constant Integer_Sum := Sum (A);
36          --  ERROR: declaring constant of
37          --         limited type
38
39          A1 : Const_Integer_Access :=
40                 S1'Unchecked_Access;
41          --  ERROR: using 'Unchecked_Access
42          --         attribute
43
44          A2 : access Integer := null;
45          --  ERROR: declaring object of
46          --         anonymous access type
47       begin
48          S / L);
49
50 private
51
52    type Integer_Sum is new Integer;
53
54 end Integer_Arrays;
```

Listing 27: integer_arrays.adb

```
1  package body Integer_Arrays is
2
3     function Sum (Arr : Integer_Array)
4                   return Integer is
5     begin
6        return Acc : Integer := 0 do
7           for V of Arr loop
8              Acc := Acc + V;
9           end loop;
10       end return;
11    end Sum;
12
```

(continues on next page)

(continued from previous page)

```
13    function Sum (Arr : Integer_Array)
14                  return Integer_Sum is
15      (Integer_Sum (Integer'(Sum (Arr))));
16
17 end Integer_Arrays;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Declare_Expressions.Integer_
 ↪Arrays_Error
MD5: e1f72f817baea87f66fb34b6aa8d1949
```

Build output

```
integer_arrays.ads:28:10: error: "aliased" not allowed in declare_expression
integer_arrays.ads:31:10: error: object renaming or constant declaration expected
integer_arrays.ads:32:10: error: object renaming or constant declaration expected
integer_arrays.ads:35:10: error: object renaming or constant declaration expected

 ↪declare_expression
integer_arrays.ads:44:15: error: anonymous access type not allowed in declare_
 ↪expression
gprbuild: *** compilation phase failed
```

In this version of the Avg function, we see many errors in the declarative part of the declare expression. If we convert the declare expression into an actual function implementation, however, those declarations won't trigger compilation errors. (Feel free to try this out!)

26.1.5 Reduction Expressions

Note: This feature was introduced in Ada 2022.

A reduction expression reduces a list of values into a single value. For example, we can reduce the list `[2, 3, 4]` to a single value:

- by adding the values of the list: `2 + 3 + 4 = 9`, or
- by multiplying the values of the list: `2 * 3 * 4 = 24`.

We write a reduction expression by using the Reduce attribute and providing the reducer and its initial value:

- the reducer is the operator (e.g.: `+` or `*`) that we use to *combine* the values of the list;
- the initial value is the value that we use before all other values of the list.

For example, if we use `+` as the operator and `0` an the initial value, we get the reduction expression: `0 + 2 + 3 + 4 = 9`. This can be implemented using an array:

Listing 28: show_reduction_expression.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Reduction_Expression is
4     A : array (1 .. 3) of Integer;
5     I : Integer;
6  begin
7     A := [2, 3, 4];
8     I := A'Reduce ("+", 0);
```

(continues on next page)

(continued from previous page)

```
9
10    Put_Line ("A = "
11              & A'Image);
12    Put_Line ("I = "
13              & I'Image);
14 end Show_Reduction_Expression;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Reduction_Expressions.
 ↪Simple_Reduction_Expression
MD5: 1a0164b3c4768125c8dbbe8a0f4955a1
```

Runtime output

```
A =
[ 2,  3,  4]
I =  9
```

Here, we have the array A with a list of values. The A'Reduce ("+", 0) expression reduces the list of values of A into a single value — in this case, an integer value that is stored in I. This statement is equivalent to:

```
I := 0;
for E of A loop
   I := I + E;
end loop;
```

Naturally, we can reduce the array using the * operator:

Listing 29: show_reduction_expression.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Reduction_Expression is
4     A : array (1 .. 3) of Integer;
5     I : Integer;
6  begin
7     A := [2, 3, 4];
8     I := A'Reduce ("*", 1);
9
10    Put_Line ("A = "
11              & A'Image);
12    Put_Line ("I = "
13              & I'Image);
14 end Show_Reduction_Expression;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Reduction_Expressions.
 ↪Simple_Reduction_Expression
MD5: 415b1ee8b21cca6d2438a34c88e7e2df
```

Runtime output

```
A =
[ 2,  3,  4]
I =  24
```

In this example, we call A'Reduce ("*", 1) to reduce the list. (Note that we use an

initial value of one because it is the identity element[126] of a multiplication, so the complete operation is: `1 * 2 * 3 * 4 = 24`.)

In the Ada Reference Manual

- Reduction Expressions[127]

Value sequences

In addition to arrays, we can apply reduction expression to value sequences, which consist of an iterated element association — for example, `[for I in 1 .. 3 => I + 1]`. We can simply *append* the reduction expression to a value sequence:

Listing 30: show_reduction_expression.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Reduction_Expression is
   I : Integer;
begin
   I := [for I in 1 .. 3 =>
           I + 1]'Reduce ("+", 0);
   Put_Line ("I = "
             & I'Image);

   I := [for I in 1 .. 3 =>
           I + 1]'Reduce ("*", 1);
   Put_Line ("I = "
             & I'Image);
end Show_Reduction_Expression;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Reduction_Expressions.
 ↪Reduction_Expression_Value_Sequences
MD5: e714f69700e3f0387314ee0e531620c4
```

Runtime output

```
I =  9
I =  24
```

In this example, we create the value sequence `[for I in 1 .. 3 => I + 1]` and reduce it using the `+` and `*` operators. (Note that the operations in this example have the same results as in the previous examples using arrays.)

[126] https://en.wikipedia.org/wiki/Identity_element
[127] http://www.ada-auth.org/standards/22rm/html/RM-4-5-10.html

Custom reducers

In the previous examples, we've used standard operators such as + and * as the reducer. We can, however, write our own reducers and pass them to the Reduce attribute. For example:

Listing 31: show_reduction_expression.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Reduction_Expression is
   type Integer_Array is
     array (Positive range <>) of Integer;

   A : Integer_Array (1 .. 3);
   I : Long_Integer;

   procedure Accumulate
     (Accumulator : in out Long_Integer;
      Value       : Integer) is
   begin
      Accumulator := Accumulator
                     + Long_Integer (Value);
   end Accumulate;

begin
   A := [2, 3, 4];
   I := A'Reduce (Accumulate, 0);

   Put_Line ("A = "
             & A'Image);
   Put_Line ("I = "
             & I'Image);
end Show_Reduction_Expression;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Reduction_Expressions.
 ↪Custom_Reducer_Procedure
MD5: 3190a1ff6a8027268ca96a75cf214714
```

Runtime output

```
A =
[ 2,  3,  4]
I =  9
```

In this example, we implement the `Accumulate` procedure as our reducer, which is called to accumulate the individual elements (integer values) of the list. We pass this procedure to the Reduce attribute in the `I := A'Reduce (Accumulate, 0)` statement, which is equivalent to:

```
I := 0;
for E of A loop
   Accumulate (I, E);
end loop;
```

A custom reducer must have the following parameters:

1. The accumulator parameter, which stores the interim result — and the final result as well, once all elements of the list have been processed.
2. The value parameter, which is a single element from the list.

Note that the accumulator type doesn't need to match the type of the individual components. In this example, we're using `Integer` as the component type, while the accumulator type is `Long_Integer`. (For this kind of reducers, using `Long_Integer` instead of `Integer` for the accumulator type makes lots of sense due to the risk of triggering overflows while the reducer is accumulating values — e.g. when accumulating a long list with larger numbers.)

In the example above, we've implemented the reducer as a procedure. However, we can also implement it as a function. In this case, the accumulated value is returned by the function:

Listing 32: show_reduction_expression.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Reduction_Expression is
   type Integer_Array is
     array (Positive range <>) of Integer;

   A : Integer_Array (1 .. 3);
   I : Long_Integer;

   function Accumulate
     (Accumulator : Long_Integer;
      Value       : Integer)
      return Long_Integer is
   begin
      return Accumulator + Long_Integer (Value);
   end Accumulate;

begin
   A := [2, 3, 4];
   I := A'Reduce (Accumulate, 0);

   Put_Line ("A = "
             & A'Image);
   Put_Line ("I = "
             & I'Image);
end Show_Reduction_Expression;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Reduction_Expressions.
 ↪Custom_Reducer_Function
MD5: ee5d5bb2b151ef7552d752c7e452127d
```

Runtime output

```
A =
[ 2,  3,  4]
I =  9
```

In this example, we converted the `Accumulate` procedure into a function (while the core implementation is essentially the same).

Note that the reduction expression remains the same, independently of whether we're using a procedure or a function as the reducer. Therefore, the statement with the reduction expression in this example is the same as in the previous example: `I := A'Reduce (Accumulate, 0);`. Now that we're using a function, this statement is equivalent to:

```
I := 0;
for E of A loop
```

(continues on next page)

(continued from previous page)

```
   I := Accumulate (I, E);
end loop;
```

Other accumulator types

The accumulator type isn't restricted to scalars: in fact, we could use record types as well. For example:

Listing 33: show_reduction_expression.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Reduction_Expression is
   type Integer_Array is
     array (Positive range <>) of Integer;

   A : Integer_Array (1 .. 3);

   type Integer_Accumulator is record
      Value : Long_Integer;
      Count : Integer;
   end record;

   function Accumulate
     (Accumulator : Integer_Accumulator;
      Value       : Integer)
      return Integer_Accumulator is
   begin
      return (Value => Accumulator.Value
                       + Long_Integer (Value),
              Count => Accumulator.Count + 1);
   end Accumulate;

   function Zero return Integer_Accumulator is
     (Value => 0, Count => 0);

   function Average (Acc : Integer_Accumulator)
                     return Float is
     (Float (Acc.Value) / Float (Acc.Count));

   Acc : Integer_Accumulator;

begin
   A := [2, 3, 4];

   Acc := A'Reduce (Accumulate, Zero);
   Put_Line ("Acc = "
             & Acc'Image);
   Put_Line ("Avg = "
             & Average (Acc)'Image);
end Show_Reduction_Expression;
```

In this example, we're using the `Integer_Accumulator` record type in our reducer — the `Accumulate` function. In this case, we're not only accumulating the values, but also counting the number of elements in the list. (Of course, we could have used `A'Length` for that as well.)

Also, we're not limited to numeric types: we can also create a reducer using strings as the accumulator type. In fact, we can display the initial value and the elements of the list by using unbounded strings:

Listing 34: show_reduction_expression.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

procedure Show_Reduction_Expression is
   type Integer_Array is
     array (Positive range <>) of Integer;

   A : Integer_Array (1 .. 3);

   function Unbounded_String_List
     (Accumulator : Unbounded_String;
      Value       : Integer)
          return Unbounded_String is
   begin
      return Accumulator
             & ", " & Value'Image;
   end Unbounded_String_List;

begin
   A := [2, 3, 4];

   Put_Line ("A = "
             & A'Image);
   Put_Line ("L = "
             & To_String (A'Reduce
               (Unbounded_String_List,
                  To_Unbounded_String ("0"))));
end Show_Reduction_Expression;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Expressions.Reduction_Expressions.
 ↪Reducer_String_Accumulator
MD5: 43c54e93e404a235c8721db7c691a864
```

Runtime output

```
A =
[ 2,  3,  4]
L = 0,  2,  3,  4
```

In this case, the "accumulator" is concatenating the initial value and individual values of the list into a string.

26.2 Statements

26.2.1 Simple and Compound Statements

We can classify statements as either simple or compound. Simple statements don't contain other statements; think of them as "atomic units" that cannot be further divided. Compound statements, on the other hand, may contain other — simple or compound — statements.

Here are some examples from each category:

Category	Examples
Simple statements	Null statement, assignment, subprogram call, etc.
Compound statements	If statement, case statement, loop statement, block statement

In the Ada Reference Manual

- 5.1 Simple and Compound Statements - Sequences of Statements[128]

26.2.2 Labels

We can use labels to identify statements in the code. They have the following format: **<<Some_Label>>**. We write them right before the statement we want to apply it to. Let's see an example of labels with simple statements:

Listing 35: show_statement_identifier.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Statement_Identifier is
4     pragma Warnings (Off, "is not referenced");
5  begin
6     <<Show_Hello>> Put_Line ("Hello World!");
7     <<Show_Test>>  Put_Line ("This is a test.");
8
9     <<Show_Separator>>
10    <<Show_Block_Separator>>
11    Put_Line ("====================");
12 end Show_Statement_Identifier;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Statements.Labels.Simple_Labels
MD5: 820f5963b476af5c04314fd4373d2286
```

Runtime output

```
Hello World!
This is a test.
====================
```

Here, we're labeling each statement. For example, we use the `Show_Hello` label to identify the `Put_Line ("Hello World!");` statement. Note that we can use multiple labels a single statement. In this code example, we use the `Show_Separator` and `Show_Block_Separator` labels for the same statement.

In the Ada Reference Manual

- 5.1 Simple and Compound Statements - Sequences of Statements[129]

[128] http://www.ada-auth.org/standards/22rm/html/RM-5-1.html
[129] http://www.ada-auth.org/standards/22rm/html/RM-5-1.html

Labels and goto statements

Labels are mainly used in combination with **goto** statements. (Although pretty much uncommon, we could potentially use labels to indicate important statements in the code.) Let's see an example where we use a **goto** `label;` statement to *jump* to a specific label:

Listing 36: show_cleanup.adb

```
procedure Show_Cleanup is
   pragma Warnings (Off, "always false");

   Some_Error : Boolean;
begin
   Some_Error := False;

   if Some_Error then
      goto Cleanup;
   end if;

   <<Cleanup>> null;
end Show_Cleanup;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Statements.Labels.Label_Goto
MD5: 0ce06582bbefae818d4da3b7d2d3436b
```

Here, we transfer the control to the *cleanup* statement as soon as an error is detected.

Use-case: Continue

Another use-case is that of a `Continue` label in a loop. Consider a loop where we want to skip further processing depending on a condition:

Listing 37: show_continue.adb

```
procedure Show_Continue is
   function Is_Further_Processing_Needed
     (Dummy : Integer)
      return Boolean
   is
   begin
      --  Dummy implementation
      return False;
   end Is_Further_Processing_Needed;

   A : constant array (1 .. 10) of Integer :=
        (others => 0);
begin
   for E of A loop

      --  Some stuff here...

      if Is_Further_Processing_Needed (E) then

         --  Do more stuff...

         null;
      end if;
   end loop;
end Show_Continue;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Statements.Labels.Label_Continue_1
MD5: 115eeaf08d5fb072d707d6325fe9cfd0
```

In this example, we call the `Is_Further_Processing_Needed (E)` function to check whether further processing is needed or not. If it's needed, we continue processing in the **if** statement. We could simplify this code by just using a `Continue` label at the end of the loop and a **goto** statement:

Listing 38: show_continue.adb

```
procedure Show_Continue is
   function Is_Further_Processing_Needed
     (Dummy : Integer)
      return Boolean
   is
   begin
      --  Dummy implementation
      return False;
   end Is_Further_Processing_Needed;

   A : constant array (1 .. 10) of Integer :=
     (others => 0);
begin
   for E of A loop

      --  Some stuff here...

      if not Is_Further_Processing_Needed (E) then
         goto Continue;
      end if;

      --  Do more stuff...

      <<Continue>>
   end loop;
end Show_Continue;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Statements.Labels.Label_Continue_2
MD5: 260b52ead782adf76eee5cf3c4e8332b
```

Here, we use a `Continue` label at the end of the loop and jump to it in the case that no further processing is needed. Note that, in this example, we don't have a statement after the `Continue` label because the label itself is at the end of a statement — to be more specific, at the end of the loop statement. In such cases, there's an implicit **null** statement.

Historically

Since Ada 2012, we can simply write:

```
loop
   --  Some statements...

   <<Continue>>
end loop;
```

If a label is used at the end of a sequence of statements, a **null** statement is implied. In previous versions of Ada, however, that is not the case. Therefore, when using those versions of the language, we must write at least a **null** statement:

```
loop
   --  Some statements...

   <<Continue>> null;
end loop;
```

Labels and compound statements

We can use labels with compound statements as well. For example, we can label a **for** loop:

Listing 39: show_statement_identifier.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Statement_Identifier is
   pragma Warnings (Off, "is not referenced");

   Arr   : constant array (1 .. 5) of Integer :=
             (1, 4, 6, 42, 49);
   Found : Boolean := False;
begin
   <<Find_42>> for E of Arr loop
      if E = 42 then
         Found := True;
         exit;
      end if;
   end loop;

   Put_Line ("Found: " & Found'Image);
end Show_Statement_Identifier;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Statements.Labels.Loop_Label
MD5: 5ca80b5a379ba0b08ccfaa4c6eab64d5
```

Runtime output

```
Found: TRUE
```

For further reading...

In addition to labels, loops and block statements allow us to use a statement identifier. In simple terms, instead of writing **<<Some_Label>>**, we write `Some_Label :`.

We could rewrite the previous code example using a loop statement identifier:

Listing 40: show_statement_identifier.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Statement_Identifier is
   Arr   : constant array (1 .. 5) of Integer :=
             (1, 4, 6, 42, 49);
   Found : Boolean := False;
begin
   Find_42 : for E of Arr loop
```

(continues on next page)

(continued from previous page)

```
      if E = 42 then
         Found := True;
         exit Find_42;
      end if;
   end loop Find_42;

   Put_Line ("Found: " & Found'Image);
end Show_Statement_Identifier;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Statements.Labels.Loop_Statement_
 ↪Identifier
MD5: e52cb5eea9427addf3cabe64dd73bc2d
```

Runtime output

```
Found: TRUE
```

Loop statement and block statement identifiers are generally preferred over labels. Later in this chapter, we discuss this topic in more detail.

26.2.3 Exit loop statement

We've introduced bare loops back in the *Introduction to Ada course* (page 15). In this section, we'll briefly discuss loop names and exit loop statements.

A bare loop has this form:

```
loop
    exit when Some_Condition;
end loop;
```

We can name a loop by using a loop statement identifier:

```
Loop_Name:
   loop
      exit Loop_Name when Some_Condition;
   end loop Loop_Name;
```

In this case, we have to use the loop's name after **end loop**. Also, having a name for a loop allows us to indicate which loop we're exiting from: **exit** Loop_Name **when**.

Let's see a complete example:

Listing 41: show_vector_cursor_iteration.adb

```
with Ada.Text_IO;            use Ada.Text_IO;
with Ada.Containers.Vectors;

procedure Show_Vector_Cursor_Iteration is

   package Integer_Vectors is new
     Ada.Containers.Vectors
       (Index_Type   => Positive,
        Element_Type => Integer);

   use Integer_Vectors;
```

(continues on next page)

(continued from previous page)

```
12
13    V : constant Vector := 20 & 10 & 0 & 13;
14    C : Cursor;
15 begin
16    C := V.First;
17    Put_Line ("Vector elements are: ");
18
19    Show_Elements :
20       loop
21          exit Show_Elements when C = No_Element;
22
23          Put_Line ("Element: "
24                    & Integer'Image (V (C)));
25          C := Next (C);
26       end loop Show_Elements;
27
28 end Show_Vector_Cursor_Iteration;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Statements.Exit_Loop_Statement.Exit_
 ↪Named_Loop
MD5: b77353f6ed98f8ddb32c73c47d249020
```

Runtime output

```
Vector elements are:
Element:  20
Element:  10
Element:  0
Element:  13
```

Naming a loop is particularly useful when we have nested loops and we want to exit directly from the inner loop:

Listing 42: show_inner_loop_exit.adb

```
1  procedure Show_Inner_Loop_Exit is
2     pragma Warnings (Off);
3
4     Cond : Boolean := True;
5  begin
6
7     Outer_Processing : loop
8
9        Inner_Processing : loop
10          exit Outer_Processing when Cond;
11       end loop Inner_Processing;
12
13    end loop Outer_Processing;
14
15 end Show_Inner_Loop_Exit;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Statements.Exit_Loop_Statement.Inner_
 ↪Loop_Exit
MD5: b5c7434f1bf23c2cb8f81e4c13a31386
```

Here, we indicate that we exit from the `Outer_Processing` loop in case a condition `Cond` is met, even if we're actually within the inner loop.

In the Ada Reference Manual

- 5.7 Exit Statements[130]

26.2.4 If, case and loop statements

In the Introduction to Ada course, we talked about *if statements* (page 11), *loop statements* (page 13), and *case statements* (page 16). This is a very simple code example with these statements:

Listing 43: show_if_case_loop_statements.adb

```
procedure Show_If_Case_Loop_Statements is
   pragma Warnings (Off);

   Reset     : Boolean := False;
   Increment : Boolean := True;
   Val       : Integer := 0;
begin
   --
   --  If statement
   --
   if Reset then
      Val := 0;
   elsif Increment then
      Val := Val + 1;
   else
      Val := Val - 1;
   end if;

   --
   --  Loop statement
   --
   for I in 1 .. 5 loop
      Val := Val * 2 - I;
   end loop;

   --
   --  Case statement
   --
   case Val is
      when 0 .. 5 =>
         null;
      when others =>
         Val := 5;
   end case;

end Show_If_Case_Loop_Statements;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Statements.If_Case_Loop_Statements.
↪Example
MD5: 4fdc7f00e5218ed59d9eb050339567f1
```

In this section, we'll look into a more advanced detail about the case statement.

[130] http://www.ada-auth.org/standards/22rm/html/RM-5-7.html

In the Ada Reference Manual

- 5.3 If Statements[131]
- 5.4 Case Statements[132]
- 5.5 Loop Statements[133]

Case statements and expressions

As we know, the case statement has a choice expression (`case Choice_Expression is`), which is expected to be a discrete type. Also, this expression can be a function call or a type conversion, for example — in additional to being a variable or a constant.

As we discussed *earlier on* (page 585), if we use parentheses, the contents between those parentheses is parsed as an expression. In the context of case statements, the expression is first evaluated before being used as a choice expression. Consider the following code example:

Listing 44: scales.ads

```
package Scales is

   type Satisfaction_Scale is (Very_Dissatisfied,
                               Dissatisfied,
                               OK,
                               Satisfied,
                               Very_Satisfied);

   type Scale is range 0 .. 10;

   function To_Satisfaction_Scale
     (S : Scale)
      return Satisfaction_Scale;

end Scales;
```

Listing 45: scales.adb

```
package body Scales is

   function To_Satisfaction_Scale
     (S : Scale)
      return Satisfaction_Scale
   is
      Satisfaction : Satisfaction_Scale;
   begin
      case (S) is
         when 0 .. 2  =>
            Satisfaction := Very_Dissatisfied;
         when 3 .. 4  =>
            Satisfaction := Dissatisfied;
         when 5 .. 6  =>
            Satisfaction := OK;
         when 7 .. 8  =>
            Satisfaction := Satisfied;
```

(continues on next page)

[131] http://www.ada-auth.org/standards/22rm/html/RM-5-3.html
[132] http://www.ada-auth.org/standards/22rm/html/RM-5-4.html
[133] http://www.ada-auth.org/standards/22rm/html/RM-5-5.html

(continued from previous page)

```
         when 9 .. 10 =>
            Satisfaction := Very_Satisfied;
      end case;

      return Satisfaction;
   end To_Satisfaction_Scale;

end Scales;
```

Listing 46: show_case_statement_expression.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Scales;      use Scales;

procedure Show_Case_Statement_Expression is
   Score : constant Scale := 0;
begin
   Put_Line ("Score: "
             & Scale'Image (Score)
             & Satisfaction_Scale'Image (
                 To_Satisfaction_Scale (Score)));

end Show_Case_Statement_Expression;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Statements.If_Case_Loop_Statements.Case_
↪Statement_Expression
MD5: 353ff771291e0c994ec052e818f9720c
```

Build output

```
scales.adb:9:07: error: missing case values: -128 .. -1
scales.adb:9:07: error: missing case values: 11 .. 127
gprbuild: *** compilation phase failed
```

When we try to compile this code example, the compiler complains about missing values in the `To_Satisfaction_Scale` function. As we mentioned in the *Introduction to Ada course* (page 16), every possible value for the choice expression needs to be covered by a unique branch of the case statement. In principle, it *seems* that we're actually covering all possible values of the `Scale` type, which ranges from 0 to 10. However, we've written `case (S) is` instead of `case S is`. Because of the parentheses, `(S)` is evaluated as an expression. In this case, the expected range of the case statement is not `Scale'Range`, but the range of its *base type* (page 283) `Scale'Base'Range`.

In other languages

In C, the switch-case statement requires parentheses for the choice expression:

Listing 47: main.c

```

#include <stdio.h>

int main(int argc, const char * argv[])
{
   int s = 0;

   switch (s)
```

(continues on next page)

(continued from previous page)

```
   {
      case 0:
      case 1:
         printf("Value in the 0 -- 1 range\n");
      default:
         printf("Value > 1\n");
   }
}
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Statements.If_Case_Loop_Statements.Case_
 ↪Statement_C
MD5: 64ef6b15f1bdf14ca9273964ec5e1755
```

Runtime output

```
Value in the 0 -- 1 range
Value > 1
```

In Ada, parentheses aren't expected in the choice expression. Therefore, we shouldn't write `case (S) is` in a C-like fashion — unless, of course, we really want to evaluate an expression in the case statement.

26.2.5 Block Statements

We've introduced block statements back in the *Introduction to Ada course* (page 19). They have this simple form:

Listing 48: show_block_statement.adb

```
procedure Show_Block_Statement is
   pragma Warnings (Off);
begin

   --  BLOCK STARTS HERE:
   declare
      I : Integer;
   begin
      I := 0;
   end;

end Show_Block_Statement;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Statements.Block_Statements.Simple_
 ↪Block_Statement
MD5: 61134b3899620c6d9ed68974fae33b5e
```

We can use an identifier when writing a block statement. (This is similar to loop statement identifiers that we discussed in the previous section.) In this example, we implement a block called `Simple_Block`:

Listing 49: show_block_statement.adb

```
procedure Show_Block_Statement is
   pragma Warnings (Off);
```

(continues on next page)

(continued from previous page)

```
begin

   Simple_Block : declare
      I : Integer;
   begin
      I := 0;
   end Simple_Block;

end Show_Block_Statement;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Statements.Block_Statements.Block_
 ↪Statement_Identifier
MD5: b327b7675931d9b994637671c806c7c3
```

Note that we must write `end Simple_Block;` when we use the `Simple_Block` identifier.

Block statement identifiers are useful:

- to indicate the begin and the end of a block — as some blocks might be long or nested in other blocks;
- to indicate the purpose of the block (i.e. as code documentation).

In the Ada Reference Manual

- 5.6 Block Statements[134]

26.2.6 Extended return statement

A common idiom in Ada is to build up a function result in a local object, and then return that object:

Listing 50: show_return.adb

```
procedure Show_Return is

   type Array_Of_Natural is
     array (Positive range <>) of Natural;

   function Sum (A : Array_Of_Natural)
                 return Natural
   is
      Result : Natural := 0;
   begin
      for Index in A'Range loop
         Result := Result + A (Index);
      end loop;
      return Result;
   end Sum;

begin
   null;
end Show_Return;
```

Code block metadata

[134] http://www.ada-auth.org/standards/22rm/html/RM-5-6.html

```
Project: Courses.Advanced_Ada.Control_Flow.Statements.Extended_Return_Statements.
 ↪Simple_Return
MD5: 16e85a8cba869802f912627c40a64c20
```

Since Ada 2005, a notation called the extended return statement is available: this allows you to declare the result object and return it as part of one statement. It looks like this:

Listing 51: show_extended_return.adb

```
procedure Show_Extended_Return is

   type Array_Of_Natural is
     array (Positive range <>) of Natural;

   function Sum (A : Array_Of_Natural)
                 return Natural
   is
   begin
      return Result : Natural := 0 do
         for Index in A'Range loop
            Result := Result + A (Index);
         end loop;
      end return;
   end Sum;

begin
   null;
end Show_Extended_Return;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Statements.Extended_Return_Statements.
 ↪Extended_Return
MD5: d6d6edaf800a0e346ff8ede13cbbe100
```

The return statement here creates `Result`, initializes it to `0`, and executes the code between **`do`** and **`end return`**. When **`end return`** is reached, `Result` is automatically returned as the function result.

In the Ada Reference Manual

- 6.5 Return Statements[135]

Other usages of extended return statements

Note: This section was originally written by Robert A. Duff and published as Gem #10: Limited Types in Ada 2005[136].

While the `extended_return_statement` was added to the language specifically to support *limited constructor functions* (page 958), it comes in handy whenever you want a local name for the function result:

[135] http://www.ada-auth.org/standards/22rm/html/RM-6-5.html
[136] https://www.adacore.com/gems/ada-gem-10

Listing 52: show_string_construct.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_String_Construct is

   function Make_String
     (S          : String;
      Prefix     : String;
      Use_Prefix : Boolean) return String
   is
      Length : Natural := S'Length;
   begin
      if Use_Prefix then
         Length := Length + Prefix'Length;
      end if;

      return Result : String (1 .. Length) do

         --  fill in the characters
         if Use_Prefix then
            Result
              (1 .. Prefix'Length) := Prefix;

            Result
              (Prefix'Length + 1 .. Length) := S;
         else
            Result := S;
         end if;

      end return;
   end Make_String;

   S1 : String := "Ada";
   S2 : String := "Make_With_";
begin
   Put_Line ("No prefix:   "
             & Make_String (S1, S2, False));
   Put_Line ("With prefix: "
             & Make_String (S1, S2, True));
end Show_String_Construct;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Statements.Extended_Return_Statements.
 ↪Extended_Return_Other_Usages
MD5: a2b26ceed06a0ab66aff6c2b59c02003
```

Runtime output

```
No prefix:   Ada
With prefix: Make_With_Ada
```

In this example, we first calculate the length of the string and store it in `Length`. We then use this information to initialize the return object of the `Make_String` function.

26.3 Subprograms

26.3.1 Parameter Modes and Associations

In this section, we discuss some details about parameter modes and associations. First of all, as we know, parameters can be either formal or actual:

- Formal parameters are the ones we see in a subprogram declaration and implementation;
- Actual parameters are the ones we see in a subprogram call.
  - Note that actual parameters are also called *subprogram arguments* in other languages.

We define parameter associations as the connection between an actual parameter in a subprogram call and its declaration as a formal parameter in a subprogram specification or body.

In the Ada Reference Manual

- 6.2 Formal Parameter Modes[137]
- 6.4.1 Parameter Associations[138]

Formal Parameter Modes

We already discussed formal parameter modes in the *Introduction to Ada* (page 28) course:

`in`	Parameter can only be read, not written
`out`	Parameter can be written to, then read
`in out`	Parameter can be both read and written

As this topic was already discussed in that course — and we used parameter modes extensively in all code examples from that course —, we won't introduce the topic again here. Instead, we'll look into some of the more advanced details.

By-copy and by-reference

In the *Introduction to Ada* (page 28) course, we saw that parameter modes don't correspond directly to how parameters are actually passed. In fact, an `in out` parameter could be passed by copy. For example:

Listing 53: check_param_passing.ads

```
1 with System;
2
3 procedure Check_Param_Passing
4   (Formal : System.Address;
5    Actual : System.Address);
```

[137] http://www.ada-auth.org/standards/22rm/html/RM-6-2.html
[138] http://www.ada-auth.org/standards/22rm/html/RM-6-4-1.html

Listing 54: check_param_passing.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with System.Address_Image;

procedure Check_Param_Passing
  (Formal : System.Address;
   Actual : System.Address) is
begin
   Put_Line ("Formal parameter at "
             & System.Address_Image (Formal));
   Put_Line ("Actual parameter at "
             & System.Address_Image (Actual));
   if System.Address_Image (Formal) =
      System.Address_Image (Actual)
   then
      Put_Line
        ("Parameter is passed by reference.");
   else
      Put_Line
        ("Parameter is passed by copy.");
   end if;
end Check_Param_Passing;
```

Listing 55: machine_x.ads

```
with System;

package Machine_X is

   procedure Update_Value
     (V  : in out Integer;
      AV :        System.Address);

end Machine_X;
```

Listing 56: machine_x.adb

```
with Check_Param_Passing;

package body Machine_X is

   procedure Update_Value
     (V  : in out Integer;
      AV :        System.Address) is
   begin
      V := V + 1;
      Check_Param_Passing (Formal => V'Address,
                           Actual => AV);
   end Update_Value;

end Machine_X;
```

Listing 57: show_by_copy_by_ref_params.adb

```
with Machine_X; use Machine_X;

procedure Show_By_Copy_By_Ref_Params is
   A : Integer := 5;
begin
```

(continues on next page)

(continued from previous page)

```
6     Update_Value (A, A'Address);
7  end Show_By_Copy_By_Ref_Params;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Parameter_Modes_
 ↪Associations.By_Copy_By_Ref_Params
MD5: e437d3432703124496f0a217177959eb
```

Runtime output

```
Formal parameter at 00007FFFA43D791C
Actual parameter at 00007FFFA43D793C
Parameter is passed by copy.
```

As we can see by running this example,

- the integer variable A in the Show_By_Copy_By_Ref_Params procedure

and

- the V parameter in the Update_Value procedure

have different addresses, so they are different objects. Therefore, we conclude that this parameter is being passed by value, even though it has the **in out** mode. (We talk more about addresses and the 'Address attribute *later on* (page 401)).

As we know, when a parameter is passed by copy, it is first copied to a temporary object. In the case of a parameter with **in out** mode, the temporary object is copied back to the original (actual) parameter at the end of the subprogram call. In our example, the temporary object indicated by V is copied back to A at the end of the call to Update_Value.

In Ada, it's not the parameter mode that determines whether a parameter is passed by copy or by reference, but rather its type. We can distinguish between three categories:

1. By-copy types;
2. By-reference types;
3. *Unspecified* types.

Obviously, parameters of by-copy types are passed by copy and parameters of by-reference type are passed by reference. However, if a category isn't specified — i.e. when the type is neither a by-copy nor a by-reference type —, the decision is essentially left to the compiler.

As a rule of thumb, we can say that;

- elementary types — and any type that is essentially elementary, such as a private type whose full view is an elementary type — are passed by copy;
- tagged and explicitly limited types — and other types that are essentially tagged, such as task types — are passed by reference.

The following table provides more details:

Type category	Parameter passing	List of types
By copy	By copy	• Elementary types • Descendant of a private type whose full type is a by-copy type
By reference	By reference	• Tagged types • Task and protected types • Explicitly limited record types • Composite types with at least one subcomponent of a by-reference type • Private types whose full type is a by-reference type • Any descendant of the types mentioned above
Unspecified	Either by copy or by reference	• Any type not mentioned above

Note that, for parameters of limited types, only those parameters whose type is *explicitly* limited are always passed by reference. We discuss this topic in more details *in another chapter* (page 967).

Let's see an example:

Listing 58: machine_x.ads

```
1  with System;
2
3  package Machine_X is
4
5     type Integer_Array is
6       array (Positive range <>) of Integer;
7
8     type Rec is record
9        A : Integer;
10    end record;
11
12    type Rec_Array is record
13       A   : Integer;
14       Arr : Integer_Array (1 .. 100);
15    end record;
16
17    type Tagged_Rec is tagged record
18       A : Integer;
19    end record;
20
21    procedure Update_Value
22      (R  : in out Rec;
```

(continues on next page)

(continued from previous page)

      AR :        System.Address);

   procedure Update_Value
     (RA  : in out Rec_Array;
      ARA :        System.Address);

   procedure Update_Value
     (R  : in out Tagged_Rec;
      AR :        System.Address);

end Machine_X;
```

Listing 59: machine_x.adb

```
with Check_Param_Passing;

package body Machine_X is

   procedure Update_Value
     (R  : in out Rec;
      AR :        System.Address)
   is
   begin
      R.A := R.A + 1;
      Check_Param_Passing (Formal => R'Address,
                           Actual => AR);
   end Update_Value;

   procedure Update_Value
     (RA  : in out Rec_Array;
      ARA :        System.Address)
   is
   begin
      RA.A := RA.A + 1;
      Check_Param_Passing (Formal => RA'Address,
                           Actual => ARA);
   end Update_Value;

   procedure Update_Value
     (R  : in out Tagged_Rec;
      AR :        System.Address)
   is
   begin
      R.A := R.A + 1;
      Check_Param_Passing (Formal => R'Address,
                           Actual => AR);
   end Update_Value;

end Machine_X;
```

Listing 60: show_by_copy_by_ref_params.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Machine_X;   use Machine_X;

procedure Show_By_Copy_By_Ref_Params is
   TR : Tagged_Rec := (A   => 5);
   R  : Rec        := (A   => 5);
   RA : Rec_Array  := (A   => 5,
                       Arr => (others => 0));
```

(continues on next page)

(continued from previous page)

```
9  begin
10    Put_Line ("Tagged record");
11    Update_Value (TR, TR'Address);
12
13    Put_Line ("Untagged record");
14    Update_Value (R,  R'Address);
15
16    Put_Line ("Untagged record with array");
17    Update_Value (RA, RA'Address);
18 end Show_By_Copy_By_Ref_Params;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Parameter_Modes_
 ↪Associations.By_Copy_By_Ref_Params
MD5: 3ca46380c4df36af9393041181ff2f17
```

Runtime output

```
Tagged record
Formal parameter at 00007FFEE3FB1200
Actual parameter at 00007FFEE3FB1200
Parameter is passed by reference.
Untagged record
Formal parameter at 00007FFEE3FB104C
Actual parameter at 00007FFEE3FB11FC
Parameter is passed by copy.
Untagged record with array
Formal parameter at 00007FFEE3FB1060
Actual parameter at 00007FFEE3FB1060
Parameter is passed by reference.
```

When we run this example, we see that the object of tagged type (Tagged_Rec) is passed by reference to the Update_Value procedure. In the case of the objects of untagged record types, you might see this:

- the parameter of Rec type — which is an untagged record with a single component of integer type —, the parameter is passed by copy;
- the parameter of Rec_Array type — which is an untagged record with a large array of 100 components —, the parameter is passed by reference.

Because Rec and Rec_Array are neither by-copy nor by-reference types, the decision about how to pass them to the Update_Value procedure is made by the compiler. (Thus, it is possible that you see different results when running the code above.)

Bounded errors

When we use parameters of types that are neither by-copy nor by-reference types, we might encounter the situation where we have the same object bound to different names in a subprogram. For example, if:

- we use a global object Global_R of a record type Rec

and

- we have a subprogram with an in-out parameter of the same record type Rec

and

- we pass Global_R as the actual parameter for the in-out parameter of this subprogram,

then we have two access paths to this object: one of them using the global variable directly, and the other one using it indirectly via the in-out parameter. This situation could lead to undefined behavior or to a program error. Consider the following code example:

Listing 61: machine_x.ads

```
with System;

package Machine_X is

   type Rec is record
      A : Integer;
   end record;

   Global_R : Rec := (A => 0);

   procedure Update_Value
     (R  : in out Rec;
      AR :        System.Address);

end Machine_X;
```

Listing 62: machine_x.adb

```
with Ada.Text_IO;         use Ada.Text_IO;

with Check_Param_Passing;

package body Machine_X is

   procedure Update_Value
     (R  : in out Rec;
      AR :        System.Address)
   is
      procedure Show_Vars is
      begin
         Put_Line ("Global_R.A: "
                   & Integer'Image (Global_R.A));
         Put_Line ("R.A:        "
                   & Integer'Image (R.A));
      end Show_Vars;
   begin
      Check_Param_Passing (Formal => R'Address,
                           Actual => AR);

      Put_Line ("Incrementing Global_R.A...");
      Global_R.A := Global_R.A + 1;
      Show_Vars;

      Put_Line ("Incrementing R.A...");
      R.A := R.A + 5;
      Show_Vars;
   end Update_Value;

end Machine_X;
```

Listing 63: show_by_copy_by_ref_params.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Machine_X;   use Machine_X;

procedure Show_By_Copy_By_Ref_Params is
```

(continues on next page)

(continued from previous page)

```
begin
   Put_Line ("Calling Update_Value...");
   Update_Value (Global_R,  Global_R'Address);

   Put_Line ("After call to Update_Value...");
   Put_Line ("Global_R.A: "
             & Integer'Image (Global_R.A));
end Show_By_Copy_By_Ref_Params;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Parameter_Modes_
 ↪Associations.By_Copy_By_Ref_Params
MD5: 96be7054b7ff64a304705edf6b15f031
```

Runtime output

```
Calling Update_Value...
Formal parameter at 00007FFCE420962C
Actual parameter at 00000000008003BC
Parameter is passed by copy.
Incrementing Global_R.A...
Global_R.A:  1
R.A:         0
Incrementing R.A...
Global_R.A:  1
R.A:         5
After call to Update_Value...
Global_R.A:  5
```

In the `Update_Value` procedure, because `Global_R` and `R` have a type that is neither a by-pass nor a by-reference type, the language does not specify whether the old or the new value would be read in the calls to `Put_Line`. In other words, the actual behavior is undefined. Also, this situation might raise the `Program_Error` exception.

Important

As a general advice:

- you should be very careful when using global variables and
- you should avoid passing them as parameters in situations such as the one illustrated in the code example above.

Aliased parameters

When a parameter is specified as *aliased*, it is always passed by reference, independently of the type we're using. In this sense, we can use this keyword to circumvent the rules mentioned so far. (We discuss more about *aliasing* (page 777) and *aliased parameters* (page 785) later on.)

Let's rewrite a previous code example that has a parameter of elementary type and change it to *aliased*:

Listing 64: machine_x.ads

```
with System;

```

(continues on next page)

(continued from previous page)

```
package Machine_X is

   procedure Update_Value
     (V  : aliased in out Integer;
      AV :                System.Address);

end Machine_X;
```

Listing 65: machine_x.adb

```
with Check_Param_Passing;

package body Machine_X is

   procedure Update_Value
     (V  : aliased in out Integer;
      AV :                System.Address)
   is
   begin
      V := V + 1;
      Check_Param_Passing (Formal => V'Address,
                           Actual => AV);
   end Update_Value;

end Machine_X;
```

Listing 66: show_by_copy_by_ref_params.adb

```
with Machine_X; use Machine_X;

procedure Show_By_Copy_By_Ref_Params is
   A : aliased Integer := 5;
begin
   Update_Value (A, A'Address);
end Show_By_Copy_By_Ref_Params;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Parameter_Modes_
 ↪Associations.By_Copy_By_Ref_Params
MD5: c066af3a7081815d0a7598733f9e6aec
```

Runtime output

```
Formal parameter at 00007FFFF01B01CC
Actual parameter at 00007FFFF01B01CC
Parameter is passed by reference.
```

As we can see, A is now passed by reference.

Note that we can only pass aliased objects to aliased parameters. If we try to pass a non-aliased object, we get a compilation error:

Listing 67: show_by_copy_by_ref_params.adb

```
with Machine_X; use Machine_X;

procedure Show_By_Copy_By_Ref_Params is
   A : Integer := 5;
begin
```

(continues on next page)

(continued from previous page)

```
6     Update_Value (A, A'Address);
7  end Show_By_Copy_By_Ref_Params;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Parameter_Modes_
 ↪Associations.By_Copy_By_Ref_Params
MD5: 9e6586e0b771de68040131cae81799b8
```

Build output

```
show_by_copy_by_ref_params.adb:6:18: error: actual for aliased formal "V" must be␣
 ↪aliased object
gprbuild: *** compilation phase failed
```

Again, we discuss more about *aliased parameters* (page 785) and *aliased objects* (page 778) later on in the context of access types.

Parameter Associations

When actual parameters are associated with formal parameters, some rules are checked. As a typical example, the type of each actual parameter must match the type of the corresponding actual parameter. In this section, we see some details about how this association is made and some of the potential errors.

In the Ada Reference Manual

- 6.4.1 Parameter Associations[139]

Parameter order and association

As we already know, when calling subprograms, we can use positional or named parameter association — or a mixture of both. Also, parameters can have default values. Let's see some examples:

Listing 68: operations.ads

```
1  package Operations is
2
3     procedure Add (Left  : in out Integer;
4                    Right :        Float := 1.0);
5
6  end Operations;
```

Listing 69: operations.adb

```
1  package body Operations is
2
3     procedure Add (Left  : in out Integer;
4                    Right :        Float := 1.0) is
5     begin
6        Left := Left + Integer (Right);
7     end Add;
```

(continues on next page)

[139] http://www.ada-auth.org/standards/22rm/html/RM-6-4-1.html

(continued from previous page)

```
8
9  end Operations;
```

Listing 70: show_param_association.adb

```
1  with Operations; use Operations;
2
3  procedure Show_Param_Association is
4     A : Integer := 5;
5  begin
6     --  Positional association
7     Add (A, 2.0);
8
9     --  Positional association
10    --  (using default value)
11    Add (A);
12
13    --  Named association
14    Add (Left  => A,
15         Right => 2.0);
16
17    --  Named association (inversed order)
18    Add (Right => 2.0,
19         Left  => A);
20
21    --  Mixed positional / named association
22    Add (A, Right => 2.0);
23 end Show_Param_Association;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Parameter_Modes_
 ↪Associations.Param_Association_1
MD5: 64d3f44ac2bf72317fae22658f6d218e
```

This code snippet has examples of positional and name parameter association. Also, it has an example of mixed positional / named parameter association. In most cases, the actual A parameter is associated with the formal `Left` parameter, and the actual 2.0 parameter is associated with the formal `Right` parameter.

In addition to that, parameters can have default values, so, when we write `Add (A)`, the A variable is associated with the `Left` parameter and the default value (1.0) is associated with the `Right` parameter.

Also, when we use named parameter association, the parameter order is irrelevant: we can, for example, write the last parameter as the first one. Therefore, we can write `Add (Right => 2.0, Left => A)` instead of `Add (Left => A, Right => 2.0)`.

Ambiguous calls

Ambiguous calls can be detected by the compiler during parameter association. For example, when we have both default values in parameters and subprogram overloading, the compiler might be unable to decide which subprogram we're calling:

Listing 71: operations.ads

```
1  package Operations is
2
3     procedure Add (Left  : in out Integer);
```

(continues on next page)

(continued from previous page)

```
4
5     procedure Add (Left  : in out Integer;
6                    Right :        Float := 1.0);
7
8  end Operations;
```

Listing 72: operations.adb

```
1  package body Operations is
2
3     procedure Add (Left  : in out Integer) is
4     begin
5        Left := Left + 1;
6     end Add;
7
8     procedure Add (Left  : in out Integer;
9                    Right :        Float := 1.0) is
10    begin
11       Left := Left + Integer (Right);
12    end Add;
13
14 end Operations;
```

Listing 73: show_param_association.adb

```

show_param_association.adb:6:04: error: possible interpretation at operations.ads:3
gprbuild: *** compilation phase failed
```

As we see in this example, the Add procedure is overloaded. The first instance has one parameter, and the second instance has two parameters, where the second parameter has a default value. When we call Add with just one parameter, the compiler cannot decide whether we intend to call

- the first instance of Add with one parameter

or

- the second instance of Add using the default value for the second parameter.

In this specific case, there are multiple options to solve the issue, but all of them involve redesigning the package specification:

- we could just rename one of Add procedures (thereby eliminating the subprogram overloading);
- we could rename the first parameter of one of the Add procedures and use named parameter association in the call to the procedure;
  - For example, we could rename the parameter to `Value` and call `Add (Value => A)`.
- remove the default value from the second parameter of the second instance of Add.

Overlapping actual parameters

When we have more than one **`out`** or **`in out`** parameters in a subprogram, we might run into the situation where the actual parameter overlaps with another parameter. For example:

Listing 74: machine_x.ads

```
package Machine_X is

   procedure Update_Value (V1 : in out Integer;
                           V2 :    out Integer);

end Machine_X;
```

Listing 75: machine_x.adb

```
package body Machine_X is

   procedure Update_Value (V1 : in out Integer;
                           V2 :    out Integer) is
   begin
      V1 := V1 + 1;
      V2 := V2 + 1;
   end Update_Value;

end Machine_X;
```

Listing 76: show_by_copy_by_ref_params.adb

```
with Machine_X; use Machine_X;

procedure Show_By_Copy_By_Ref_Params is
   A : Integer := 5;
begin
   Update_Value (A, A);
end Show_By_Copy_By_Ref_Params;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Parameter_Modes_
 ↪Associations.Illegal_Calls
MD5: d18a7056463fee9298dd1fdef0a31daf
```

Build output

```
show_by_copy_by_ref_params.adb:6:18: error: writable actual for "V1" overlaps with␣
 ↪actual for "V2"
gprbuild: *** compilation phase failed
```

In this case, we're using A for both output parameters in the call to Update_Value. Passing one variable to more than one output parameter in a given call is forbidden in Ada, so this triggers a compilation error. Depending on the specific context, you could solve this issue by using temporary variables for the other output parameters.

26.3.2 Operators

Operators are commonly used for variables of scalar types such as **Integer** and **Float**. In these cases, they replace *usual* function calls. (To be more precise, operators are function calls, but written in a different format.) For example, we simply write `A := A + B + C;` when we want to add three integer variables. A hypothetical, non-intuitive version of this operation could be `A := Add (Add (A, B), C);`. In such cases, operators allow for expressing function calls in a more intuitive way.

Many primitive operators exist for scalar types. We classify them as follows:

Category	Operators
Logical	**and**, **or**, **xor**
Relational	=, /=, <, <=, >, >=
Unary adding	+, -
Binary adding	+, -, &
Multiplying	*, /, **mod**, **rem**
Highest precedence	**, **abs**, **not**

In the Ada Reference Manual

- 4.5 Operators and Expression Evaluation[140]

User-defined operators

For non-scalar types, not all operators are defined. For example, it wouldn't make sense to expect a compiler to include an addition operator for a record type with multiple components. Exceptions to this rule are the equality and inequality operators (= and /=), which are defined for any type (be it scalar, record types, and array types).

For array types, the concatenation operator (&) is a primitive operator:

Listing 77: integer_arrays.ads

```
1  package Integer_Arrays is
2
3     type Integer_Array is
4       array (Positive range <>) of Integer;
5
6  end Integer_Arrays;
```

Listing 78: show_array_concatenation.adb

```
1  with Ada.Text_IO;    use Ada.Text_IO;
2  with Integer_Arrays; use Integer_Arrays;
3
4  procedure Show_Array_Concatenation is
```

(continues on next page)

[140] http://www.ada-auth.org/standards/22rm/html/RM-4-5.html

(continued from previous page)

```
   A, B : Integer_Array (1 .. 5);
   R    : Integer_Array (1 .. 10);
begin
   A := (1 & 2 & 3 & 4 & 5);
   B := (6 & 7 & 8 & 9 & 10);
   R := A & B;

   for E of R loop
      Put (E'Image & ' ');
   end loop;
   New_Line;
end Show_Array_Concatenation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Operators.Integer_Arrays_
 ↪Concat
MD5: 1899e66ec1d0b36b10d8b89fc2dfac0e
```

Runtime output

```
 1  2  3  4  5  6  7  8  9  10
```

In this example, we're using the primitive & operator to concatenate the A and B arrays in the assignment to R. Similarly, we're concatenating individual components (integer values) to create an aggregate that we assign to A and B.

In contrast to this, the addition operator is not available for arrays:

Listing 79: integer_arrays.ads

```
package Integer_Arrays is

   type Integer_Array is
     array (Positive range <>) of Integer;

end Integer_Arrays;
```

Listing 80: show_array_addition.adb

```
with Ada.Text_IO;    use Ada.Text_IO;
with Integer_Arrays; use Integer_Arrays;

procedure Show_Array_Addition is
   A, B, R : Integer_Array (1 .. 5);
begin
   A := (1 & 2 & 3 & 4 & 5);
   B := (6 & 7 & 8 & 9 & 10);
   R := A + B;

   for E of R loop
      Put (E'Image & ' ');
   end loop;
   New_Line;

end Show_Array_Addition;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Operators.Integer_Arrays_
 ↪Addition
```

(continues on next page)

(continued from previous page)

```
MD5: d94f9791523359d390a7cafd900d1268
```

Build output

```
show_array_addition.adb:9:11: error: there is no applicable operator "+" for type
 ↪"Integer_Array" defined at integer_arrays.ads:3
gprbuild: *** compilation phase failed
```

We can, however, define *custom* operators for any type. For example, if a specific type doesn't have a predefined addition operator, we can define our own + operator for it.

Note that we're limited to the operator symbols that are already defined by the Ada language (see the previous table for the complete list of operators). In other words, the operator we define must be selected from one of those existing symbols; we cannot use new symbols for custom operators.

In other languages

Some programming languages — such as Haskell — allow you to define and use custom operator symbols. For example, in Haskell, you can create a new "broken bar" (¦) operator for integer values:

```
(¦) :: Int -> Int -> Int
a ¦ b = a + a + b

main = putStrLn $ show (2 ¦ 3)
```

This is not possible in Ada.

Let's define a custom addition operator that adds individual components of the `Integer_Array` type:

Listing 81: integer_arrays.ads

```
1  package Integer_Arrays is
2
3     type Integer_Array is
4       array (Positive range <>) of Integer;
5
6     function "+" (Left, Right : Integer_Array)
7                   return Integer_Array
8       with Post =>
9         (for all I in "+"'Result'Range =>
10           "+"'Result (I) = Left (I) + Right (I));
11
12 end Integer_Arrays;
```

Listing 82: integer_arrays.adb

```
1  package body Integer_Arrays is
2
3     function "+" (Left, Right : Integer_Array)
4                   return Integer_Array
5     is
6        R : Integer_Array (Left'Range);
7     begin
8        for I in Left'Range loop
9           R (I) := Left (I) + Right (I);
10       end loop;
```

(continues on next page)

(continued from previous page)

```
11
12       return R;
13    end "+";
14
15 end Integer_Arrays;
```

Listing 83: show_array_addition.adb

```
1  with Ada.Text_IO;    use Ada.Text_IO;
2  with Integer_Arrays; use Integer_Arrays;
3
4  procedure Show_Array_Addition is
5     A, B, R : Integer_Array (1 .. 5);
6  begin
7     A := (1 & 2 & 3 & 4 & 5);
8     B := (6 & 7 & 8 & 9 & 10);
9     R := A + B;
10
11    for E of R loop
12       Put (E'Image & ' ');
13    end loop;
14    New_Line;
15
16 end Show_Array_Addition;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Operators.Integer_Arrays_
↪Addition
MD5: 6f50fa47270d97d3fb50379b6275777d
```

Runtime output

```
 7  9  11  13  15
```

Now, the `R := A + B` line doesn't trigger a compilation error anymore because the `+` operator is defined for the `Integer_Array` type.

In the implementation of the `+`, we return an array with the range of the `Left` array where each component is the sum of the `Left` and `Right` arrays. In the declaration of the `+` operator, we're defining the expected behavior in the postcondition. Here, we're saying that, for each index of the resulting array (`for all I in "+"'Result'Range`), the value of each component of the resulting array at that specific index is the sum of the components from the `Left` and `Right` arrays at the same index (`"+"'Result (I) = Left (I) + Right (I)`). (`for all` denotes a *quantified expression* (page 590).)

Note that, in this implementation, we assume that the range of `Right` is a subset of the range of `Left`. If that is not the case, the `Constraint_Error` exception will be raised at runtime in the loop. (You can test this by declaring `B` as `Integer_Array (5 .. 10)`, for example.)

We can also define custom operators for record types. For example, we could declare two `+` operators for a record containing the name and address of a person:

Listing 84: addresses.ads

```
1  package Addresses is
2
3     type Person is private;
4
5     function "+" (Name    : String;
```

(continues on next page)

(continued from previous page)

```
                 Address : String)
                 return Person;
   function "+" (Left, Right : Person)
                 return Person;

   procedure Display (P : Person);

private

   subtype Name_String    is String (1 .. 40);
   subtype Address_String is String (1 .. 100);

   type Person is record
      Name    : Name_String;
      Address : Address_String;
   end record;

end Addresses;
```

Listing 85: addresses.adb

```
with Ada.Strings.Fixed; use Ada.Strings.Fixed;
with Ada.Text_IO;       use Ada.Text_IO;

package body Addresses is

   function "+" (Name    : String;
                 Address : String)
                 return Person
   is
   begin
      return (Name    =>
                Head (Name,
                      Name_String'Length),
              Address =>
                Head (Address,
                      Address_String'Length));
   end "+";

   function "+" (Left, Right : Person)
                 return Person
   is
   begin
      return (Name    => Left.Name,
              Address => Right.Address);
   end "+";

   procedure Display (P : Person) is
   begin
      Put_Line ("Name:    " & P.Name);
      Put_Line ("Address: " & P.Address);
      New_Line;
   end Display;

end Addresses;
```

Listing 86: show_address_addition.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Addresses;   use Addresses;
```

(continues on next page)

(continued from previous page)

```
3
4  procedure Show_Address_Addition is
5     John : Person := "John" + "4 Main Street";
6     Jane : Person := "Jane" + "7 High Street";
7  begin
8     Display (John);
9     Display (Jane);
10    Put_Line ("----------------");
11
12    Jane := Jane + John;
13    Display (Jane);
14 end Show_Address_Addition;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Operators.Rec_Operator
MD5: c69ff43ed5a80a0c62bad87eada14301
```

Runtime output

```
Name:    John
Address: 4 Main Street

Name:    Jane
Address: 7 High Street

----------------
Name:    Jane
Address: 4 Main Street
```

In this example, the first + operator takes two strings — with the name and address of a person — and returns an object of Person type. We use this operator to initialize the John and Jane variables.

The second + operator in this example brings two people together. Here, the person on the left side of the + operator moves to the home of the person on the right side. In this specific case, Jane is moving to John's house.

As a small remark, we usually expect that the + operator is commutative. In other words, changing the order of the elements in the operation doesn't change the result. However, in our definition above, this is *not* the case, as we can confirm by comparing the operation in both orders:

Listing 87: show_address_addition.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2  with Addresses;   use Addresses;
3
4  procedure Show_Address_Addition is
5     John : constant Person :=
6               "John" + "4 Main Street";
7     Jane : constant Person :=
8               "Jane" + "7 High Street";
9  begin
10    if Jane + John = John + Jane then
11       Put_Line ("It's commutative!");
12    else
13       Put_Line ("It's not commutative!");
14    end if;
15 end Show_Address_Addition;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Operators.Rec_Operator
MD5: 2af6e1a31100a1d0fa786d42cc93c09b
```

Runtime output

```
It's not commutative!
```

In this example, we're using the primitive = operator for the Person to assess whether the result of the addition is commutative.

In the Ada Reference Manual

- 6.1 Subprogram Declarations[141]

26.3.3 Expression functions

Usually, we implement Ada functions with a construct like this: `begin return X; end;`. In other words, we create a `begin ... end;` block and we have at least one `return` statement in that block. An expression function, in contrast, is a function that is implemented with a simple expression in parentheses, such as `(X);`. In this case, we don't use a `begin ... end;` block or a `return` statement.

As an example of an expression, let's say we want to implement a function named `Is_Zero` that checks if the value of the integer parameter `I` is zero. We can implement this function with the expression `I = 0`. In the usual approach, we would create the implementation by writing `is begin return I = 0; end Is_Zero;`. When using expression functions, however, we can simplify the implementation by just writing `is (I = 0);`. This is the complete code of `Is_Zero` using an expression function:

Listing 88: expr_func.ads

```
1  package Expr_Func is
2
3     function Is_Zero (I : Integer)
4                       return Boolean is
5       (I = 0);
6
7  end Expr_Func;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Expression_Functions.Simple_
↪Expression_Function_1
MD5: 44779999566f764279e1c2f292226f95
```

An expression function has the same effect as the usual version using a block. In fact, the code above is similar to this implementation of the `Is_Zero` function using a block:

Listing 89: expr_func.ads

```
1  package Expr_Func is
2
3     function Is_Zero (I : Integer)
4                       return Boolean;
```

(continues on next page)

[141] http://www.ada-auth.org/standards/22rm/html/RM-6-1.html

(continued from previous page)

```
5
6  end Expr_Func;
```

Listing 90: expr_func.adb

```
1  package body Expr_Func is
2
3     function Is_Zero (I : Integer)
4                       return Boolean is
5     begin
6        return I = 0;
7     end Is_Zero;
8
9  end Expr_Func;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Expression_Functions.Simple_
 ↪Expression_Function_2
MD5: 4d90b1c63928cbaf9c86a6cc6421bb61
```

The only difference between these two versions of the Expr_Func packages is that, in the first version, the package specification contains the implementation of the Is_Zero function, while, in the second version, the implementation is in the body of the Expr_Func package.

An expression function can be, at same time, the specification and the implementation of a function. Therefore, in the first version of the Expr_Func package above, we don't have a separate implementation of the Is_Zero function because (I = 0) is the actual implementation of the function. Note that this is only possible for expression functions; you cannot have a function implemented with a block in a package specification. For example, the following code is wrong and won't compile:

Listing 91: expr_func.ads

```
1  package Expr_Func is
2
3     function Is_Zero (I : Integer)
4                       return Boolean is
5     begin
6        return I = 0;
7     end Is_Zero;
8
9  end Expr_Func;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Expression_Functions.Simple_
 ↪Expression_Function_3
MD5: 919f9c101b3224006e1302130eba8dd2
```

We can, of course, separate the function declaration from its implementation as an expression function. For example, we can rewrite the first version of the Expr_Func package and move the expression function to the body of the package:

Listing 92: expr_func.ads

```
1  package Expr_Func is
2
3     function Is_Zero (I : Integer)
```

(continues on next page)

(continued from previous page)

```
                     return Boolean;

end Expr_Func;
```

Listing 93: expr_func.adb

```
package body Expr_Func is

   function Is_Zero (I : Integer)
                     return Boolean is
     (I = 0);

end Expr_Func;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Expression_Functions.Simple_
 ↪Expression_Function_4
MD5: 491a491da92636a35579f870969aaf08
```

In addition, we can use expression functions in the private part of a package specification. For example, the following code declares the `Is_Valid` function in the specification of the `My_Data` package, while its implementation is an expression function in the private part of the package specification:

Listing 94: my_data.ads

```
package My_Data is

   type Data is private;

   function Is_Valid (D : Data)
                      return Boolean;

private

   type Data is record
      Valid : Boolean;
   end record;

   function Is_Valid (D : Data)
                      return Boolean is
     (D.Valid);

end My_Data;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Expression_Functions.
 ↪Private_Expression_Function_1
MD5: beb57eca67b3954097e0f7ac00ea70c9
```

Naturally, we could write the function implementation in the package body instead:

Listing 95: my_data.ads

```
package My_Data is

   type Data is private;

```

(continues on next page)

(continued from previous page)

```
   function Is_Valid (D : Data)
                      return Boolean;

private

   type Data is record
      Valid : Boolean;
   end record;

end My_Data;
```

Listing 96: my_data.adb

```
package body My_Data is

   function Is_Valid (D : Data)
                      return Boolean is
     (D.Valid);

end My_Data;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Expression_Functions.
 ↪Private_Expression_Function_2
MD5: 3c6e2a3c53c7c8e1a7b86efccdc3bf8d
```

In the Ada Reference Manual

- 6.8 Expression functions[142]

26.3.4 Overloading

Note: This section was originally written by Robert A. Duff and published as Gem #50: Overload Resolution[143].

Ada allows overloading of subprograms, which means that two or more subprogram declarations with the same name can be visible at the same place. Here, "name" can refer to operator symbols, like `"+"`. Ada also allows overloading of various other notations, such as literals and aggregates.

In most languages that support overloading, overload resolution is done "bottom up" — that is, information flows from inner constructs to outer constructs. As usual, computer folks draw their trees upside-down, with the root at the top. For example, if we have two procedures `Print`:

Listing 97: show_overloading.adb

```
procedure Show_Overloading is

   package Types is
      type Sequence is null record;
```

(continues on next page)

[142] http://www.ada-auth.org/standards/22rm/html/RM-6-8.html
[143] https://www.adacore.com/gems/gem-50

(continued from previous page)

```
      type Set is null record;

      procedure Print (S : Sequence) is null;
      procedure Print (S : Set) is null;
   end Types;

   use Types;

   X : Sequence;
begin

   --  Compiler selects Print (S : Sequence)
   Print (X);
end Show_Overloading;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Overloading.Overloading
MD5: 020c4f04285c80c1050d8edbaf2dbcae
```

the type of X determines which `Print` is meant in the call.

Ada is unusual in that it supports top-down overload resolution as well:

Listing 98: show_top_down_overloading.adb

```
procedure Show_Top_Down_Overloading is

   package Types is
      type Sequence is null record;
      type Set is null record;

      function Empty return Sequence is
        ((others => <>));

      function Empty return Set is
        ((others => <>));

      procedure Print_Sequence (S : Sequence) is
        null;

      procedure Print_Set (S : Set) is
        null;
   end Types;

   use Types;

   X : Sequence;
begin
   --  Compiler selects function
   --  Empty return Sequence
   Print_Sequence (Empty);
end Show_Top_Down_Overloading;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Overloading.Overloading
MD5: 3b776a3efdee3d7e583ddbf5159c9a1b
```

The type of the formal parameter S of `Print_Sequence` determines which `Empty` is meant in the call. In C++, for example, the equivalent of the `Print (X)` example would resolve, but the `Print_Sequence (Empty)` would be illegal, because C++ does not use top-down

information.

If we overload things too heavily, we can cause ambiguities:

Listing 99: show_overloading_error.adb

```
procedure Show_Overloading_Error is

   package Types is
      type Sequence is null record;
      type Set is null record;

      function Empty return Sequence is
        ((others => <>));

      function Empty return Set is
        ((others => <>));

      procedure Print (S : Sequence) is
        null;

      procedure Print (S : Set) is
        null;
   end Types;

   use Types;

   X : Sequence;
begin
   Print (Empty);  -- Illegal!
end Show_Overloading_Error;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Overloading.Overloading
MD5: 5182c517a1afff4568ab2404ac66fda8
```

Build output

```
show_overloading_error.adb:24:04: error: ambiguous expression (cannot resolve
 ↪"Print")
show_overloading_error.adb:24:04: error: possible interpretation at line 16
show_overloading_error.adb:24:04: error: possible interpretation at line 13
show_overloading_error.adb:24:11: error: ambiguous call to "Empty"
show_overloading_error.adb:24:11: error: interpretation at line 10
show_overloading_error.adb:24:11: error: interpretation at line 7
gprbuild: *** compilation phase failed
```

The call is ambiguous, and therefore illegal, because there are two possible meanings. One way to resolve the ambiguity is to use a qualified expression to say which type we mean:

```
Print (Sequence'(Empty));
```

Note that we're now using both bottom-up and top-down overload resolution: `Sequence'` determines which `Empty` is meant (top down) and which `Print` is meant (bottom up). You can qualify an expression, even if it is not ambiguous according to Ada rules — you might want to clarify the type because it might be ambiguous for human readers.

Of course, you could instead resolve the `Print (Empty)` example by modifying the source code so the names are unique, as in the earlier examples. That might well be the best solution, assuming you can modify the relevant sources. Too much overloading can be confusing. How much is "too much" is in part a matter of taste.

Ada really needs to have top-down overload resolution, in order to resolve literals. In some

languages, you can tell the type of a literal by looking at it, for example appending L (letter el) means "the type of this literal is long int". That sort of kludge won't work in Ada, because we have an open-ended set of integer types:

Listing 100: show_literal_resolution.adb

```
procedure Show_Literal_Resolution is

   type Apple_Count is range 0 .. 100;

   procedure Peel (Count : Apple_Count) is null;
begin
   Peel (20);
end Show_Literal_Resolution;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Overloading.Literal_
 ↪Resolution
MD5: f428b6b4c642c44ede6bc21e7522c532
```

You can't tell by looking at the literal `20` what its type is. The type of formal parameter **`Count`** tells us that `20` is an `Apple_Count`, as opposed to some other type, such as `Standard.Long_Integer`.

Technically, the type of `20` is `universal_integer`, which is implicitly converted to `Apple_Count` — it's really the result type of that implicit conversion that is at issue. But that's an obscure point — you won't go *too* far wrong if you think of the integer literal notation as being overloaded on all integer types.

Developers sometimes wonder why the compiler can't resolve something that seems obvious. For example:

Listing 101: show_literal_resolution_error.adb

```
procedure Show_Literal_Resolution_Error is

   type Apple_Count is range 0 .. 100;
   procedure Slice (Count : Apple_Count) is null;

   type Orange_Count is range 0 .. 10_000;
   procedure Slice (Count : Orange_Count) is null;
begin
   Slice (Count => (10_000));  --  Illegal!
end Show_Literal_Resolution_Error;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Overloading.Literal_
 ↪Resolution_Error
MD5: 4789d8eea9b82649ba8e453bb861688a
```

Build output

```
show_literal_resolution_error.adb:9:04: error: ambiguous expression (cannot␣
 ↪resolve "Slice")
show_literal_resolution_error.adb:9:04: error: possible interpretation at line 7
show_literal_resolution_error.adb:9:04: error: possible interpretation at line 4
gprbuild: *** compilation phase failed
```

This call is ambiguous, and therefore illegal. But why? Clearly the developer must have meant the `Orange_Count` one, because `10_000` is out of range for `Apple_Count`. And all the relevant expressions happen to be static.

Well, a good rule of thumb in language design (for languages with overloading) is that the overload resolution rules should not be "too smart". We want this example to be illegal to avoid confusion on the part of developers reading the code. As usual, a qualified expression fixes it:

```
Slice (Count => Orange_Count'(10_000));
```

Another example, similar to the literal, is the aggregate. Ada uses a simple rule: the type of an aggregate is determined top down (i.e., from the context in which the aggregate appears). Bottom-up information is not used; that is, the compiler does not look inside the aggregate in order to determine its type.

Listing 102: show_record_resolution_error.adb

```
procedure Show_Record_Resolution_Error is

   type Complex is record
      Re, Im : Float;
   end record;

   procedure Grind (X : Complex) is null;
   procedure Grind (X : String) is null;
begin
   Grind (X => (Re => 1.0, Im => 1.0));
   --  ^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^
   --  Illegal!
end Show_Record_Resolution_Error;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Overloading.Record_
 ↪Resolution_Error
MD5: e3dd1f1d0c403bcf672f4bab881b8ef9
```

Build output

```
show_record_resolution_error.adb:10:04: error: ambiguous expression (cannot␣
 ↪resolve "Grind")
show_record_resolution_error.adb:10:04: error: possible interpretation at line 8
show_record_resolution_error.adb:10:04: error: possible interpretation at line 7
gprbuild: *** compilation phase failed
```

There are two `Grind` procedures visible, so the type of the aggregate could be `Complex` or **`String`**, so it is ambiguous and therefore illegal. The compiler is not required to notice that there is only one type with components `Re` and `Im`, of some real type — in fact, the compiler is not *allowed* to notice that, for overloading purposes.

We can qualify as usual:

```
Grind (X => Complex'(Re => 1.0, Im => 1.0));
```

Only after resolving that the type of the aggregate is `Complex` can the compiler look inside and make sure `Re` and `Im` make sense.

This not-too-smart rule for aggregates helps prevent confusion on the part of developers reading the code. It also simplifies the compiler, and makes the overload resolution algorithm reasonably efficient.

26.3.5 Operator Overloading

We've seen *previously* (page 631) that we can define custom operators for any type. We've also seen that subprograms can be *overloaded* (page 640). Since operators are functions, we're essentially talking about operator overloading, as we're defining the same operator (say + or -) for different types.

As another example of operator overloading, in the Ada standard library, operators are defined for the Complex type of the Ada.Numerics.Generic_Complex_Types package. This package contains not only the definition of the + operator for two objects of Complex type, but also for combination of Complex and other types. For instance, we can find these declarations:

```
function "+" (Left, Right : Complex)
              return Complex;
function "+" (Left : Complex;   Right : Real'Base)
              return Complex;
function "+" (Left : Real'Base; Right : Complex)
              return Complex;
```

This example shows that the + operator — as well as other operators — are being overloaded in the Generic_Complex_Types package.

In the Ada Reference Manual

- 6.6 Overloading of Operators[144]
- G.1.1 Complex Types[145]

26.3.6 Operator Overriding

We can also override operators of derived types. This allows for modifying the behavior of operators for the corresponding derived types.

To override an operator of a derived type, we simply implement a function for that operator. This is the same as how we implement custom operators (as we've seen previously).

As an example, when adding two fixed-point values, the result might be out of range, which causes an exception to be raised. A common strategy to avoid exceptions in this case is to saturate the resulting value. This strategy is typically employed in signal processing algorithms, for example.

In this example, we declare and use the 32-bit fixed-point type TQ31:

Listing 103: fixed_point.ads

```
1 package Fixed_Point is
2
3    D : constant := 2.0 ** (-31);
4    type TQ31 is delta D range -1.0 .. 1.0 - D;
5
6 end Fixed_Point;
```

[144] http://www.ada-auth.org/standards/22rm/html/RM-6-6.html
[145] http://www.ada-auth.org/standards/22rm/html/RM-G-1-1.html

Listing 104: show_sat_op.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Fixed_Point; use Fixed_Point;

procedure Show_Sat_Op is
   A, B, C : TQ31;
begin
   A := TQ31'Last;
   B := TQ31'Last;
   C := A + B;

   Put_Line (A'Image   & " + "
             & B'Image & " = "
             & C'Image);

   A := TQ31'First;
   B := TQ31'First;
   C := A + B;

   Put_Line (A'Image   & " + "
             & B'Image & " = "
             & C'Image);

end Show_Sat_Op;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Operator_Overriding.Fixed_
 ↪Point_Exception
MD5: 15d8860773ec7c0e505d0ee94781ae14
```

Runtime output

```

raised CONSTRAINT_ERROR : show_sat_op.adb:9 overflow check failed
```

Here, we're using the standard `+` operator, which raises a `Constraint_Error` exception in the `C := A + B;` statement due to an overflow. Let's now override the addition operator and enforce saturation when the result is out of range:

Listing 105: fixed_point.ads

```
package Fixed_Point is

   D : constant := 2.0 ** (-31);
   type TQ31 is delta D range -1.0 .. 1.0 - D;

   function "+" (Left, Right : TQ31)
                 return TQ31;

end Fixed_Point;
```

Listing 106: fixed_point.adb

```
package body Fixed_Point is

   function "+" (Left, Right : TQ31)
                 return TQ31
   is
      type TQ31_2 is
        delta TQ31'Delta
```

(continues on next page)

(continued from previous page)

```
        range TQ31'First * 2.0 .. TQ31'Last * 2.0;

      L   : constant TQ31_2 := TQ31_2 (Left);
      R   : constant TQ31_2 := TQ31_2 (Right);
      Res : TQ31_2;
   begin
      Res := L + R;

      if Res > TQ31_2 (TQ31'Last) then
         return TQ31'Last;
      elsif Res < TQ31_2 (TQ31'First) then
         return TQ31'First;
      else
         return TQ31 (Res);
      end if;
   end "+";

end Fixed_Point;
```

Listing 107: show_sat_op.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Fixed_Point; use Fixed_Point;

procedure Show_Sat_Op is
   A, B, C : TQ31;
begin
   A := TQ31'Last;
   B := TQ31'Last;
   C := A + B;

   Put_Line (A'Image   & " + "
             & B'Image & " = "
             & C'Image);

   A := TQ31'First;
   B := TQ31'First;
   C := A + B;

   Put_Line (A'Image   & " + "
             & B'Image & " = "
             & C'Image);

end Show_Sat_Op;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Operator_Overriding.Fixed_
 ↪Point_Operator_Overloading
MD5: 6317bcf9c278c01f86dbdcb761d86240
```

Runtime output

```
 0.9999999995 +  0.9999999995 =  0.9999999995
-1.0000000000 + -1.0000000000 = -1.0000000000
```

In the implementation of the overridden + operator of the TQ31 type, we declare another type (TQ31_2) with a wider range than TQ31. We use variables of the TQ31_2 type to perform the actual addition, and then we verify whether the result is still in TQ31's range. If it is, we simply convert the result *back* to the TQ31 type. Otherwise, we saturate it — using either the first or last value of the TQ31 type.

When overriding operators, the overridden operator replaces the original one. For example, in the `A + B` operation of the `Show_Sat_Op` procedure above, we're using the overridden version of the `+` operator, which performs saturation. Therefore, this operation doesn't raise an exception (as it was the case with the original `+` operator).

26.3.7 Nonreturning procedures

Usually, when calling a procedure P, we expect that it returns to the caller's *thread of control* after performing some action in the body of P. However, there are situations where a procedure never returns. We can indicate this fact by using the `No_Return` aspect in the subprogram declaration.

A typical example is that of a server that is designed to run forever until the process is killed or the machine where the server runs is switched off. This server can be implemented as an endless loop. For example:

Listing 108: servers.ads

```
package Servers is

   procedure Run_Server
     with No_Return;

end Servers;
```

Listing 109: servers.adb

```
package body Servers is

   procedure Run_Server is
   begin
      pragma Warnings
        (Off,
         "implied return after this statement");
      while True loop
         --  Processing happens here...
         null;
      end loop;
   end Run_Server;

end Servers;
```

Listing 110: show_endless_loop.adb

```
with Servers; use Servers;

procedure Show_Endless_Loop is
begin
   Run_Server;
end Show_Endless_Loop;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Nonreturning_Procedures.
 ↪Server_Proc
MD5: 3f859b6e2aca8e31367658632e84126c
```

In this example, `Run_Server` doesn't exit from the `while True` loop, so it never returns to the `Show_Endless_Loop` procedure.

The same situation happens when we call a procedure that raises an exception unconditionally. In that case, exception handling is triggered, so that the procedure never returns to the caller. An example is that of a logging procedure that writes a message before raising an exception internally:

Listing 111: loggers.ads

```
package Loggers is

   Logged_Failure : exception;

   procedure Log_And_Raise (Msg : String)
     with No_Return;

end Loggers;
```

Listing 112: loggers.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Loggers is

   procedure Log_And_Raise (Msg : String) is
   begin
      Put_Line (Msg);
      raise Logged_Failure;
   end Log_And_Raise;

end Loggers;
```

Listing 113: show_no_return_exception.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Loggers;     use Loggers;

procedure Show_No_Return_Exception is
   Check_Passed : constant Boolean := False;
begin
   if not Check_Passed then
      Log_And_Raise ("Check failed!");
      Put_Line ("This line will not be reached!");
   end if;
end Show_No_Return_Exception;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Nonreturning_Procedures.Log_
 ↪Exception
MD5: 10b4933d8c862d14ade54935cbd2b541
```

In this example, `Log_And_Raise` writes a message to the user and raises the `Logged_Failure`, so it never returns to the `Show_No_Return_Exception` procedure.

We could implement exception handling in the `Show_No_Return_Exception` procedure, so that the `Logged_Failure` exception could be handled there after it's raised in `Log_And_Raise`. However, this wouldn't be considered a *normal* return to the procedure because it wouldn't return to the point where it should (i.e. to the point where `Put_Line` is about to be called, right after the call to the `Log_And_Raise` procedure).

If a nonreturning procedure returns nevertheless, this is considered a program error, so that the `Program_Error` exception is raised. For example:

Listing 114: loggers.ads

```
package Loggers is

   Logged_Failure : exception;

   procedure Log_And_Raise (Msg : String)
     with No_Return;

end Loggers;
```

Listing 115: loggers.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Loggers is

   procedure Log_And_Raise (Msg : String) is
   begin
      Put_Line (Msg);
   end Log_And_Raise;

end Loggers;
```

Listing 116: show_no_return_exception.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Loggers;     use Loggers;

procedure Show_No_Return_Exception is
   Check_Passed : constant Boolean := False;
begin
   if not Check_Passed then
      Log_And_Raise ("Check failed!");
      Put_Line ("This line will not be reached!");
   end if;
end Show_No_Return_Exception;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Nonreturning_Procedures.
 ↪Erroneous_Log_Exception
MD5: e44fd8df0529dda5749e85b9e300a999
```

Build output

```
loggers.adb:7:07: warning: implied return after this statement will raise Program_
 ↪Error [enabled by default]
loggers.adb:7:07: warning: procedure "Log_And_Raise" is marked as No_Return␣
 ↪[enabled by default]
```

Runtime output

```
Check failed!

raised PROGRAM_ERROR : loggers.adb:7 implicit return with No_Return
```

Here, Program_Error is raised when Log_And_Raise returns to the Show_No_Return_Exception procedure.

In the Ada Reference Manual

- 6.5.1 Nonreturning Subprograms[146]

26.3.8 Inline subprograms

Inlining[147] refers to a kind of optimization where the code of a subprogram is expanded at the point of the call in place of the call itself.

In modern compilers, inlining depends on the optimization level selected by the user. For example, if we select the higher optimization level, the compiler will perform automatic inlining agressively.

In the GNAT toolchain

The highest optimization level (`-O3`) of GNAT performs aggressive automatic inlining. This could mean that this level inlines too much rather than not enough. As a result, the cache may become an issue and the overall performance may be worse than the one we would achieve by compiling the same code with optimization level 2 (`-O2`). Therefore, the general recommendation is to not *just* select `-O3` for the optimized version of an application, but instead compare it the optimized version built with `-O2`.

It's important to highlight that the inlining we're referring above happens automatically, so the decision about which subprogram is inlined depends entirely on the compiler. However, in some cases, it's better to reduce the optimization level and perform manual inlining instead of automatic inlining. We do that by using the `Inline` aspect.

Let's look at this example:

Listing 117: float_arrays.ads

```
package Float_Arrays is

   type Float_Array is
     array (Positive range <>) of Float;

   function Average (Data : Float_Array)
                     return Float
     with Inline;

end Float_Arrays;
```

Listing 118: float_arrays.adb

```
package body Float_Arrays is

   function Average (Data : Float_Array)
                     return Float
   is
      Total : Float := 0.0;
   begin
      for Value of Data loop
         Total := Total + Value;
      end loop;
      return Total / Float (Data'Length);
   end Average;

end Float_Arrays;
```

[146] http://www.ada-auth.org/standards/22rm/html/RM-6-5-1.html
[147] https://en.wikipedia.org/wiki/Inline_expansion

Listing 119: compute_average.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Float_Arrays; use Float_Arrays;

procedure Compute_Average is
   Values        : constant Float_Array :=
                     (10.0, 11.0, 12.0, 13.0);
   Average_Value : Float;
begin
   Average_Value := Average (Values);
   Put_Line ("Average = "
             & Float'Image (Average_Value));
end Compute_Average;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Inline_Subprograms.Inlining_
 ↪Float_Arrays
MD5: 246bc11e8a969d69873f416f583f450e
```

Runtime output

```
Average =  1.15000E+01
```

When compiling this example, the compiler will most probably inline `Average` in the `Compute_Average` procedure. Note, however, that the `Inline` aspect is just a *recommendation* to the compiler. Sometimes, the compiler might not be able to follow this recommendation, so it won't inline the subprogram.

These are some examples of situations where the compiler might not be able to inline a subprogram:

- when the code is too large,
- when it's too complicated — for example, when it involves exception handling —, or
- when it contains tasks, etc.

In the GNAT toolchain

In order to effectively use the `Inline` aspect, we need to set the optimization level to at least `-O1` and use the `-gnatn` switch, which instructs the compiler to take the `Inline` aspect into account.

In addition to the `Inline` aspect, in GNAT, we also have the (implementation-defined) `Inline_Always` aspect. In contrast to the former aspect, however, the `Inline_Always` aspect isn't primarily related to performance. Instead, it should be used when the functionality would be incorrect if inlining was not performed by the compiler. Examples of this are procedures that insert Assembly instructions that only make sense when the procedure is inlined, such as memory barriers.

Similar to the `Inline` aspect, there might be situations where a subprogram has the `Inline_Always` aspect, but the compiler is unable to inline it. In this case, we get a compilation error from GNAT.

Note that we can use the `Inline` aspect for generic subprograms as well. When we do this, we indicate to the compiler that we wish it inlines all instances of that generic subprogram.

In the Ada Reference Manual

- 6.3.2 Inline Expansion of Subprograms[148]

26.3.9 Null Procedures

Null procedures are procedures that don't have any effect, as their body is empty. We declare a null procedure by simply writing **is null** in its declaration. For example:

Listing 120: null_procs.ads

```
package Null_Procs is

   procedure Do_Nothing (Msg : String) is null;

end Null_Procs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Null_Procedures.Null_Proc_1
MD5: a8a801e6c71d8177db61e4aa131b8832
```

As expected, calling a null procedure doesn't have any effect. For example:

Listing 121: show_null_proc.adb

```
with Null_Procs; use Null_Procs;

procedure Show_Null_Proc is
begin
   Do_Nothing ("Hello");
end Show_Null_Proc;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Null_Procedures.Null_Proc_1
MD5: 274eed0b0952b9aa7e422933ece42d86
```

Null procedures are equivalent to implementing a procedure with a body that only contains **null**. Therefore, the Do_Nothing procedure above is equivalent to this:

Listing 122: null_procs.ads

```
package Null_Procs is

   procedure Do_Nothing (Msg : String);

end Null_Procs;
```

Listing 123: null_procs.adb

```
package body Null_Procs is

   procedure Do_Nothing (Msg : String) is
   begin
      null;
   end Do_Nothing;

end Null_Procs;
```

[148] http://www.ada-auth.org/standards/22rm/html/RM-6-3-2.html

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Null_Procedures.Null_Proc_1
MD5: d0c9dc9265ebbaa9603681182dee1d92
```

Null procedures and overriding

We can use null procedures as a way to simulate interfaces for non-tagged types — similar to what actual interfaces do for tagged types. For example, we may start by declaring a type and null procedures that operate on that type. For example, let's model a very simple API:

Listing 124: simple_storage.ads

```
package Simple_Storage is

   type Storage_Model is null record;

   procedure Set (S : in out Storage_Model;
                  V :        String) is null;
   procedure Display (S : Storage_Model) is null;

end Simple_Storage;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Null_Procedures.Simple_
 ↪Storage_Model
MD5: 553e78bc15dcec1302be4b5f484ac21f
```

Here, the API of the `Storage_Model` type consists of the `Set` and `Display` procedures. Naturally, we can use objects of the `Storage_Model` type in an application, but this won't have any effect:

Listing 125: show_null_proc.adb

```
with Ada.Text_IO;    use Ada.Text_IO;
with Simple_Storage; use Simple_Storage;

procedure Show_Null_Proc is
   S : Storage_Model;
begin
   Put_Line ("Setting 24...");
   Set (S, "24");
   Display (S);
end Show_Null_Proc;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Null_Procedures.Simple_
 ↪Storage_Model
MD5: 523b3e7239e683f2d879caa9139106ca
```

Runtime output

```
Setting 24...
```

By itself, the `Storage_Model` type is not very useful. However, we can derive other types from it and override the null procedures. Let's say we want to implement the `Integer_Storage` type to store an integer value:

Listing 126: simple_storage.ads

```
package Simple_Storage is

   type Storage_Model is null record;

   procedure Set (S : in out Storage_Model;
                  V :        String) is null;
   procedure Display (S : Storage_Model) is null;

   type Integer_Storage is private;

   procedure Set (S : in out Integer_Storage;
                  V :        String);
   procedure Display (S : Integer_Storage);

private

   type Integer_Storage is record
      V : Integer := 0;
   end record;

end Simple_Storage;
```

Listing 127: simple_storage.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Simple_Storage is

   procedure Set (S : in out Integer_Storage;
                  V :        String) is
   begin
      S.V := Integer'Value (V);
   end Set;

   procedure Display (S : Integer_Storage) is
   begin
      Put_Line ("Value: " & S.V'Image);
   end Display;

end Simple_Storage;
```

Listing 128: show_null_proc.adb

```
with Ada.Text_IO;    use Ada.Text_IO;
with Simple_Storage; use Simple_Storage;

procedure Show_Null_Proc is
   S : Integer_Storage;
begin
   Put_Line ("Setting 24...");
   Set (S, "24");
   Display (S);
end Show_Null_Proc;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Subprograms.Null_Procedures.Simple_
 ↪Storage_Model
MD5: 55d491d1ef72fb7be2bf0d2a212f335b
```

Runtime output

```
Setting 24...
Value:  24
```

In this example, we can view `Storage_Model` as a sort of interface for derived non-tagged types, while the derived types — such as `Integer_Storage` — provide the actual implementation.

The section on *null records* (page 420) contains an extended example that makes use of null procedures.

In the Ada Reference Manual

- 6.7 Null Procedures[149]

26.4 Exceptions

26.4.1 Asserts

When we want to indicate a condition in the code that must always be valid, we can use the pragma `Assert`. As the name implies, when we use this pragma, we're *asserting* some truth about the source-code. (We can also use the procedural form, as we'll see later.)

Important

Another method to assert the truth about the source-code is to use *pre and post-conditions* (page 1975).

A simple assert has this form:

Listing 129: show_pragma_assert.adb

```
1 procedure Show_Pragma_Assert is
2    I : constant Integer := 10;
3
4    pragma Assert (I = 10);
5 begin
6    null;
7 end Show_Pragma_Assert;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Asserts.Pragma_Assert_1
MD5: 8d40817304515169d0d5670904ca1e01
```

In this example, we're asserting that the value of `I` is always 10. We could also display a message if the assertion is false:

Listing 130: show_pragma_assert.adb

```
1 procedure Show_Pragma_Assert is
2    I : constant Integer := 11;
3
```

(continues on next page)

[149] http://www.ada-auth.org/standards/22rm/html/RM-6-7.html

(continued from previous page)

```
   pragma Assert (I = 10, "I is not 10");
begin
   null;
end Show_Pragma_Assert;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Asserts.Pragma_Assert_2
MD5: b70fa67c92542ade39c388964ce12302
```

Build output

```
show_pragma_assert.adb:4:19: warning: assertion will fail at run time [-gnatw.a]
```

Runtime output

```

raised ADA.ASSERTIONS.ASSERTION_ERROR : I is not 10
```

Similarly, we can use the procedural form of `Assert`. For example, the code above can implemented as follows:

Listing 131: show_procedure_assert.adb

```
with Ada.Assertions; use Ada.Assertions;

procedure Show_Procedure_Assert is
   I : constant Integer := 11;

begin
   Assert (I = 10, "I is not 10");
end Show_Procedure_Assert;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Asserts.Procedure_Assert
MD5: cbab23645ff89d4adffcaaddaeb6f0e3
```

Runtime output

```

raised ADA.ASSERTIONS.ASSERTION_ERROR : I is not 10
```

Note that a call to `Assert` is simply translated to a check — and the `Assertion_Error` exception from the `Ada.Assertions` package being raised in the case that the check fails. For example, the code above roughly corresponds to this:

Listing 132: show_assertion_error.adb

```
with Ada.Assertions; use Ada.Assertions;

procedure Show_Assertion_Error is
   I : constant Integer := 11;

begin
   if I /= 10 then
      raise Assertion_Error with "I is not 10";
   end if;

end Show_Assertion_Error;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Asserts.Assertion_Error
MD5: 9c846acf998ca7adabd47c3b5a6ce39f
```

Runtime output

```

raised ADA.ASSERTIONS.ASSERTION_ERROR : I is not 10
```

In the Ada Reference Manual

- 11.4.2 Pragmas Assert and Assertion_Policy[150]

26.4.2 Assertion policies

We can activate and deactivate assertions based on assertion policies. We can do that by using the pragma `Assertion_Policy`. As an argument to this pragma, we indicate whether a specific policy must be checked or ignored.

For example, we can deactivate assertion checks by specifying `Assert => Ignore`. Similarly, we can activate assertion checks by specifying `Assert => Check`. Let's see a code example:

Listing 133: show_pragma_assertion_policy.adb

```
1  procedure Show_Pragma_Assertion_Policy is
2     I : constant Integer := 11;
3
4     pragma Assertion_Policy (Assert => Ignore);
5  begin
6     pragma Assert (I = 10);
7  end Show_Pragma_Assertion_Policy;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Assertion_Policies.Pragma_
 ↪Assertion_Policy_1
MD5: 39b8aa4a34b6169c03b54074f4136519
```

Build output

```
show_pragma_assertion_policy.adb:6:19: warning: assertion would fail at run time [-
 ↪gnatw.a]
```

Here, we're specifying that asserts shall be ignored. Therefore, the call to the pragma `Assert` doesn't raise an exception. If we replace `Ignore` with `Check` in the call to `Assertion_Policy`, the assert will raise the `Assertion_Error` exception.

The following table presents all policies that we can set:

[150] http://www.ada-auth.org/standards/22rm/html/RM-11-4-2.html

Policy	Descripton
`Assert`	Check assertions
`Static_Predicate`	Check static predicates
`Dynamic_Predicate`	Check dynamic predicates
`Pre`	Check pre-conditions
`Pre'Class`	Check pre-condition of classes of tagged types
`Post`	Check post-conditions
`Post'Class`	Check post-condition of classes of tagged types
`Type_Invariant`	Check type invariants
`Type_Invariant'Class`	Check type invariant of classes of tagged types

In the GNAT toolchain

Compilers are free to include policies that go beyond the ones listed above. For example, GNAT includes the following policies — called *assertion kinds* in this context:

- `Assertions`
- `Assert_And_Cut`
- `Assume`
- `Contract_Cases`
- `Debug`
- `Ghost`
- `Initial_Condition`
- `Invariant`
- `Invariant'Class`
- `Loop_Invariant`
- `Loop_Variant`
- `Postcondition`
- `Precondition`
- `Predicate`
- `Refined_Post`
- `Statement_Assertions`
- `Subprogram_Variant`

Also, in addtion to `Check` and `Ignore`, GNAT allows you to set a policy to `Disable` and `Suppressible`.

You can read more about them in the GNAT Reference Manual[151].

You can specify multiple policies in a single call to `Assertion_Policy`. For example, you can activate all policies by writing:

[151] https://gcc.gnu.org/onlinedocs/gnat_rm/Pragma-Assertion_005fPolicy.html

Listing 134: show_multiple_assertion_policies.adb

```
procedure Show_Multiple_Assertion_Policies is
   pragma Assertion_Policy
     (Assert               => Check,
      Static_Predicate     => Check,
      Dynamic_Predicate    => Check,
      Pre                  => Check,
      Pre'Class            => Check,
      Post                 => Check,
      Post'Class           => Check,
      Type_Invariant       => Check,
      Type_Invariant'Class => Check);
begin
   null;
end Show_Multiple_Assertion_Policies;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Assertion_Policies.Multiple_
 ↪Assertion_Policies
MD5: 3abbf97160b755b84cc4f7e652ca5551
```

In the GNAT toolchain

With GNAT, policies can be specified in multiple ways. In addition to calls to `Assertion_Policy`, you can use configuration pragmas files[152]. You can use these files to specify all pragmas that are relevant to your application, including `Assertion_Policy`. In addition, you can manage the granularity for those pragmas. For example, you can use a global configuration pragmas file for your complete application, or even different files for each source-code file you have.

Also, by default, all policies listed in the table above are deactivated, i.e. they're all set to `Ignore`. You can use the command-line switch `-gnata` to activate them.

Note that the `Assert` procedure raises an exception independently of the assertion policy (`Assertion_Policy (Assert => Ignore)`). For example:

Listing 135: show_assert_procedure_policy.adb

```
with Ada.Text_IO;    use Ada.Text_IO;
with Ada.Assertions; use Ada.Assertions;

procedure Show_Assert_Procedure_Policy is
   pragma Assertion_Policy (Assert => Ignore);

   I : constant Integer := 1;
begin
   Put_Line ("------ Pragma Assert -----");
   pragma Assert (I = 0);

   Put_Line ("---- Procedure Assert ----");
   Assert (I = 0);

   Put_Line ("Finished.");
end Show_Assert_Procedure_Policy;
```

Code block metadata

[152] https://gcc.gnu.org/onlinedocs/gnat_ugn/The-Configuration-Pragmas-Files.html#The-Configuration-Pragmas-Files

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Assertion_Policies.Assert_
 ↪Procedure_Policy
MD5: 7be3bab24d856081afeddabe40afc84f
```

Build output

```
show_assert_procedure_policy.adb:10:19: warning: assertion would fail at run time␣
 ↪[-gnatw.a]
```

Runtime output

```
------ Pragma Assert -----
---- Procedure Assert ----

raised ADA.ASSERTIONS.ASSERTION_ERROR : a-assert.adb:42
```

Here, the **pragma** *Assert* is ignored due to the assertion policy. However, the call to `Assert` is not ignored.

In the Ada Reference Manual

- 11.4.2 Pragmas Assert and Assertion_Policy[153]

26.4.3 Checks and exceptions

This table shows all language-defined checks and the associated exceptions:

Check	Exception
Access_Check	Constraint_Error
Discriminant_Check	Constraint_Error
Division_Check	Constraint_Error
Index_Check	Constraint_Error
Length_Check	Constraint_Error
Overflow_Check	Constraint_Error
Range_Check	Constraint_Error
Tag_Check	Constraint_Error
Accessibility_Check	Program_Error
Allocation_Check	Program_Error
Elaboration_Check	Program_Error
Storage_Check	Storage_Error

In addition, we can use `All_Checks` to refer to all those checks above at once.

Let's discuss each check and see code examples where those checks are performed. Note that all examples are erroneous, so please avoid reusing them elsewhere.

[153] http://www.ada-auth.org/standards/22rm/html/RM-11-4-2.html

Access Check

As you know, an object of an access type might be null. It would be an error to dereference this object, as it doesn't indicate a valid position in memory. Therefore, the access check verifies that an access object is not null when dereferencing it. For example:

Listing 136: show_access_check.adb

```
procedure Show_Access_Check is

   type Integer_Access is access Integer;

   AI : Integer_Access;
begin
   AI.all := 10;
end Show_Access_Check;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Checks_And_Exceptions.Access_
 ↪Check
MD5: 4db8b63efb23caa7da926d4ec9f204bf
```

Build output

```
show_access_check.adb:5:04: warning: variable "AI" is read but never assigned [-
 ↪gnatwv]
show_access_check.adb:7:04: warning: null value not allowed here [enabled by␣
 ↪default]
show_access_check.adb:7:04: warning: Constraint_Error will be raised at run time␣
 ↪[enabled by default]
```

Runtime output

```

raised CONSTRAINT_ERROR : show_access_check.adb:7 access check failed
```

Here, the value of AI is null by default, so we cannot dereference it.

The access check also performs this verification when assigning to a subtype that excludes null (**not null access**). (You can find more information about this topic in the section about *not null access* (page 808).) For example:

Listing 137: show_access_check.adb

```
procedure Show_Access_Check is

   type Integer_Access is
     access all Integer;

   type Safe_Integer_Access is
     not null access all Integer;

   AI  : Integer_Access;
   SAI : Safe_Integer_Access := new Integer;

begin
   SAI := Safe_Integer_Access (AI);
end Show_Access_Check;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Checks_And_Exceptions.Access_
 ↪Check_2
MD5: 47895a404e2a111476cd67f43c12d4b5
```

Build output

```
show_access_check.adb:9:04: warning: variable "AI" is read but never assigned [-
 ↪gnatwv]
show_access_check.adb:13:32: warning: null value not allowed here [enabled by␣
 ↪default]
show_access_check.adb:13:32: warning: Constraint_Error will be raised at run time␣
 ↪[enabled by default]
```

Runtime output

```

raised CONSTRAINT_ERROR : show_access_check.adb:13 access check failed
```

Here, the value of AI is null (by default), so we cannot assign it to SAI because its type excludes null.

Note that, if we remove the `:= new Integer` assignment from the declaration of SAI, the null exclusion fails in the declaration itself (because the default value of the access type is `null`).

Discriminant Check

As we've seen earlier, a variant record is a record with discriminants that allows for changing its structure. In operations such as an assignment, it's important to ensure that the discriminants of the objects match — i.e. to ensure that the structure of the objects matches. The discriminant check verifies whether this is the case. For example:

Listing 138: show_discriminant_check.adb

```
procedure Show_Discriminant_Check is

   type Rec (Valid : Boolean) is record
      case Valid is
         when True =>
            Counter : Integer;
         when False =>
            null;
      end case;
   end record;

   R : Rec (Valid => False);
begin
   R := (Valid  => True,
         Counter => 10);
end Show_Discriminant_Check;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Checks_And_Exceptions.
 ↪Discriminant_Check
MD5: 665ab37962f8f9c129acac543b1eb15d
```

Build output

```
show_discriminant_check.adb:14:09: warning: incorrect value for discriminant "Valid
 ↪" [enabled by default]
show_discriminant_check.adb:14:09: warning: Constraint_Error will be raised at run␣
 ↪time [enabled by default]
```

Runtime output

```
raised CONSTRAINT_ERROR : show_discriminant_check.adb:14 discriminant check failed
```

Here, R's discriminant (`Valid`) is **`False`**, so we cannot assign an object whose `Valid` discriminant is **`True`**.

Also, when accessing a component, the discriminant check ensures that this component exists for the current discriminant value:

Listing 139: show_discriminant_check.adb

```
1  procedure Show_Discriminant_Check is
2
3     type Rec (Valid : Boolean) is record
4        case Valid is
5           when True =>
6              Counter : Integer;
7           when False =>
8              null;
9        end case;
10    end record;
11
12    R : Rec (Valid => False);
13    I : Integer;
14 begin
15    I := R.Counter;
16 end Show_Discriminant_Check;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Checks_And_Exceptions.
 ↪Discriminant_Check_2
MD5: 440973b0be7c4261ddf3c2211a2c1325
```

Build output

```
show_discriminant_check.adb:15:10: warning: component not present in subtype of
 ↪"Rec" defined at line 12 [enabled by default]
show_discriminant_check.adb:15:10: warning: Constraint_Error will be raised at run␣
 ↪time [enabled by default]
```

Runtime output

```
raised CONSTRAINT_ERROR : show_discriminant_check.adb:15 discriminant check failed
```

Here, R's discriminant (`Valid`) is **`False`**, so we cannot access the `Counter` component, for it only exists when the `Valid` discriminant is **`True`**.

Division Check

The division check verifies that we're not trying to divide a value by zero when using the `/`, `rem` and `mod` operators. For example:

Listing 140: ops.ads

```
package Ops is
   function Div_Op (A, B : Integer)
                    return Integer is
     (A / B);

   function Rem_Op (A, B : Integer)
                    return Integer is
     (A rem B);

   function Mod_Op (A, B : Integer)
                    return Integer is
     (A mod B);
end Ops;
```

Listing 141: show_division_check.adb

```
with Ops; use Ops;

procedure Show_Division_Check is
   I : Integer;
begin
   I := Div_Op (10, 0);
   I := Rem_Op (10, 0);
   I := Mod_Op (10, 0);
end Show_Division_Check;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Checks_And_Exceptions.
 ↪Division_Check
MD5: 6ec0856be947eea6610cffaa0e875d45
```

Runtime output

```

raised CONSTRAINT_ERROR : ops.ads:4 divide by zero
```

All three calls in the `Show_Division_Check` procedure — to the `Div_Op`, `Rem_Op` and `Mod_Op` functions — can raise an exception because we're using 0 as the second argument, which makes the division check in those functions fail.

Index Check

We use indices to access components of an array. An index check verifies that the index we're using to access a specific component is within the array's bounds. For example:

Listing 142: show_index_check.adb

```
procedure Show_Index_Check is

   type Integer_Array is
     array (Positive range <>) of Integer;

```

(continues on next page)

(continued from previous page)

```
   function Value_Of (A : Integer_Array;
                      I : Integer)
                      return Integer
   is
      type Half_Integer_Array is new
        Integer_Array (A'First ..
                       A'First + A'Length / 2);

      A_2 : Half_Integer_Array := (others => 0);
   begin
      return A_2 (I);
   end Value_Of;

   Arr_1 : Integer_Array (1 .. 10) :=
             (others => 1);

begin
   Arr_1 (10) := Value_Of (Arr_1, 10);

end Show_Index_Check;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Checks_And_Exceptions.Index_
 ↪Check
MD5: fa791718701c4ac805badf368df9064e
```

Runtime output

```

raised CONSTRAINT_ERROR : show_index_check.adb:16 index check failed
```

The range of A_2 — which is passed as an argument to the Value_Of function — is 1 to 6. However, in that function call, we're trying to access position 10, which is outside A_2 's bounds.

Length Check

In array assignments, both arrays must have the same length. To ensure that this is the case, a length check is performed. For example:

Listing 143: show_length_check.adb

```
procedure Show_Length_Check is

   type Integer_Array is
     array (Positive range <>) of Integer;

   procedure Assign (To   : out Integer_Array;
                     From :     Integer_Array) is
   begin
      To := From;
   end Assign;

   Arr_1 : Integer_Array (1 .. 10);
   Arr_2 : Integer_Array (1 .. 9) :=
             (others => 1);

begin
```

(continues on next page)

(continued from previous page)

```
17    Assign (Arr_1, Arr_2);
18 end Show_Length_Check;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Checks_And_Exceptions.Length_
 ↪Check
MD5: a521afd0a46a67d260e8b0bd5f046ce4
```

Runtime output

```

raised CONSTRAINT_ERROR : show_length_check.adb:9 length check failed
```

Here, the length of `Arr_1` is 10, while the length of `Arr_2` is 9, so we cannot assign `Arr_2` (`From` parameter) to `Arr_1` (`To` parameter) in the `Assign` procedure.

Overflow Check

Operations on scalar objects might lead to overflow, which, if not checked, lead to wrong information being computed and stored. Therefore, an overflow check verifies that the value of a scalar object is within the base range of its type. For example:

Listing 144: show_overflow_check.adb

```
1  procedure Show_Overflow_Check is
2     A, B : Integer;
3  begin
4     A := Integer'Last;
5     B := 1;
6
7     A := A + B;
8  end Show_Overflow_Check;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Checks_And_Exceptions.
 ↪Overflow_Check
MD5: baa46d9085cbd14863aaa7e24dc7b9cc
```

Build output

```
show_overflow_check.adb:7:11: warning: value not in range of type "Standard.Integer
 ↪" [enabled by default]
show_overflow_check.adb:7:11: warning: Constraint_Error will be raised at run time␣
 ↪[enabled by default]
```

Runtime output

```

raised CONSTRAINT_ERROR : show_overflow_check.adb:7 overflow check failed
```

In this example, `A` already has the last possible value of the `Integer'Base` range, so increasing it by one causes an overflow error.

Range Check

The range check verifies that a scalar value is within a specific range — for instance, the range of a subtype. Let's see an example:

Listing 145: show_range_check.adb

```
procedure Show_Range_Check is

   subtype Int_1_10 is Integer range 1 .. 10;

   I : Int_1_10;

begin
   I := 11;
end Show_Range_Check;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Checks_And_Exceptions.Range_
 ↪Check
MD5: 54b1d67d98d97a58d4265a854fcfa992
```

Build output

```
show_range_check.adb:8:09: warning: value not in range of type "Int_1_10" defined␣
 ↪at line 3 [enabled by default]
show_range_check.adb:8:09: warning: Constraint_Error will be raised at run time␣
 ↪[enabled by default]
```

Runtime output

```

raised CONSTRAINT_ERROR : show_range_check.adb:8 range check failed
```

In this example, we're trying to assign 11 to the variable I of the Int_1_10 subtype, which has a range from 1 to 10. Since 11 is outside that range, the range check fails.

Tag Check

The tag check ensures that the tag of a tagged object matches the expected tag in a dispatching operation. For example:

Listing 146: p.ads

```
package P is

   type T is tagged null record;
   type T1 is new T with null record;
   type T2 is new T with null record;

end P;
```

Listing 147: show_tag_check.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Ada.Tags;

with P;           use P;

```

(continues on next page)

(continued from previous page)

```
procedure Show_Tag_Check is

   A1 : T'Class := T1'(null record);
   A2 : T'Class := T2'(null record);

begin
   Put_Line ("A1'Tag: "
             & Ada.Tags.Expanded_Name (A1'Tag));
   Put_Line ("A2'Tag: "
             & Ada.Tags.Expanded_Name (A2'Tag));

   A2 := A1;

end Show_Tag_Check;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Checks_And_Exceptions.Tag_
 ↪Check
MD5: 5a685be7804200a884649f54c175ee42
```

Runtime output

```
A1'Tag: P.T1
A2'Tag: P.T2

raised CONSTRAINT_ERROR : show_tag_check.adb:17 tag check failed
```

Here, A1 and A2 have different tags:

- A1'Tag = T1'Tag, while
- A2'Tag = T2'Tag.

Since the tags don't match, the tag check fails in the assignment of A1 to A2.

Accessibility Check

The accessibility check verifies that the accessibility level of an entity matches the expected level. We discuss accessibility levels *in a later chapter* (page 788).

Let's look at an example that mixes access types and anonymous access types. Here, we use an anonymous access type in the declaration of A1 and a named access type in the declaration of A2:

Listing 148: p.ads

```
package P is

   type T is tagged null record;
   type T_Class is access all T'Class;

end P;
```

Listing 149: show_accessibility_check.adb

```
with P; use P;

procedure Show_Accessibility_Check is

```

(continues on next page)

(continued from previous page)

```
   A1 : access T'Class := new T;
   A2 : T_Class;

begin
   A2 := T_Class (A1);

end Show_Accessibility_Check;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Checks_And_Exceptions.
 ↪Accessibility_Check
MD5: 7120d908b55ef576db93e9a15db257f2
```

Build output

```
show_accessibility_check.adb:9:19: warning: accessibility check fails [enabled by␣
 ↪default]
show_accessibility_check.adb:9:19: warning: Program_Error will be raised at run␣
 ↪time [enabled by default]
```

Runtime output

```

raised PROGRAM_ERROR : show_accessibility_check.adb:9 accessibility check failed
```

The anonymous type (`access T'Class`), which is used in the declaration of `A1`, doesn't have the same accessibility level as the `T_Class` type. Therefore, the accessibility check fails during the `T_Class (A1)` conversion.

We can see the accessibility check failing in this example as well:

Listing 150: show_accessibility_check.adb

```
with P; use P;

procedure Show_Accessibility_Check is

   A : access T'Class := new T;

   procedure P (A : T_Class) is null;

begin
   P (T_Class (A));

end Show_Accessibility_Check;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Checks_And_Exceptions.
 ↪Accessibility_Check
MD5: 97db82410dd3459249d0e7a97118b7ef
```

Build output

```
show_accessibility_check.adb:10:16: warning: accessibility check fails [enabled by␣
 ↪default]
show_accessibility_check.adb:10:16: warning: Program_Error will be raised at run␣
 ↪time [enabled by default]
```

Runtime output

```
raised PROGRAM_ERROR : show_accessibility_check.adb:10 accessibility check failed
```

Again, the check fails in the `T_Class (A)` conversion and raises a `Program_Error` exception.

Allocation Check

The allocation check ensures, when a task is about to be created, that its master has not been completed. Also, it ensures that the finalization has not started.

This is an example adapted from AI-00280[154]:

Listing 151: p.ads

```
with Ada.Finalization;
with Ada.Unchecked_Deallocation;

package P is
   type T1 is new
     Ada.Finalization.Controlled with null record;
   procedure Finalize (X : in out T1);

   type T2 is new
     Ada.Finalization.Controlled with null record;
   procedure Finalize (X : in out T2);

   X1 : T1;

   type T2_Ref is access T2;
   procedure Free is new
     Ada.Unchecked_Deallocation (T2, T2_Ref);
end P;
```

Listing 152: p.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body P is

   procedure Finalize (X : in out T1) is
      X2 : T2_Ref := new T2;
   begin
      Put_Line ("Finalizing T1...");
      Free (X2);
   end Finalize;

   procedure Finalize (X : in out T2) is
   begin
      Put_Line ("Finalizing T2...");
   end Finalize;

end P;
```

Listing 153: show_allocation_check.adb

```
with P; use P;

procedure Show_Allocation_Check is
```

(continues on next page)

[154] http://www.ada-auth.org/cgi-bin/cvsweb.cgi/ais/ai-00280.txt?rev=1.12&raw=N

(continued from previous page)

```
   X2 : T2_Ref := new T2;
begin
   Free (X2);
end Show_Allocation_Check;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Checks_And_Exceptions.
 ↪Allocation_Check
MD5: 915e8ab21e550c981503c014bcceade1
```

Runtime output

```
Finalizing T2...

raised PROGRAM_ERROR : finalize/adjust raised exception
```

Here, in the finalization of the X1 object of T1 type, we're trying to create an object of T2 type while the finalization of the master has already started. (Note that X1 was declared in the P package.) This is forbidden, so the allocation check raises a `Program_Error` exception.

Elaboration Check

The elaboration check verifies that subprograms — or protected entries, or task activations — have been elaborated before being called.

This is an example adapted from AI-00064[155]:

Listing 154: p.ads

```
function P return Integer;
```

Listing 155: p.adb

```
function P return Integer is
begin
   return 1;
end P;
```

Listing 156: show_elaboration_check.adb

```
with P;

procedure Show_Elaboration_Check is

   function F return Integer;

   type Pointer_To_Func is
     access function return Integer;

   X : constant Pointer_To_Func := P'Access;

   Y : constant Integer := F;
   Z : constant Pointer_To_Func := X;

   --  Renaming-as-body
   function F return Integer renames Z.all;
```

(continues on next page)

[155] http://www.ada-auth.org/cgi-bin/cvsweb.cgi/ais/ai-00064.txt?rev=1.12&raw=N

(continued from previous page)

```
17 begin
18    null;
19 end Show_Elaboration_Check;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Checks_And_Exceptions.
 ↪Elaboration_Check
MD5: 80a39df912aae8788296f81ee9d4a79e
```

Build output

```
show_elaboration_check.adb:12:28: warning: cannot call "F" before body seen␣
 ↪[enabled by default]
show_elaboration_check.adb:12:28: warning: Program_Error will be raised at run␣
 ↪time [enabled by default]
```

Runtime output

```

raised PROGRAM_ERROR : show_elaboration_check.adb:12 access before elaboration
```

This is a curious example: first, we declare a function F and assign the value returned by this function to constant Y in its declaration. Then, we declare F as a renamed function, thereby providing a body to F — this is called renaming-as-body. Consequently, the compiler doesn't complain that a body is missing for function F. (If you comment out the function renaming, you'll see that the compiler can then detect the missing body.) Therefore, at runtime, the elaboration check fails because the body of the first declaration of the F function is actually missing.

Storage Check

The storage check ensures that the storage pool has enough space when allocating memory. Let's revisit an example that we *discussed earlier* (page 355):

Listing 157: custom_types.ads

```
1  package Custom_Types is
2
3     type UInt_7 is range 0 .. 127;
4
5     type UInt_7_Reserved_Access is access UInt_7
6       with Storage_Size => 8;
7
8  end Custom_Types;
```

Listing 158: show_storage_check.adb

```
1  with Ada.Text_IO;  use Ada.Text_IO;
2
3  with Custom_Types; use Custom_Types;
4
5  procedure Show_Storage_Check is
6
7     RAV1, RAV2 : UInt_7_Reserved_Access;
8
9  begin
10    Put_Line ("Allocating RAV1...");
```

(continues on next page)

(continued from previous page)

```
11    RAV1 := new UInt_7;
12
13    Put_Line ("Allocating RAV2...");
14    RAV2 := new UInt_7;
15
16    New_Line;
17 end Show_Storage_Check;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Checks_And_Exceptions.
 ↪Storage_Check
MD5: 4e4bd284adb1c1d97f8f7563068c18de
```

Runtime output

```
Allocating RAV1...
Allocating RAV2...

raised STORAGE_ERROR : s-poosiz.adb:108 explicit raise
```

On each allocation (`new UInt_7`), a storage check is performed. Because there isn't enough reserved storage space before the second allocation, the checks fails and raises a `Storage_Error` exception.

In the Ada Reference Manual

- 11.5 Suppressing Checks[156]

26.4.4 `Ada.Exceptions` package

Note: Parts of this section were originally published as Gem #142 : Exception-ally[157]

The standard Ada run-time library provides the package `Ada.Exceptions`. This package provides a number of services to help analyze exceptions.

Each exception is associated with a (short) message that can be set by the code that raises the exception, as in the following code:

```
raise Constraint_Error with "some message";
```

Historically

Since Ada 2005, we can use the `raise Constraint_Error with "some message"` syntax. In Ada 95, you had to call the `Raise_Exception` procedure:

```
Ada.Exceptions.Raise_Exception         --  Ada 95
  (Constraint_Error'Identity, "some message");
```

In Ada 83, there was no way to do it at all.

The new syntax is now very convenient, and developers should be encouraged to provide as much information as possible along with the exception.

[156] http://www.ada-auth.org/standards/22rm/html/RM-11-5.html
[157] https://www.adacore.com/gems/gem-142-exceptions

In the GNAT toolchain

The length of the message is limited to 200 characters by default in GNAT, and messages longer than that will be truncated.

In the Ada Reference Manual

- 11.4.1 The Package Exceptions[158]

Retrieving exception information

Exceptions also embed information set by the run-time itself that can be retrieved by calling the `Exception_Information` function. The function `Exception_Information` also displays the `Exception_Message`.

For example:

```
exception
   when E : others =>
     Put_Line
       (Ada.Exceptions.Exception_Information (E));
```

In the GNAT toolchain

In the case of GNAT, the information provided by an exception might include the source location where the exception was raised and a nonsymbolic traceback.

You can also retrieve this information individually. Here, you can use:

- the `Exception_Name` functions — and its derivatives `Wide_Exception_Name` and `Wide_Wide_Exception_Name` — to retrieve the name of an exception.
- the `Exception_Message` function to retrieve the message associated with an exception.

Let's see a complete example:

Listing 159: show_exception_info.adb

```
1  with Ada.Text_IO;    use Ada.Text_IO;
2  with Ada.Exceptions; use Ada.Exceptions;
3
4  procedure Show_Exception_Info is
5
6     Custom_Exception : exception;
7
8     procedure Nested is
9     begin
10       raise Custom_Exception
11         with "We got a problem";
12    end Nested;
13
14 begin
15    Nested;
16
```

(continues on next page)

[158] http://www.ada-auth.org/standards/22rm/html/RM-11-4-1.html

(continued from previous page)

```
exception
   when E : others =>
      Put_Line ("Exception info: "
                & Exception_Information (E));
      Put_Line ("Exception name: "
                & Exception_Name (E));
      Put_Line ("Exception msg:  "
                & Exception_Message (E));
end Show_Exception_Info;
```

Collecting exceptions

Save_Occurrence

You can save an exception occurrence using the Save_Occurrence procedure. (Note that a Save_Occurrence function exists as well.)

For example, the following application collects exceptions into a list and displays them after running the Test_Exceptions procedure:

Listing 160: exception_tests.ads

```
with Ada.Exceptions; use Ada.Exceptions;

package Exception_Tests is

   Custom_Exception : exception;

   type All_Exception_Occur is
     array (Positive range <>) of
       Exception_Occurrence;

   procedure Test_Exceptions
     (All_Occur  : in out All_Exception_Occur;
      Last_Occur :    out Integer);

end Exception_Tests;
```

Listing 161: exception_tests.adb

```
package body Exception_Tests is

   procedure Save_To_List
     (E          :        Exception_Occurrence;
      All_Occur  : in out All_Exception_Occur;
      Last_Occur : in out Integer)
   is
      L : Integer renames Last_Occur;
      O : All_Exception_Occur renames All_Occur;
   begin
      L := L + 1;
      if L > O'Last then
         raise Constraint_Error
           with "Cannot save occurrence";
      end if;

      Save_Occurrence (Target => O (L),
                       Source => E);
```

(continues on next page)

(continued from previous page)

```
   end Save_To_List;

   procedure Test_Exceptions
     (All_Occur  : in out All_Exception_Occur;
      Last_Occur :    out Integer)
   is

      procedure Nested_1 is
      begin
         raise Custom_Exception
           with "We got a problem";
      exception
         when E : others =>
            Save_To_List (E,
                          All_Occur,
                          Last_Occur);
      end Nested_1;

      procedure Nested_2 is
      begin
         raise Constraint_Error
           with "Constraint is not correct";
      exception
         when E : others =>
            Save_To_List (E,
                          All_Occur,
                          Last_Occur);
      end Nested_2;

   begin
      Last_Occur := 0;

      Nested_1;
      Nested_2;
   end Test_Exceptions;

end Exception_Tests;
```

Listing 162: show_exception_info.adb

```
with Ada.Text_IO;    use Ada.Text_IO;
with Ada.Exceptions; use Ada.Exceptions;

with Exception_Tests; use Exception_Tests;

procedure Show_Exception_Info is
   L : Integer;
   O : All_Exception_Occur (1 .. 10);
begin
   Test_Exceptions (O, L);

   for I in O 'First .. L loop
      Put_Line (Exception_Information (O (I)));
   end loop;
end Show_Exception_Info;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Exceptions_Package.Save_
 ↪Occurrence
MD5: da0cc5db7039e1458dbcf8be49db969d
```

Runtime output

```
raised EXCEPTION_TESTS.CUSTOM_EXCEPTION : We got a problem

raised CONSTRAINT_ERROR : Constraint is not correct
```

In the Save_To_List procedure of the Exception_Tests package, we call the Save_Occurrence procedure to store the exception occurrence to the All_Occur array. In the Show_Exception_Info, we display all the exception occurrences that we collected.

Read and Write attributes

Similarly, we can use files to read and write exception occurrences. To do that, we can simply use the Read and Write attributes.

Listing 163: exception_occurrence_stream.adb

```
with Ada.Text_IO;

with Ada.Streams.Stream_IO;
use  Ada.Streams.Stream_IO;

with Ada.Exceptions;
use  Ada.Exceptions;

procedure Exception_Occurrence_Stream is

   Custom_Exception : exception;

   S : Stream_Access;

   procedure Nested_1 is
   begin
      raise Custom_Exception
        with "We got a problem";
   exception
      when E : others =>
         Exception_Occurrence'Write (S, E);
   end Nested_1;

   procedure Nested_2 is
   begin
      raise Constraint_Error
        with "Constraint is not correct";
   exception
      when E : others =>
         Exception_Occurrence'Write (S, E);
   end Nested_2;

   F         : File_Type;
   File_Name : constant String :=
                 "exceptions_file.bin";
begin
   Create (F, Out_File, File_Name);
   S := Stream (F);

   Nested_1;
   Nested_2;

```

(continues on next page)

(continued from previous page)

```
43    Close (F);
44
45    Read_Exceptions : declare
46       E : Exception_Occurrence;
47    begin
48       Open (F, In_File, File_Name);
49       S := Stream (F);
50
51       while not End_Of_File (F) loop
52          Exception_Occurrence'Read (S, E);
53
54          Ada.Text_IO.Put_Line
55            (Exception_Information (E));
56       end loop;
57       Close (F);
58    end Read_Exceptions;
59
60 end Exception_Occurrence_Stream;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Exceptions_Package.Exception_
↪Occurrence_Stream
MD5: 3d9f2bd9480aa6dcc250b249b9ef4870
```

Runtime output

```
raised EXCEPTION_OCCURRENCE_STREAM.CUSTOM_EXCEPTION : We got a problem

raised CONSTRAINT_ERROR : Constraint is not correct
```

In this example, we store the exceptions raised in the application in the *exceptions_file.bin* file. In the exception part of procedures Nested_1 and Nested_2, we call Exception_Occurrence'Write to store an exception occurence in the file. In the Read_Exceptions block, we read the exceptions from the the file by calling Exception_Occurrence'Read.

Debugging exceptions in the GNAT toolchain

Here is a typical exception handler that catches all unexpected exceptions in the application:

Listing 164: main.adb

```
1  with Ada.Exceptions;
2  with Ada.Text_IO;   use Ada.Text_IO;
3
4  procedure Main is
5
6     procedure Nested is
7     begin
8        raise Constraint_Error
9                with "some message";
10    end Nested;
11
12 begin
13    Nested;
14
```

(continues on next page)

(continued from previous page)

```
15 exception
16    when E : others =>
17       Put_Line
18        (Ada.Exceptions.Exception_Information (E));
19 end Main;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Exceptions_Package.Exception_
 ↪Information
MD5: f95068ca90d79b92a7c2031322349153
```

Runtime output

```
raised CONSTRAINT_ERROR : some message

```

The output we get when running the application is not very informative. To get more information, we need to rerun the program in the debugger. To make the session more interesting though, we should add debug information in the executable, which means using the `-g` switch in the **gnatmake** command.

The session would look like the following (omitting some of the output from the debugger):

```
> rm *.o      # Cleanup previous compilation
> gnatmake -g main.adb
> gdb ./main
(gdb)  catch exception
(gdb)  run
Catchpoint 1, CONSTRAINT_ERROR at 0x0000000000402860 in main.nested () at main.
 ↪adb:8
8               raise Constraint_Error with "some message";

(gdb) bt
#0  <__gnat_debug_raise_exception> (e=0x62ec40 <constraint_error>) at s-excdeb.
 ↪adb:43
#1  0x000000000040426f in ada.exceptions.complete_occurrence (x=x@entry=0x637050)
at a-except.adb:934
#2  0x000000000040427b in ada.exceptions.complete_and_propagate_occurrence (
x=x@entry=0x637050) at a-except.adb:943
#3  0x00000000004042d0 in <__gnat_raise_exception> (e=0x62ec40 <constraint_error>,
message=...) at a-except.adb:982
#4  0x0000000000402860 in main.nested ()
#5  0x000000000040287c in main ()
```

And we now know exactly where the exception was raised. But in fact, we could have this information directly when running the application. For this, we need to bind the application with the switch `-E`, which tells the binder to store exception tracebacks in exception occurrences. Let's recompile and rerun the application.

```
> rm *.o   # Cleanup previous compilation
> gnatmake -g main.adb -bargs -E
> ./main

Exception name: CONSTRAINT_ERROR
Message: some message
Call stack traceback locations:
0x10b7e24d1 0x10b7e24ee 0x10b7e2472
```

The traceback, as is, is not very useful. We now need to use another tool that is bundled with GNAT, called **addr2line**. Here is an example of its use:

```
> addr2line -e main --functions --demangle 0x10b7e24d1 0x10b7e24ee 0x10b7e2472
/path/main.adb:8
_ada_main
/path/main.adb:12
main
/path/b~main.adb:240
```

This time we do have a symbolic backtrace, which shows information similar to what we got in the debugger.

For users on OSX machines, **addr2line** does not exist. On these machines, however, an equivalent solution exists. You need to link your application with an additional switch, and then use the tool **atos**, as in:

```
> rm *.o
> gnatmake -g main.adb -bargs -E -largs -Wl,-no_pie
> ./main

Exception name: CONSTRAINT_ERROR
Message: some message
Call stack traceback locations:
0x1000014d1 0x1000014ee 0x100001472
> atos -o main 0x1000014d1 0x1000014ee 0x100001472
main__nested.2550 (in main) (main.adb:8)
_ada_main (in main) (main.adb:12)
main (in main) + 90
```

We will now discuss a relatively new switch of the compiler, namely `-gnateE`. When used, this switch will generate extra information in exception messages.

Let's amend our test program to:

Listing 165: main.adb

```
1  with Ada.Exceptions;
2  with Ada.Text_IO;      use Ada.Text_IO;
3
4  procedure Main is
5
6     procedure Nested (Index : Integer) is
7        type T_Array is array (1 .. 2) of Integer;
8        T : constant T_Array := (10, 20);
9     begin
10       Put_Line (T (Index)'Img);
11    end Nested;
12
13 begin

19        (Ada.Exceptions.Exception_Information (E));
20 end Main;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Exceptions_Package.Exception_
 ↪Information
MD5: 3590f2bf48f6ed1cf7745d576924cad4
```

Runtime output

```
raised CONSTRAINT_ERROR : main.adb:10:17 index check failed
index 3 not in 1..2
```

When running the application, we see that the exception information (traceback) is the same as before, but this time the exception message is set automatically by the compiler. So we know we got a `Constraint_Error` because an incorrect index was used at the named source location (`main.adb`, line 10). But the significant addition is the second line of the message, which indicates exactly the cause of the error. Here, we wanted to get the element at index 3, in an array whose range of valid indexes is from 1 to 2. (No need for a debugger in this case.)

The column information on the first line of the exception message is also very useful when dealing with null pointers. For instance, a line such as:

```
A := Rec1.Rec2.Rec3.Rec4.all;
```

where each of the Rec is itself a pointer, might raise `Constraint_Error` with a message "access check failed". This indicates for sure that one of the pointers is null, and by using the column information it is generally easy to find out which one it is.

26.4.5 Exception renaming

We can rename exceptions by using the an exception renaming declaration in this form `Renamed_Exception : exception renames Existing_Exception;`. For example:

Listing 166: show_exception_renaming.adb

```
1 procedure Show_Exception_Renaming is
2    CE : exception renames Constraint_Error;
3 begin
4    raise CE;
5 end Show_Exception_Renaming;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Exception_Renaming.Exception_
 ↪Renaming
MD5: ff20825162ee9eef6ac8ed329da2a80f
```

Runtime output

```

raised CONSTRAINT_ERROR : show_exception_renaming.adb:4
```

Exception renaming creates a new view of the original exception. If we rename an exception from package A in package B, that exception will become visible in package B. For example:

Listing 167: internal_exceptions.ads

```
1 package Internal_Exceptions is
2
3    Int_E : exception;
4
5 end Internal_Exceptions;
```

Listing 168: test_constraints.ads

```
with Internal_Exceptions;

package Test_Constraints is

   Ext_E : exception renames
             Internal_Exceptions.Int_E;

end Test_Constraints;
```

Listing 169: show_exception_renaming_view.adb

```
with Ada.Text_IO;    use Ada.Text_IO;
with Ada.Exceptions; use Ada.Exceptions;

with Test_Constraints; use Test_Constraints;

procedure Show_Exception_Renaming_View is
begin
   raise Ext_E;
exception
   when E : others =>
      Put_Line
       (Ada.Exceptions.Exception_Information (E));
end Show_Exception_Renaming_View;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Exception_Renaming.Exception_
↪Renaming_View
MD5: a44e2698170c6fab79241d0f33ef8c2e
```

Runtime output

```
raised INTERNAL_EXCEPTIONS.INT_E : show_exception_renaming_view.adb:8
```

Here, we're renaming the `Int_E` exception in the `Test_Constraints` package. The `Int_E` exception isn't directly visible in the `Show_Exception_Renaming` procedure because we're not **with**ing the `Internal_Exceptions` package. However, it is indirectly visible in that procedure via the renaming (`Ext_E`) in the `Test_Constraints` package.

In the Ada Reference Manual

- 8.5.2 Exception Renaming Declarations[159]

---

[159] http://www.ada-auth.org/standards/22rm/html/RM-8-5-2.html

26.4.6 Out and Uninitialized

Note: This section was originally written by Robert Dewar and published as Gem #150: Out and Uninitialized[160]

Perhaps surprisingly, the Ada standard indicates cases where objects passed to **out** and **in out** parameters might not be updated when a procedure terminates due to an exception. Let's take an example:

Listing 170: show_out_uninitialized.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
procedure Show_Out_Uninitialized is

   procedure Local (A     : in out Integer;
                    Error : Boolean) is
   begin
      A := 1;

      if Error then
         raise Program_Error;
      end if;
   end Local;

   B : Integer := 0;

begin
   Local (B, Error => True);
exception
   when Program_Error =>
      Put_Line ("Value for B is"
                & Integer'Image (B));  --  "0"
end Show_Out_Uninitialized;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Out_Uninitialized.Out_
 ↪Uninitialized_1
MD5: cebcf14e9fd088e38b98a5132d9fd998
```

Runtime output

```
Value for B is 0
```

This program outputs a value of 0 for B, whereas the code indicates that A is assigned before raising the exception, and so the reader might expect B to also be updated.

The catch, though, is that a compiler must by default pass objects of elementary types (scalars and access types) by copy and might choose to do so for other types (records, for example), including when passing **out** and **in out** parameters. So what happens is that while the formal parameter A is properly initialized, the exception is raised before the new value of A has been copied back into B (the copy will only happen on a normal return).

In the GNAT toolchain

In general, any code that reads the actual object passed to an **out** or **in out** parameter after an exception is suspect and should be avoided. GNAT has useful warnings here, so that if we simplify the above code to:

[160] https://www.adacore.com/gems/gem-150out-and-uninitialized

Listing 171: show_out_uninitialized_warnings.adb

```
with Ada.Text_IO;  use Ada.Text_IO;

procedure Show_Out_Uninitialized_Warnings is

    procedure Local (A : in out Integer) is
    begin
       A := 1;
       raise Program_Error;
    end Local;

   B : Integer := 0;

begin
   Local (B);
exception
   when others =>
      Put_Line ("Value for B is"
                & Integer'Image (B));
end Show_Out_Uninitialized_Warnings;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Out_Uninitialized.Out_
 ↪Uninitialized_2
MD5: 5b6960974c729ea37a70fb313d6e5084
```

Build output

```
show_out_uninitialized_warnings.adb:7:10: warning: assignment to pass-by-copy␣
 ↪formal may have no effect [enabled by default]
show_out_uninitialized_warnings.adb:7:10: warning: "raise" statement may result in␣
 ↪abnormal return (RM 6.4.1(17)) [enabled by default]
```

Runtime output

```
Value for B is 0
```

We now get a compilation warning that the pass-by-copy formal may have no effect.

Of course, GNAT is not able to point out all such errors (see first example above), which in general would require full flow analysis.

The behavior is different when using parameter types that the standard mandates be passed by reference, such as tagged types for instance. So the following code will work as expected, updating the actual parameter despite the exception:

Listing 172: show_out_initialized_rec.adb

```
with Ada.Text_IO;  use Ada.Text_IO;

procedure Show_Out_Initialized_Rec is

   type Rec is tagged record
      Field : Integer;
   end record;

   procedure Local (A : in out Rec) is
   begin
      A.Field := 1;
```

(continues on next page)

(continued from previous page)

```
      raise Program_Error;
   end Local;

   V : Rec;

begin
   V.Field := 0;
   Local (V);
exception
   when others =>
      Put_Line ("Value of Field is"
                & V.Field'Img); -- "1"
end Show_Out_Initialized_Rec;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Out_Uninitialized.Out_
 ↪Uninitialized_3
MD5: 370031a404657ea18ffabf3c1d507cd4
```

Runtime output

```
Value of Field is 1
```

In the GNAT toolchain

It's worth mentioning that GNAT provides a pragma called `Export_Procedure` that forces reference semantics on **`out`** parameters. Use of this pragma would ensure updates of the actual parameter prior to abnormal completion of the procedure. However, this pragma only applies to library-level procedures, so the examples above have to be rewritten to avoid the use of a nested procedure, and really this pragma is intended mainly for use in interfacing with foreign code. The code below shows an example that ensures that B is set to 1 after the call to `Local`:

Listing 173: exported_procedures.ads

```
package Exported_Procedures is

  procedure Local (A     : in out Integer;
                   Error : Boolean);
  pragma Export_Procedure
    (Local,
     Mechanism => (A => Reference));

end Exported_Procedures;
```

Listing 174: exported_procedures.adb

```
package body Exported_Procedures is

   procedure Local (A     : in out Integer;
                    Error : Boolean) is
   begin A := 1;
      if Error then
         raise Program_Error;
      end if;
   end Local;

end Exported_Procedures;
```

Listing 175: show_out_reference.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Exported_Procedures;
use  Exported_Procedures;

procedure Show_Out_Reference is
   B : Integer := 0;
begin
   Local (B, Error => True);
exception
   when Program_Error =>
      Put_Line ("Value for B is"
                & Integer'Image (B)); -- "1"
end Show_Out_Reference;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Out_Uninitialized.Out_
 ↪Uninitialized_4
MD5: aed2788be2b3ceeec19b28421c53fc66
```

Runtime output

```
Value for B is 1
```

In the case of direct assignments to global variables, the behavior in the presence of exceptions is somewhat different. For predefined exceptions, most notably `Constraint_Error`, the optimization permissions allow some flexibility in whether a global variable is or is not updated when an exception occurs (see Ada RM 11.6[161]). For instance, the following code makes an incorrect assumption:

```
X := 0;     -- about to try addition
Y := Y + 1; -- see if addition raises exception
X := 1      -- addition succeeded
```

A program is not justified in assuming that `X = 0` if the addition raises an exception (assuming X is a global here). So any such assumptions in a program are incorrect code which should be fixed.

In the Ada Reference Manual

- 11.6 Exceptions and Optimization[162]

---

[161] http://www.ada-auth.org/standards/22rm/html/RM-11-6.html

26.4.7 Suppressing checks

pragma Suppress

Note: This section was originally written by Gary Dismukes and published as Gem #63: The Effect of Pragma Suppress[163].

One of Ada's key strengths has always been its strong typing. The language imposes stringent checking of type and subtype properties to help prevent accidental violations of the type system that are a common source of program bugs in other less-strict languages such as C. This is done using a combination of compile-time restrictions (legality rules), that prohibit mixing values of different types, together with run-time checks to catch violations of various dynamic properties. Examples are checking values against subtype constraints and preventing dereferences of null access values.

At the same time, Ada does provide certain "loophole" features, such as `Unchecked_Conversion`, that allow selective bypassing of the normal safety features, which is sometimes necessary when interfacing with hardware or code written in other languages.

Ada also permits explicit suppression of the run-time checks that are there to ensure that various properties of objects are not violated. This suppression can be done using **pragma** *Suppress*, as well as by using a compile-time switch on most implementations — in the case of GNAT, with the `-gnatp` switch.

In addition to allowing all checks to be suppressed, **pragma** *Suppress* supports suppression of specific forms of check, such as `Index_Check` for array indexing, `Range_Check` for scalar bounds checking, and `Access_Check` for dereferencing of access values. (See section 11.5 of the Ada Reference Manual for further details.)

Here's a simple example of suppressing index checks within a specific subprogram:

```
procedure Main is
   procedure Sort_Array (A : in out Some_Array) is
      pragma Suppress (Index_Check);
      --      ^^^^^^^^^^^^^^^^^^^^^
      --   eliminate check overhead
   begin
     ...
   end Sort_Array;
end Main;
```

Unlike a feature such as `Unchecked_Conversion`, however, the purpose of check suppression is not to enable programs to subvert the type system, though many programmers seem to have that misconception.

What's important to understand about **pragma** *Suppress* is that it only gives permission to the implementation to remove checks, but doesn't require such elimination. The intention of `Suppress` is not to allow bypassing of Ada semantics, but rather to improve efficiency, and the Ada Reference Manual has a clear statement to that effect in the note in RM-11.5, paragraph 29:

> There is no guarantee that a suppressed check is actually removed; hence a **pragma** *Suppress* should be used only for efficiency reasons.

There is associated Implementation Advice that recommends that implementations should minimize the code executed for checks that have been suppressed, but it's still the responsibility of the programmer to ensure that the correct functioning of the program doesn't depend on checks not being performed.

[163] https://www.adacore.com/gems/gem-63

There are various reasons why a compiler might choose not to remove a check. On some hardware, certain checks may be essentially free, such as null pointer checks or arithmetic overflow, and it might be impractical or add extra cost to suppress the check. Another example where it wouldn't make sense to remove checks is for an operation implemented by a call to a run-time routine, where the check might be only a small part of a more expensive operation done out of line.

Furthermore, in many cases GNAT can determine at compile time that a given run-time check is guaranteed to be violated. In such situations, it gives a warning that an exception will be raised, and generates code specifically to raise the exception. Here's an example:

```
X : Integer range 1..10 := ...;

..

if A > B then
   X := X + 1;
  ..
end if;
```

For the assignment incrementing X, the compiler will normally generate machine code equivalent to:

```
Temp := X + 1;
if Temp > 10 then
   raise Constraint_Error;
end if;
X := Temp;
```

If range checks are suppressed, then the compiler can just generate the increment and assignment. However, if the compiler is able to somehow prove that `X = 10` at this point, it will issue a warning, and replace the entire assignment with simply:

```
raise Constraint_Error;
```

even though checks are suppressed. This is appropriate, because

1. we don't care about the efficiency of buggy code, and
2. there is no "extra" cost to the check, because if we reach that point, the code will unconditionally fail.

One other important thing to note about checks and **`pragma`** *`Suppress`* is this statement in the Ada RM (RM-11.5, paragraph 26):

> If a given check has been suppressed, and the corresponding error situation occurs, the execution of the program is erroneous.

In Ada, erroneous execution is a bad situation to be in, because it means that the execution of your program could have arbitrary nasty effects, such as unintended overwriting of memory. Note also that a program whose "correct" execution somehow depends on a given check being suppressed might work as the programmer expects, but could still fail when compiled with a different compiler, or for a different target, or even with a newer version of the same compiler. Other changes such as switching on optimization or making a change to a totally unrelated part of the code could also cause the code to start failing.

So it's definitely not wise to write code that relies on checks being removed. In fact, it really only makes sense to suppress checks once there's good reason to believe that the checks can't fail, as a result of testing or other analysis. Otherwise, you're removing an important safety feature of Ada that's intended to help catch bugs.

pragma Unsuppress

We can use **pragma** *Unsuppress* to reverse the effect of a **pragma** *Suppress*. While **pragma** *Suppress* gives permission to the compiler to remove a specific check, **pragma** *Unsuppress* revokes that permission.

Let's see an example:

Listing 176: show_index_check.adb

```
procedure Show_Index_Check is

   type Integer_Array is
     array (Positive range <>) of Integer;

   pragma Suppress (Index_Check);
   --  from now on, the compiler may
   --  eliminate index checks...

   function Unchecked_Value_Of
     (A : Integer_Array;
      I : Integer)
      return Integer
   is
      type Half_Integer_Array is new
        Integer_Array (A'First ..
                       A'First + A'Length / 2);

      A_2 : Half_Integer_Array := (others => 0);
   begin
      return A_2 (I);
   end Unchecked_Value_Of;

   pragma Unsuppress (Index_Check);
   --  from now on, index checks are
   --  typically performed...

   function Value_Of
     (A : Integer_Array;
      I : Integer)
      return Integer
   is
      type Half_Integer_Array is new
        Integer_Array (A'First ..
                       A'First + A'Length / 2);

      A_2 : Half_Integer_Array := (others => 0);
   begin
      return A_2 (I);
   end Value_Of;

   Arr_1 : Integer_Array (1 .. 10) :=
             (others => 1);

begin
   Arr_1 (10) := Unchecked_Value_Of (Arr_1, 10);
   Arr_1 (10) := Value_Of (Arr_1, 10);

end Show_Index_Check;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Control_Flow.Exceptions.Pragma_Unsuppress.Pragma_
 ↪Unsuppress
MD5: 0585b78fd57913d3172c7ab1ea6f4864
```

Runtime output

```

raised CONSTRAINT_ERROR : show_index_check.adb:39 index check failed
```

In this example, we first use a **pragma** *Suppress* (Index_Check), so the compiler is allowed to remove the index check from the Unchecked_Value_Of function. (Therefore, depending on the compiler, the call to the Unchecked_Value_Of function may complete without raising an exception.) Of course, in this specific example, suppressing the index check masks a severe issue.

In contrast, an index check is performed in the Value_Of function because of the **pragma** *Unsuppress*. As a result, the index checks fails in the call to this function, which raises a Constraint_Error exception.

In the Ada Reference Manual

- 11.5 Suppressing Checks[164]

[164] http://www.ada-auth.org/standards/22rm/html/RM-11-5.html

CHAPTER

TWENTYSEVEN

MODULAR PROGRAMMING

27.1 Packages

27.1.1 Package renaming

We've seen in the Introduction to Ada course that we can *rename packages* (page 46).

In the Ada Reference Manual

- 10.1.1 Compilation Units - Library Units[165]

Grouping packages

A use-case that we haven't mentioned in that course is that we can apply package renaming to group individual packages into a common hierarchy. For example:

Listing 1: driver_m1.ads

```
1 package Driver_M1 is
2
3 end Driver_M1;
```

Listing 2: driver_m2.ads

```
1 package Driver_M2 is
2
3 end Driver_M2;
```

Listing 3: drivers.ads

```
1 package Drivers
2   with Pure is
3
4 end Drivers;
```

Listing 4: drivers-m1.ads

```
1 with Driver_M1;
2
3 package Drivers.M1 renames Driver_M1;
```

[165] http://www.ada-auth.org/standards/22rm/html/RM-10-1-1.html

Listing 5: drivers-m2.ads

```
with Driver_M2;

package Drivers.M2 renames Driver_M2;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Package_Renaming.Package_
 ↪Renaming_1
MD5: 8d6a6bec32f7ec4397de1faf9f0b44d9
```

Here, we're renaming the `Driver_M1` and `Driver_M2` packages as child packages of the `Drivers` package, which is a *pure package* (page 1978).

Important

Note that a package that is renamed as a child package cannot refer to information from its (non-renamed) parent. In other words, `Driver_M1` (renamed as `Drivers.M1`) cannot refer to information from the `Drivers` package. For example:

Listing 6: driver_m1.ads

```
package Driver_M1 is

   Counter_2 : Integer := Drivers.Counter;

end Driver_M1;
```

Listing 7: drivers.ads

```
package Drivers is

   Counter : Integer := 0;

end Drivers;
```

Listing 8: drivers-m1.ads

```
with Driver_M1;

package Drivers.M1 renames Driver_M1;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Package_Renaming.Package_
 ↪Renaming_1_Refer_To_Parent
MD5: d174746d8151d9a2cd048ad44e853850
```

Build output

```
driver_m1.ads:3:27: error: "Drivers" is undefined
gprbuild: *** compilation phase failed
```

As expected, compilation fails here because `Drivers.Counter` isn't visible in `Driver_M1`, even though the renaming (`Drivers.M1`) creates a virtual hierarchy.

Child of renamed package

Note that we cannot create a child package using a parent package name that was introduced by a renaming. For example, let's say we want to create a child package `Ext` for the `Drivers.M1` package we've seen earlier. We cannot just declare a `Drivers.M1.Ext` package like this:

```
package Drivers.M1.Ext is

end Drivers.M1.Ext;
```

because the parent unit cannot be a renaming. The solution is to actually extend the original (non-renamed) package:

Listing 9: driver_m1-ext.ads

```
1 package Driver_M1.Ext is
2
3 end Driver_M1.Ext;
```

Listing 10: dummy.adb

```
1 --  A package called Drivers.M1.Ext is
2 --  automatically available!
3
4 with Drivers.M1.Ext;
5
6 procedure Dummy is
7 begin
8    null;
9 end Dummy;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Package_Renaming.Package_
↪Renaming_1
MD5: e338d668dbd98b1a3917a8d3d948a439
```

This works fine because any child package of a package `P` is also a child package of a renamed version of `P`. (Therefore, because `Ext` is a child package of `Driver_M1`, it is also a child package of the renamed `Drivers.M1` package.)

Backwards-compatibility via renaming

We can also use renaming to ensure backwards-compatibility when changing the package hierarchy. For example, we could adapt the previous source-code by:

- converting `Driver_M1` and `Driver_M2` to child packages of `Drivers`, and
- using package renaming to *mimic* the original names (`Driver_M1` and `Driver_M2`).

This is the adapted code:

Listing 11: drivers.ads

```
1 package Drivers
2   with Pure is
3
4 end Drivers;
```

Listing 12: drivers-m1.ads

```
--  We've converted Driver_M1 to
--  Drivers.M1:

package Drivers.M1 is

end Drivers.M1;
```

Listing 13: drivers-m2.ads

```
--  We've converted Driver_M2 to
--  Drivers.M2:

package Drivers.M2 is

end Drivers.M2;
```

Listing 14: driver_m1.ads

```
--  Original Driver_M1 package still
--  available via package renaming:

with Drivers.M1;

package Driver_M1 renames Drivers.M1;
```

Listing 15: driver_m2.ads

```
--  Original Driver_M2 package still
--  available via package renaming:

with Drivers.M2;

package Driver_M2 renames Drivers.M2;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Package_Renaming.Package_
 ↪Renaming_2
MD5: 27f8066b5f5954514fea51b6e9b9de81
```

Now, M1 and M2 are *actual* child packages of `Drivers`, but their original names are still available. By doing so, we ensure that existing software that makes use of the original packages doesn't break.

27.1.2 Private packages

In this section, we discuss the concept of private packages. However, before we proceed with the discussion, let's recapitulate some important ideas that we've seen earlier.

In the *Introduction to Ada course* (page 113), we've seen that encapsulation plays an important role in modular programming. By using the private part of a package specification, we can disclose some information, but, at the same time, prevent that this information gets accessed where it shouldn't be used directly. Similarly, we've seen that we can use the private part of a package to distinguish between the *partial and full view* (page 307) of a data type.

The main application of private packages is to create private child packages, whose purpose

is to serve as internal implementation packages within a package hierarchy. By doing so, we can expose the internals to other public child packages, but prevent that external clients can directly access them.

As we'll see next, there are many rules that ensure that internal visibility is enforced for those private child packages. At the same time, the same rules ensure that private packages aren't visible outside of the package hierarchy.

Declaration and usage

We declare private packages by using the **private** keyword. For example, let's say we have a package named `Data_Processing`:

Listing 16: data_processing.ads

```
package Data_Processing is

--  ...

end Data_Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Private_Packages.Private_
 ↪Package_Decl
MD5: 502811212890785d90c6f891d7f8e557
```

We simply write **private package** to declare a private child package named `Calculations`:

Listing 17: data_processing-calculations.ads

```
private package Data_Processing.Calculations is

--  ...

end Data_Processing.Calculations;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Private_Packages.Private_
 ↪Package_Decl
MD5: 20df8b2ac4c9aa93f03a12afd9b7ef30
```

Let's see a complete example:

Listing 18: data_processing.ads

```
package Data_Processing is

   type Data is private;

   procedure Process (D : in out Data);

private

   type Data is null record;

end Data_Processing;
```

Listing 19: data_processing-calculations.ads

```
private package Data_Processing.Calculations is

   procedure Calculate (D : in out Data);

end Data_Processing.Calculations;
```

Listing 20: data_processing.adb

```
with Data_Processing.Calculations;
use  Data_Processing.Calculations;

package body Data_Processing is

   procedure Process (D : in out Data) is
   begin
      Calculate (D);
   end Process;

end Data_Processing;
```

Listing 21: data_processing-calculations.adb

```
package body Data_Processing.Calculations is

   procedure Calculate (D : in out Data) is
   begin
      --  Dummy implementation...
      null;
   end Calculate;

end Data_Processing.Calculations;
```

Listing 22: test_data_processing.adb

```
with Data_Processing; use Data_Processing;

procedure Test_Data_Processing is
   D : Data;
begin
   Process (D);
end Test_Data_Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Private_Packages.Private_
 ↪Package
MD5: 3edd5f73938e809994347b5876014d0d
```

In this example, we refer to the private child package `Calculations` in the body of the `Data_Processing` package — by simply writing `with Data_Processing.Calculations`. After that, we can call the `Calculate` procedure normally in the `Process` procedure.

Private sibling packages

We can introduce another private package `Advanced_Calculations` as a child of `Data_Processing` and refer to the `Calculations` package in its specification:

Listing 23: data_processing.ads

```
package Data_Processing is

   type Data is private;

   procedure Process (D : in out Data);

private

   type Data is null record;

end Data_Processing;
```

Listing 24: data_processing-calculations.ads

```
private package Data_Processing.Calculations is

   procedure Calculate (D : in out Data);

end Data_Processing.Calculations;
```

Listing 25: data_processing-advanced_calculations.ads

```
with Data_Processing.Calculations;
use  Data_Processing.Calculations;

private
package Data_Processing.Advanced_Calculations is

   procedure Advanced_Calculate (D : in out Data)
     renames Calculate;

end Data_Processing.Advanced_Calculations;
```

Listing 26: data_processing.adb

```
with Data_Processing.Advanced_Calculations;
use  Data_Processing.Advanced_Calculations;

package body Data_Processing is

   procedure Process (D : in out Data) is
   begin
      Advanced_Calculate (D);
   end Process;

end Data_Processing;
```

Listing 27: data_processing-calculations.adb

```
package body Data_Processing.Calculations is

   procedure Calculate (D : in out Data) is
   begin
      --  Dummy implementation...
```

(continues on next page)

(continued from previous page)

```
      null;
   end Calculate;

end Data_Processing.Calculations;
```

Listing 28: test_data_processing.adb

```
with Data_Processing; use Data_Processing;

procedure Test_Data_Processing is
   D : Data;
begin
   Process (D);
end Test_Data_Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Private_Packages.Private_
 ↪Package_2
MD5: 32fc76ae13f1eecdd854a029793034d8
```

Note that, in the body of the `Data_Processing` package, we're now referring to the new `Advanced_Calculations` package instead of the `Calculations` package.

Referring to a private child package in the specification of another private child package is OK, but we cannot do the same in the specification of a *non-private* package. For example, let's change the specification of the `Advanced_Calculations` and make it *non-private*:

Listing 29: data_processing-advanced_calculations.ads

```
with Data_Processing.Calculations;
use  Data_Processing.Calculations;

package Data_Processing.Advanced_Calculations is

   procedure Advanced_Calculate (D : in out Data)
     renames Calculate;

end Data_Processing.Advanced_Calculations;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Private_Packages.Private_
 ↪Package_2
MD5: 27fd3bdb063a11ed7797cc44fa1e8349
```

Build output

```
data_processing-advanced_calculations.ads:1:06: error: current unit must also be␣
 ↪private descendant of "Data_Processing"
gprbuild: *** compilation phase failed
```

Now, the compilation doesn't work anymore. However, we could still refer to `Calculations` packages in the body of the `Advanced_Calculations` package:

Listing 30: data_processing-advanced_calculations.ads

```
package Data_Processing.Advanced_Calculations is

   procedure Advanced_Calculate (D : in out Data);
```

(continues on next page)

(continued from previous page)

```
4
5  end Data_Processing.Advanced_Calculations;
```

Listing 31: data_processing-advanced_calculations.adb

```
1  with Data_Processing.Calculations;
2  use  Data_Processing.Calculations;
3
4  package body Data_Processing.Advanced_Calculations
5  is
6
7     procedure Advanced_Calculate (D : in out Data)
8     is
9     begin
10      Calculate (D);
11    end Advanced_Calculate;
12
13 end Data_Processing.Advanced_Calculations;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Private_Packages.Private_
 ↪Package_2
MD5: 3f37c129a6994c6b71a25ad17dcb440e
```

This works fine as expected: we can refer to private child packages in the body of another package — as long as both packages belong to the same package tree.

Outside the package tree

While we can use a with-clause of a private child package in the body of the `Data_Processing` package, we cannot do the same outside the package tree. For example, we cannot refer to it in the `Test_Data_Processing` procedure:

Listing 32: test_data_processing.adb

```
1  with Data_Processing; use Data_Processing;
2
3  with Data_Processing.Calculations;
4  use  Data_Processing.Calculations;
5
6  procedure Test_Data_Processing is
7     D : Data;
8  begin
9     Calculate (D);
10 end Test_Data_Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Private_Packages.Private_
 ↪Package
MD5: c844327995b28d60c9a79b138a0f21d2
```

Build output

```
test_data_processing.adb:3:06: error: unit in with clause is private child unit
test_data_processing.adb:3:06: error: current unit must also have parent "Data_
 ↪Processing"
gprbuild: *** compilation phase failed
```

As expected, we get a compilation error because `Calculations` is only accessible within the `Data_Processing`, but not in the `Test_Data_Processing` procedure.

The same restrictions apply to child packages of private packages. For example, if we implement a child package of the `Calculations` package — let's name it `Calculations.Child` —, we cannot refer to it in the `Test_Data_Processing` procedure:

Listing 33: data_processing-calculations-child.ads

```
package Data_Processing.Calculations.Child is

   procedure Process (D : in out Data);

end Data_Processing.Calculations.Child;
```

Listing 34: data_processing-calculations-child.adb

```
package body Data_Processing.Calculations.Child is

   procedure Process (D : in out Data) is
   begin
      Calculate (D);
   end Process;

end Data_Processing.Calculations.Child;
```

Listing 35: test_data_processing.adb

```
with Data_Processing; use Data_Processing;

with Data_Processing.Calculations.Child;
use  Data_Processing.Calculations.Child;

procedure Test_Data_Processing is
   D : Data;
begin
   Calculate (D);
end Test_Data_Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Private_Packages.Private_
 ↪Package
MD5: 2eaf23ddbab72578246ac07424008d9d
```

Build output

```
test_data_processing.adb:3:06: error: unit in with clause is private child unit
test_data_processing.adb:3:06: error: current unit must also have parent "Data_
 ↪Processing"
test_data_processing.adb:9:04: error: "Calculate" is not visible
test_data_processing.adb:9:04: error: non-visible declaration at data_processing-
 ↪calculations.ads:3
gprbuild: *** compilation phase failed
```

Again, as expected, we get an error because `Calculations.Child` — being a child of a private package — has the same restricted view as its parent package. Therefore, it cannot be visible in the `Test_Data_Processing` procedure as well. We'll discuss more about visibility *later* (page 712).

Note that subprograms can also be declared private. We'll see this *in another section* (page 729).

Important

We've discussed package renaming *in a previous section* (page 693). We can rename a package as a private package, too. For example:

Listing 36: driver_m1.ads

```
package Driver_M1 is

end Driver_M1;
```

Listing 37: drivers.ads

```
package Drivers
  with Pure is

end Drivers;
```

Listing 38: drivers-m1.ads

```
with Driver_M1;

private package Drivers.M1 renames Driver_M1;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Private_Packages.Private_
 ↪Package_Renaming
MD5: c03584dc26abb108c9c04074234b9637
```

Obviously, `Drivers.M1` has the same restrictions as any private package:

Listing 39: test_driver.adb

```
with Driver_M1;
with Drivers.M1;

procedure Test_Driver is
begin
   null;
end Test_Driver;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Private_Packages.Private_
 ↪Package_Renaming
MD5: 55415978604ccea4eeaeb02df13cd2f4
```

Build output

```
test_driver.adb:2:06: error: unit in with clause is private child unit
test_driver.adb:2:06: error: current unit must also have parent "Drivers"
gprbuild: *** compilation phase failed
```

As expected, although we can have the `Driver_M1` package in a with clause of the `Test_Driver` procedure, we cannot do the same in the case of the `Drivers.M1` package because it is private.

In the Ada Reference Manual

- 10.1.1 Compilation Units - Library Units[166]

27.1.3 Private with clauses

Definition and usage

A private with clause allows us to refer to a package in the private part of another package. For example, if we want to refer to package P in the private part of Data, we can write **private with** P:

Listing 40: p.ads

```
package P is

   type T is null record;

end P;
```

Listing 41: data.ads

```
private with P;

package Data is

   type T2 is private;

private

   --  Information from P is
   --  visible here
   type T2 is new P.T;

end Data;
```

Listing 42: main.adb

```
with Data; use Data;

procedure Main is
   A : T2;
begin
   null;
end Main;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Private_With_Clauses.Simple_
 ↪Private_With_Clause
MD5: d0705add0dd7861c83822b0d35dacba4
```

As you can see in the example, as the information from P is available in the private part of Data, we can derive a new type T2 based on T from P. However, we cannot do the same in the visible part of Data:

[166] http://www.ada-auth.org/standards/22rm/html/RM-10-1-1.html

Listing 43: data.ads

```
private with P;

package Data is

   --  ERROR: information from P
   --  isn't visible here

   type T2 is new P.T;

end Data;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Private_With_Clauses.Simple_
 ↪Private_With_Clause
MD5: b454e875f73432f5632a20ab40ae7da6
```

Build output

```
data.ads:8:19: error: "P" is not visible
data.ads:8:19: error: non-visible declaration at p.ads:1
gprbuild: *** compilation phase failed
```

Also, the information from P is available in the package body. For example, let's declare a Process procedure in the P package and use it in the body of the Data package:

Listing 44: p.ads

```
package P is

   type T is null record;

   procedure Process (A : T) is null;

end P;
```

Listing 45: data.ads

```
private with P;

package Data is

   type T2 is private;

   procedure Process (A : T2);

private

   --  Information from P is
   --  visible here
   type T2 is new P.T;

end Data;
```

Listing 46: data.adb

```
package body Data is

   procedure Process (A : T2) is
```

(continues on next page)

(continued from previous page)

```
   begin
      P.Process (P.T (A));
   end Process;

end Data;
```

Listing 47: main.adb

```
with Data; use Data;

procedure Main is
   A : T2;
begin
   null;
end Main;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Private_With_Clauses.Simple_
↪Private_With_Clause
MD5: cecc09f95bd43dd7fd34a9e289bd2674
```

In the body of the `Data`, we can access information from the P package — as we do in the `P.Process (P.T (A))` statement of the `Process` procedure.

Referring to private child package

There's one case where using a private with clause is the only way to refer to a package: when we want to refer to a private child package in another child package. For example, here we have a package P and its two child packages: **`Private_`**`Child` and `Public_Child`:

Listing 48: p.ads

```
package P is

end P;
```

Listing 49: p-private_child.ads

```
private package P.Private_Child is

   type T is null record;

end P.Private_Child;
```

Listing 50: p-public_child.ads

```
private with P.Private_Child;

package P.Public_Child is

   type T2 is private;

private

   type T2 is new P.Private_Child.T;

end P.Public_Child;
```

Listing 51: test_parent_child.adb

```
with P.Public_Child; use P.Public_Child;

procedure Test_Parent_Child is
   A : T2;
begin
   null;
end Test_Parent_Child;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Private_With_Clauses.Private_
 ↪With_Clause
MD5: a6028416a957184be55a54f96a319e61
```

In this example, we're referring to the P.**Private_**Child package in the P.Public_Child package. As expected, this works fine. However, using a *normal* with clause doesn't work in this case:

Listing 52: p-public_child.ads

```
with P.Private_Child;

package P.Public_Child is

   type T2 is private;

private

   type T2 is new P.Private_Child.T;

end P.Public_Child;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Private_With_Clauses.Private_
 ↪With_Clause
MD5: 2f32f29ecb4ae13bb4487c94d3bf18d9
```

Build output

```
p-public_child.ads:1:06: error: current unit must also be private descendant of "P"
gprbuild: *** compilation phase failed
```

This gives an error because the information from the P.**Private_**Child, being a private child package, cannot be accessed in the public part of another child package. In summary, unless both packages are private packages, it's only possible to access the information from a private package in the private part of a non-private child package.

In the Ada Reference Manual

- 10.1.2 Context Clauses - With Clauses[167]

[167] http://www.ada-auth.org/standards/22rm/html/RM-10-1-2.html

27.1.4 Limited Visibility

Sometimes, we might face the situation where two packages depend on information from each other. Let's consider a package A that depends on a package B, and vice-versa:

Listing 53: a.ads

```
with B; use B;

package A is

   type T1 is record
      Value : T2;
   end record;

end A;
```

Listing 54: b.ads

```
with A; use A;

package B is

   type T2 is record
      Value : T1;
   end record;

end B;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Limited_Visibility.Circular_
 ↪Dependency
MD5: ae64f33706f1c58603aff2c33b02c910
```

Build output

```
a.ads:1:06: error: circular unit dependency
a.ads:1:06: error: "A (spec)" depends on "B (spec)"
a.ads:1:06: error: "B (spec)" depends on "A (spec)"
a.ads:1:06: error: "A (spec)" depends on "A (spec)"
gprbuild: *** compilation phase failed
```

Here, we have two *mutually dependent types* (page 418) T1 and T2, which are declared in two packages A and B that refer to each other. These with clauses constitute a circular dependency, so the compiler cannot compile either of those packages.

One way to solve this problem is by transforming this circular dependency into a partial dependency. We do this by limiting the visibility — using a limited with clause. To use a limited with clause for a package P, we simply write **limited with** P.

If a package A has limited visibility to a package B, then all types from package B are visible as if they had been declared as *incomplete types* (page 305). For the specific case of the previous source-code example, this would be the limited visibility to package B from package A's perspective:

```
package B is

   --  Incomplete type
   type T2;

end B;
```

As we've seen previously,

- we cannot declare objects of incomplete types, but we can declare access types and anonymous access objects of incomplete types. Also,
- we can use anonymous access types to declare *mutually dependent types* (page 418).

Keeping this information in mind, we can now correct the previous code by using limited with clauses for package A and declaring the component of the T1 record using an anonymous access type:

Listing 55: a.ads

```
limited with B;

package A is

   type T1 is record
      Ref : access B.T2;
   end record;

end A;
```

Listing 56: b.ads

```
with A; use A;

package B is

   type T2 is record
      Value : T1;
   end record;

end B;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Limited_Visibility.Limited_
 ↪Visibility
MD5: 48591850665085a6fbb184f51b658a1b
```

As expected, we can now compile the code without issues.

Note that we can also use limited with clauses for both packages. If we do that, we must declare all components using anonymous access types:

Listing 57: a.ads

```
limited with B;

package A is

   type T1 is record
      Ref : access B.T2;
   end record;

end A;
```

Listing 58: b.ads

```
limited with A;

package B is
```

(continues on next page)

(continued from previous page)

```
4
5     type T2 is record
6        Ref : access A.T1;
7     end record;
8
9  end B;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Limited_Visibility.Limited_
 ↪Visibility_2
MD5: 3884086e89400245346acfbbf0691906
```

Now, both packages A and B have limited visibility to each other.

In the Ada Reference Manual

- 10.1.2 Context Clauses - With Clauses[168]

Limited visibility and private with clauses

We can limit the visibility and use *private with clauses* (page 704) at the same time. For a package P, we do this by simply writing **limited private with** P.

Let's reuse the previous source-code example and convert types T1 and T2 to private types:

Listing 59: a.ads

```
1  limited private with B;
2
3  package A is
4
5     type T1 is private;
6
7  private
8
9     --  Here, we have limited visibility
10    --  of package B
11
12    type T1 is record
13       Ref : access B.T2;
14    end record;
15
16 end A;
```

Listing 60: b.ads

```
1  private with A;
2
3  package B is
4
5     type T2 is private;
6
7  private
8
9     use A;
```

(continues on next page)

[168] http://www.ada-auth.org/standards/22rm/html/RM-10-1-2.html

(continued from previous page)

```
10
11    --  Here, we have full visibility
12    --  of package A
13
14    type T2 is record
15       Value : T1;
16    end record;
17
18 end B;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Limited_Visibility.Limited_
 ↪Private_Visibility
MD5: b3ac546e2f55fb91229e834ca7a9783d
```

In this updated version of the source-code example, we have not only limited visibility to package B, but also, each package is just visible in the private part of the other package.

Limited visibility and other elements

It's important to mention that the limited visibility we've been discussing so far is restricted to type declarations — which are seen as incomplete types. In fact, when we use a limited with clause, all other declarations have no visibility at all! For example, let's say we have a package `Info` that declares a constant `Zero_Const` and a function `Zero_Func`:

Listing 61: info.ads

```
1  package Info is
2
3     function Zero_Func return Integer is (0);
4
5     Zero_Const : constant := 0;
6
7  end Info;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Limited_Visibility.Limited_
 ↪Private_Visibility_Other_Elements
MD5: e9b01b4d59db5982532634f9162518ce
```

Also, let's say we want to use the information (from package `Info`) in package `A`. If we have limited visibility to package `Info`, however, this information won't be visible. For example:

Listing 62: a.ads

```
1  limited private with Info;
2
3  package A is
4
5     type T1 is private;
6
7  private
8
9     type T1 is record
10       V : Integer := Info.Zero_Const;
11       W : Integer := Info.Zero_Func;
12    end record;
```

(continues on next page)

(continued from previous page)

```
13
14 end A;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Limited_Visibility.Limited_
 ↪Private_Visibility_Other_Elements
MD5: 61ecb5dc2617eecac62a05d7d2c6c0df
```

Build output

```
a.ads:10:26: error: "Zero_Const" not declared in "Info"
a.ads:11:26: error: "Zero_Func" not declared in "Info"
gprbuild: *** compilation phase failed
```

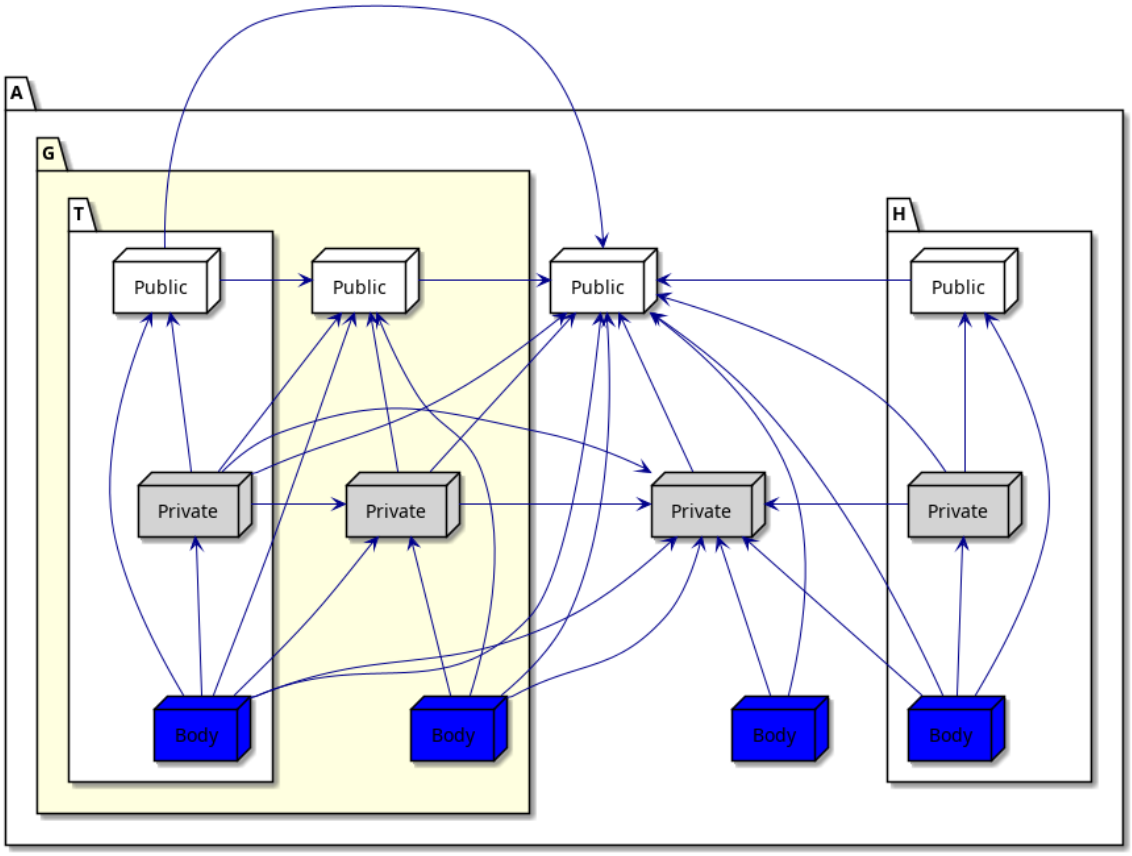
As expected, compilation fails because of the limited visibility — as `Zero_Const` and `Zero_Func` from the `Info` package are not visible in the private part of `A`. (Of course, if we revert to full visibility by simply removing the **`limited`** keyword from the example, the code compiles just fine.)

27.1.5 Visibility

In the previous sections, we already discussed visibility from various angles. However, it can be interesting to recapitulate this information with the help of diagrams that illustrate the different parts of a package and its relation with other units.

Automatic visibility

First, let's consider we have a package `A`, its children (`A.G` and `A.H`), and the grandchild `A.G.T`. As we've seen before, information of a parent package is automatically visible in its children. The following diagrams illustrates this:

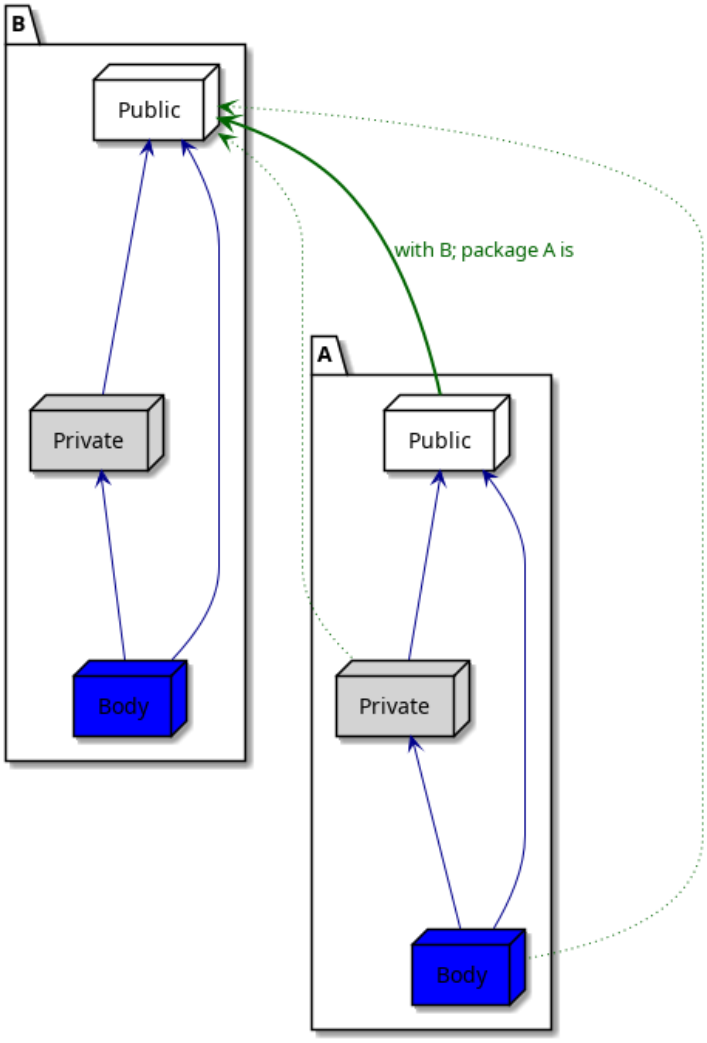


Because of this automatic visibility, many with clauses would be redundant in child packages. For example, we don't have to write `with A; package A.G is`, since the specification of package A is already visible in its child packages.

If we focus on package `A.G` (highlighted in the figure above), we see that it only has automatic visibility to its parent A, but not its child `A.G.T`. Also, it doesn't have visibility to its sibling `A.H`.

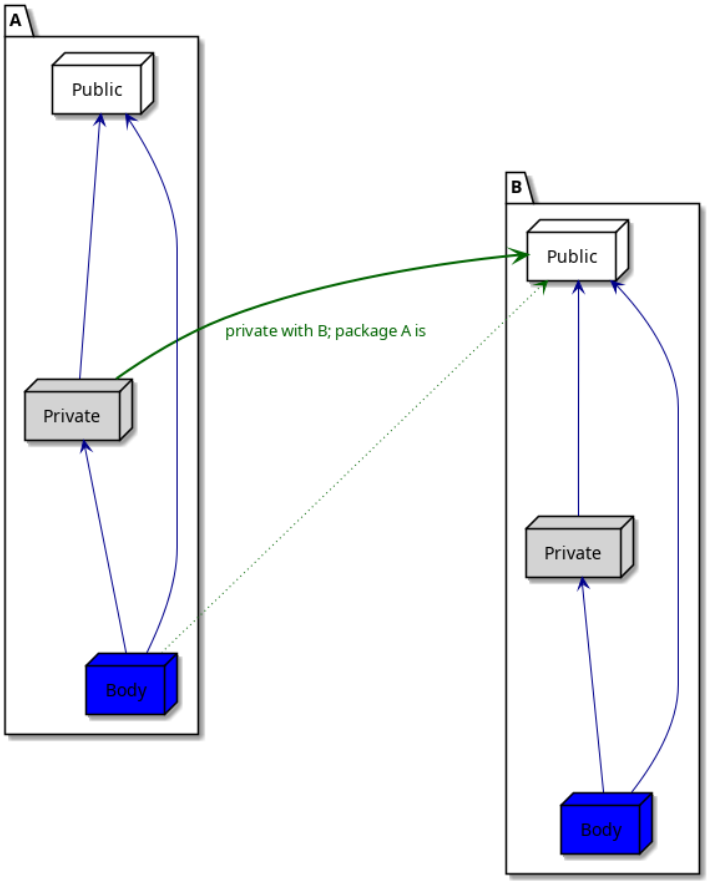
With clauses and visibility

In the rest of this section, we discuss all the situations where using with clauses is necessary to access the information of a package. Let's consider this example where we refer to a package B in the specification of a package A (using `with B`):

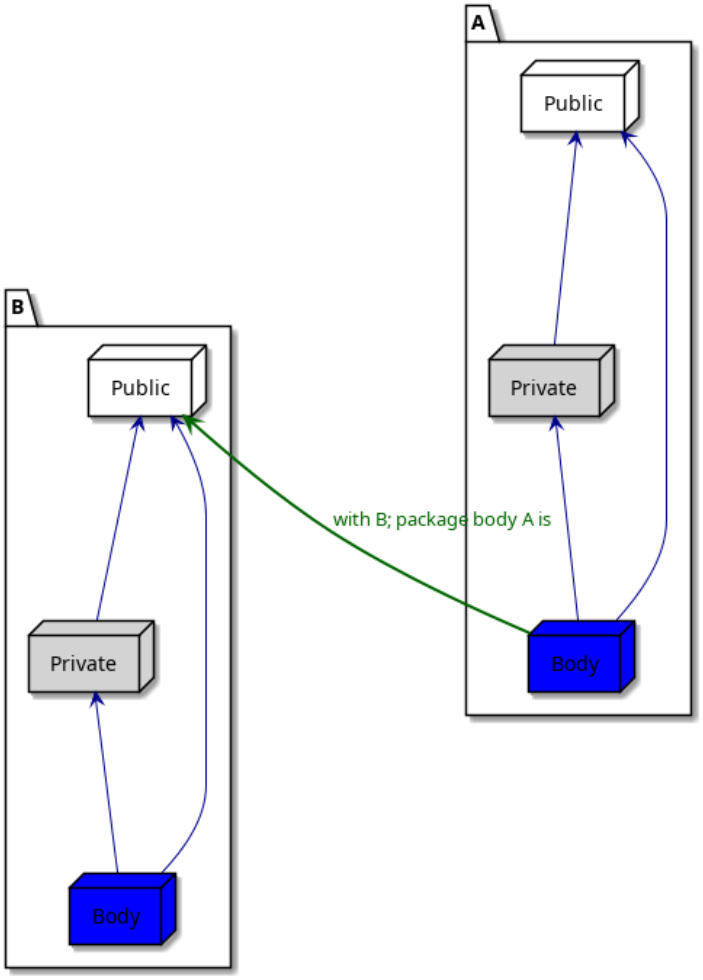


As we already know, the information from the public part of package B is visible in the public part of package A. In addition to that, it's also visible in the private part and in the body of package A. This is indicated by the dotted green arrows in the figure above.

Now, let's see the case where we refer to package B in the private part of package A (using `private with` B):



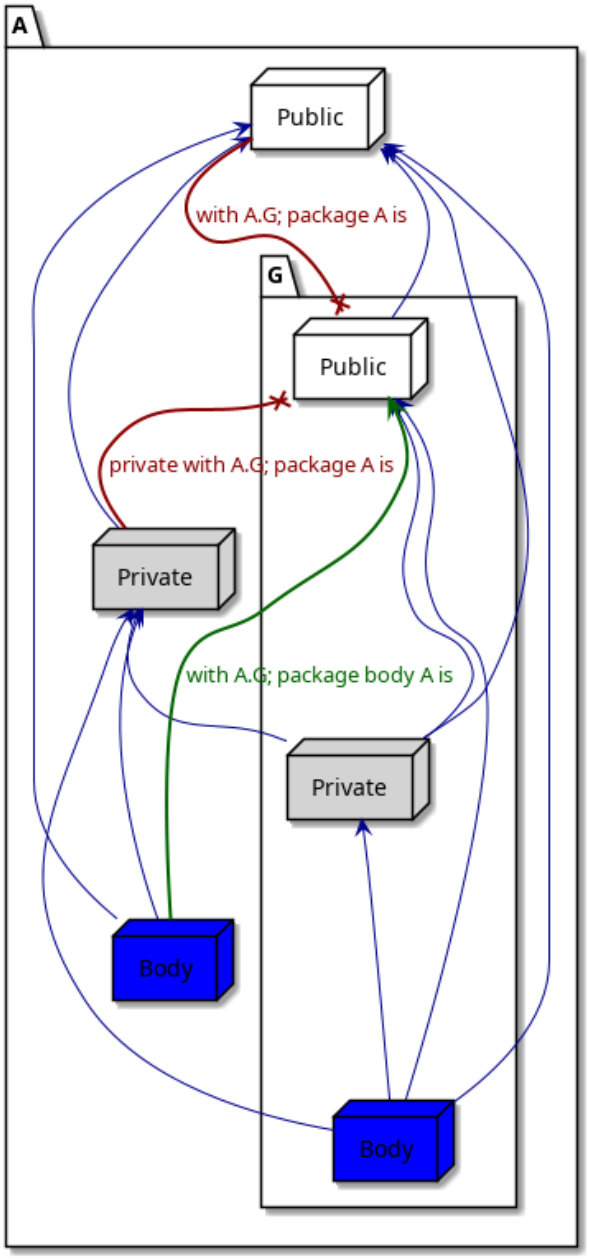
Here, the information is visible in the private part of package A, as well as in its body. Finally, let's see the case where we refer to package B in the body of package A:



Here, the information is only visible in the body of package A.

Circular dependency

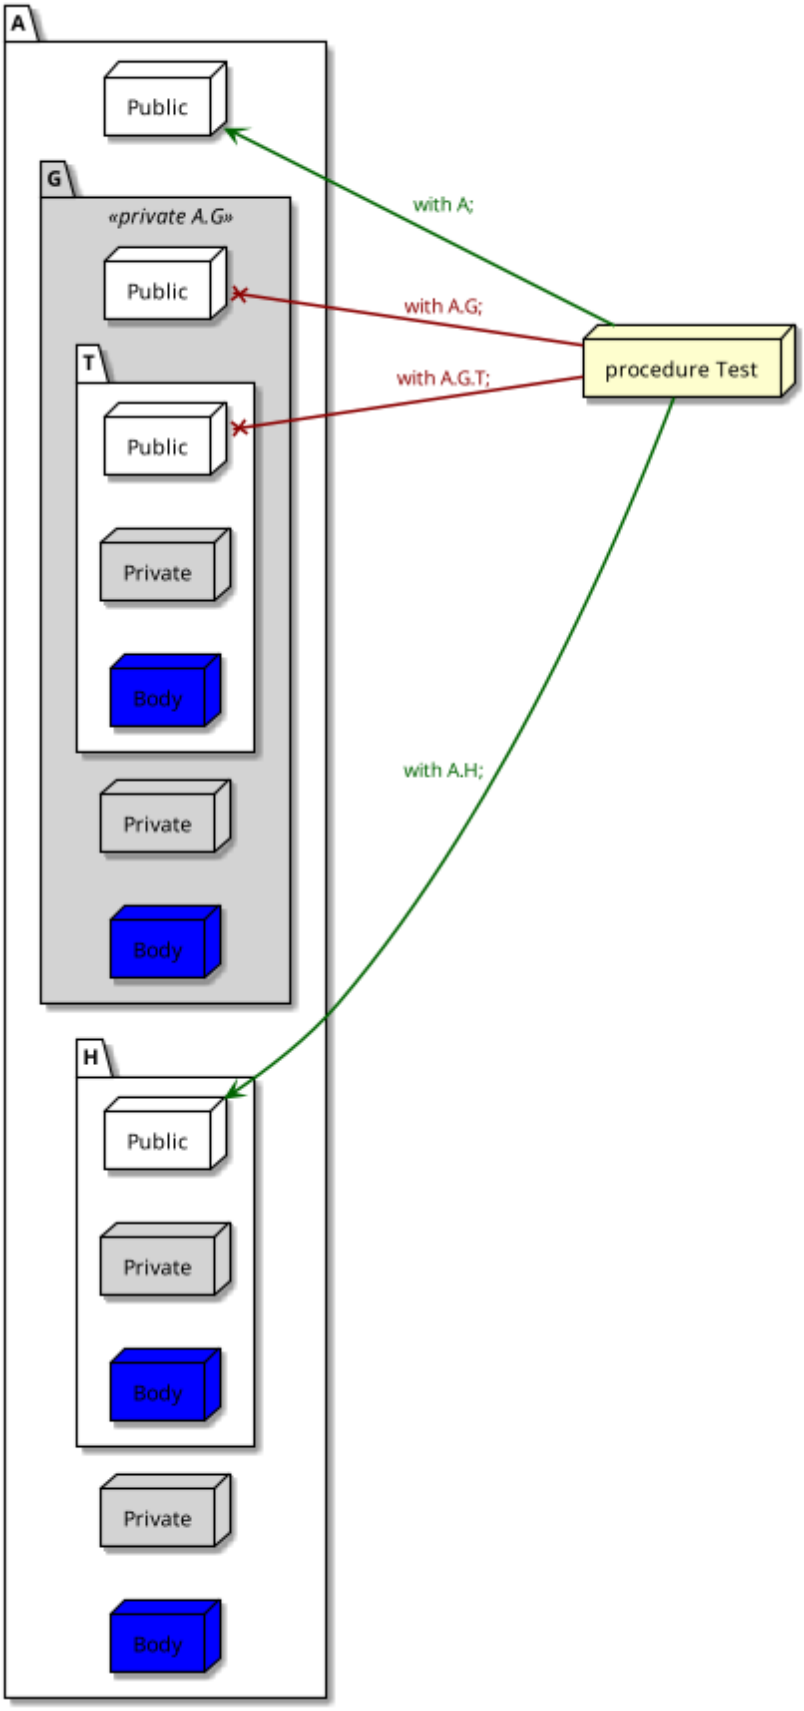
Let's return to package A and its descendants. As we've seen in previous sections, we cannot refer to a child package in the specification of its parent package because that would constitute circular dependency. (For example, we cannot write `with A.G; package A is`.) This situation — which causes a compilation error — is indicated by the red arrows in the figure below:



Note that referring to the child package `A.G` in the body of its parent is perfectly fine.

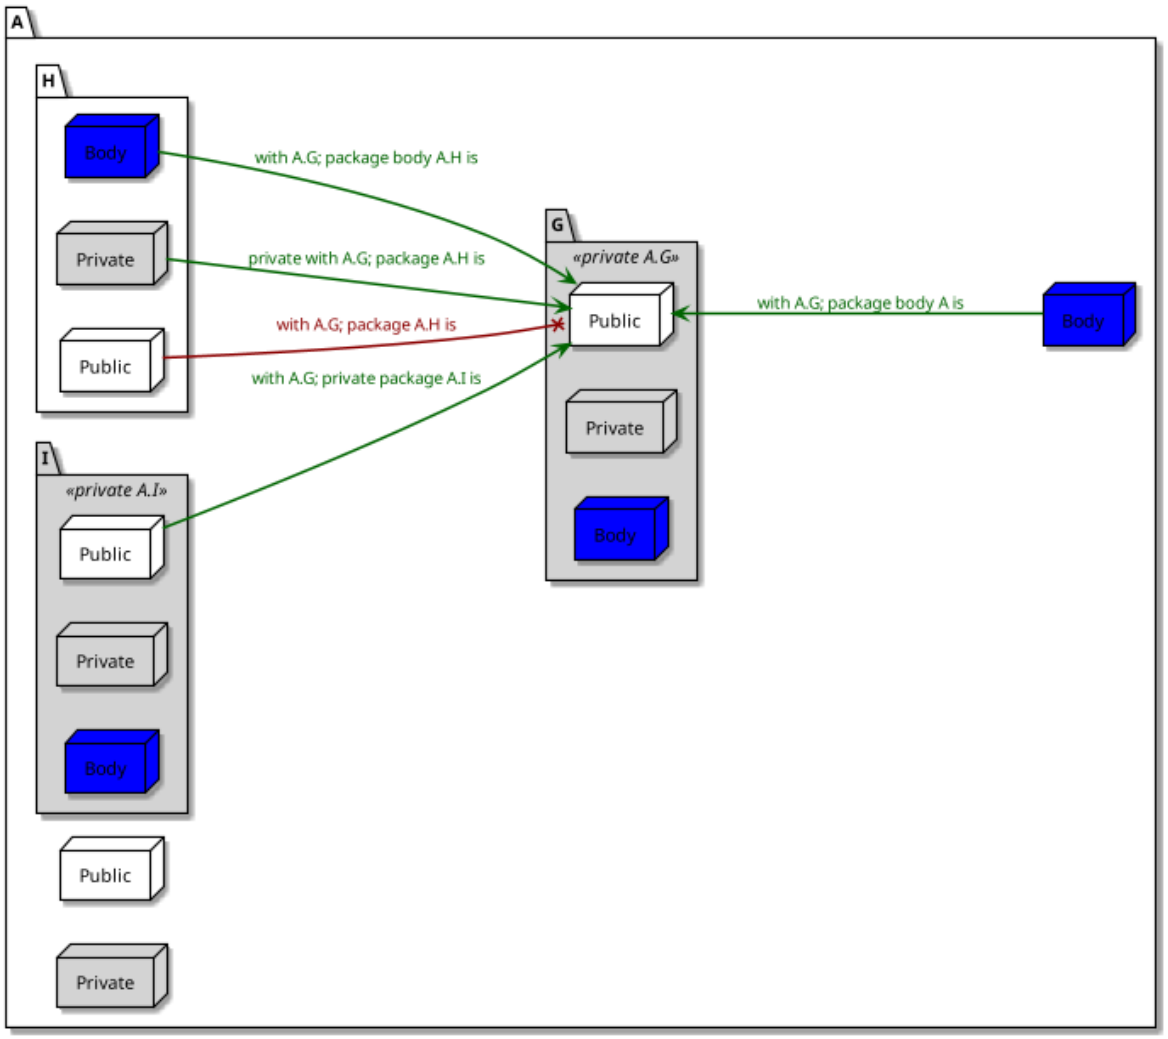
Private packages

The previous examples of this section only showed public packages. As we've seen before, we cannot refer to private packages outside of a package hierarchy, as we can see in the following example where we try to refer to package A and its descendants in the Test procedure:



As indicated by the red arrows, we cannot refer to the private child packages of A in the Test procedure, only the public child packages. Within the package hierarchy itself, we

cannot refer to the private package `A.G` in public sibling packages. For example:



Here, we cannot refer to the private package `A.G` in the public package `A.H` — as indicated by the red arrow. However, we can refer to the private package `A.G` in other private packages, such as `A.I` — as indicated by the green arrows.

27.1.6 Use type clause

Back in the *Introduction to Ada course* (page 37), we saw that use clauses provide direct visibility — in the scope where they're used — to the content of a package's visible part.

For example, consider this simple procedure:

Listing 63: display_message.adb

```
with Ada.Text_IO;

procedure Display_Message is
begin
   Ada.Text_IO.Put_Line ("Hello World!");
end Display_Message;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Use_Type_Clause.No_Use_Clause
MD5: 4c6ff19809c13ebd2fdfda482914e5f8
```

Runtime output

```
Hello World!
```

By adding `use Ada.Text_IO` to this code, we make the visible part of the `Ada.Text_IO` package directly visible in the scope of the `Display_Message` procedure, so we can now just write `Put_Line` instead of `Ada.Text_IO.Put_Line`:

Listing 64: display_message.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Display_Message is
begin
   Put_Line ("Hello World!");
end Display_Message;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Use_Type_Clause.Use_Clause
MD5: b105a777a1afd79008f8580cda432cfe
```

Runtime output

```
Hello World!
```

In this section, we discuss another example of use clauses. In addition, we introduce two specific forms of use clauses: `use type` and `use all type`.

In the Ada Reference Manual

- 8.4 Use Clauses[169]

Another use clause example

Let's now consider a simple package called `Points`, which contains the declaration of the `Point` type and two primitive: an `Init` function and an addition operator.

Listing 65: points.ads

```
package Points is

   type Point is private;

   function Init return Point;

   function "+" (P : Point;
                 I : Integer) return Point;

private

   type Point is record
      X, Y : Integer;
   end record;
```

(continues on next page)

[169] http://www.ada-auth.org/standards/22rm/html/RM-8-4.html

(continued from previous page)

```
15
16    function Init return Point is (0, 0);
17
18    function "+" (P : Point;
19                  I : Integer) return Point is
20      (P.X + I, P.Y + I);
21
22 end Points;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Use_Type_Clause.Use_Type_Clause
MD5: 1a43740d7231a3cc497e778866a12c55
```

We can implement a simple procedure that makes use of this package:

Listing 66: show_point.adb

```
1 with Points; use Points;
2
3 procedure Show_Point is
4    P : Point;
5 begin
6    P := Init;
7    P := P + 1;
8 end Show_Point;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Use_Type_Clause.Use_Type_Clause
MD5: f5d44dd1fee8cf4d1a7e730f9a7c64cc
```

Here, we have a use clause, so we have direct visibility to the content of `Points`'s visible part.

Visibility and Readability

In certain situations, however, we might want to avoid the use clause. If that's the case, we can rewrite the previous implementation by removing the use clause and specifying the `Points` package in the prefixed form:

Listing 67: show_point.adb

```
1 with Points;
2
3 procedure Show_Point is
4    P : Points.Point;
5 begin
6    P := Points.Init;
7    P := Points."+" (P, 1);
8 end Show_Point;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Use_Type_Clause.Use_Type_Clause
MD5: ca896b456a90c19b29ec4f262144c131
```

Although this code is correct, it might be difficult to read, as we have to specify the package whenever we're referring to a type or a subprogram from that package. Even worse: we now have to write operators in the prefixed form — such as `Points."+" (P, 1)`.

use type

As a compromise, we can have direct visibility to the operators of a certain type. We do this by using a use clause in the form `use type`. This allows us to simplify the previous example:

Listing 68: show_point.adb

```
with Points;

procedure Show_Point is
   use type Points.Point;

   P : Points.Point;
begin
   P := Points.Init;
   P := P + 1;
end Show_Point;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Use_Type_Clause.Use_Type_Clause
MD5: a9527276c27a67be8b5a59efcf6e5cfd
```

Note that `use type` just gives us direct visibility to the operators of a certain type, but not other primitives. For this reason, we still have to write `Points.Init` in the code example.

use all type

If we want to have direct visibility to all primitives of a certain type (and not just its operators), we need to write a use clause in the form `use all type`. This allows us to simplify the previous example even further:

Listing 69: show_point.adb

```
with Points;

procedure Show_Point is
   use all type Points.Point;

   P : Points.Point;
begin
   P := Init;
   P := P + 1;
end Show_Point;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Use_Type_Clause.Use_Type_Clause
MD5: 4a8f6edd4e1811c4e8acb24393690282
```

Now, we've removed the prefix from all operations on the P variable.

27.1.7 Use clauses and naming conflicts

Visibility issues may arise when we have multiple use clauses. For instance, we might have types with the same name declared in multiple packages. This constitutes a naming conflict; in this case, the types become hidden — so they're not directly visible anymore, even if we have a use clause.

In the Ada Reference Manual

- 8.4 Use Clauses[170]

Code example

Let's start with a code example. First, we declare and implement a generic procedure that shows the value of a Complex object:

Listing 70: show_any_complex.ads

```
with Ada.Numerics.Generic_Complex_Types;

generic
   with package Complex_Types is new
     Ada.Numerics.Generic_Complex_Types (<>);
procedure Show_Any_Complex
  (Msg : String;
   Val : Complex_Types.Complex);
```

Listing 71: show_any_complex.adb

```
with Ada.Text_IO;
with Ada.Text_IO.Complex_IO;

procedure Show_Any_Complex
  (Msg : String;
```

(continues on next page)

[170] http://www.ada-auth.org/standards/22rm/html/RM-8-4.html

(continued from previous page)

```
   Val : Complex_Types.Complex)
is
   package Complex_Float_Types_IO is new
     Ada.Text_IO.Complex_IO (Complex_Types);
   use Complex_Float_Types_IO;

   use Ada.Text_IO;
begin
   Put (Msg & " ");
   Put (Val);
   New_Line;
end Show_Any_Complex;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Use_Clause_Naming_Conflicts.
 ↪Use_Type_Clause_Complex_Types
MD5: 2527291906d3a600eecd6d36e4359c1a
```

Then, we implement a test procedure where we declare the `Complex_Float_Types` package as an instance of the **`Generic`**`_Complex_Types` package:

Listing 72: show_use.adb

```
with Ada.Numerics; use Ada.Numerics;

with Ada.Numerics.Generic_Complex_Types;

with Show_Any_Complex;

procedure Show_Use is
   package Complex_Float_Types is new
     Ada.Numerics.Generic_Complex_Types
       (Real => Float);
   use Complex_Float_Types;

   procedure Show_Complex_Float is new
     Show_Any_Complex (Complex_Float_Types);

   C, D, X : Complex;
begin
   C := Compose_From_Polar (3.0, Pi / 2.0);
   D := Compose_From_Polar (5.0, Pi / 2.0);
   X := C + D;

   Show_Complex_Float ("C:", C);
   Show_Complex_Float ("D:", D);
   Show_Complex_Float ("X:", X);
end Show_Use;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Use_Clause_Naming_Conflicts.
 ↪Use_Type_Clause_Complex_Types
MD5: cc2a612c9884539f33154680854a4c82
```

Runtime output

```
C: (-1.31134E-07, 3.00000E+00)
D: (-2.18557E-07, 5.00000E+00)
X: (-3.49691E-07, 8.00000E+00)
```

In this example, we declare variables of the Complex type, initialize them and use them in operations. Note that we have direct visibility to the package instance because we've added a simple use clause after the package instantiation — see `use Complex_Float_Types` in the example.

Naming conflict

Now, let's add the declaration of the Complex_Long_Float_Types package — a second instantiation of the `Generic_Complex_Types` package — to the code example:

Listing 73: show_use.adb

```
with Ada.Numerics; use Ada.Numerics;

with Ada.Numerics.Generic_Complex_Types;

with Show_Any_Complex;

procedure Show_Use is
   package Complex_Float_Types is new
     Ada.Numerics.Generic_Complex_Types
       (Real => Float);
   use Complex_Float_Types;

   package Complex_Long_Float_Types is new
     Ada.Numerics.Generic_Complex_Types
       (Real => Long_Float);
   use Complex_Long_Float_Types;

   procedure Show_Complex_Float is new
     Show_Any_Complex (Complex_Float_Types);

   C, D, X : Complex;
   --        ^ ERROR: type is hidden!
begin
   C := Compose_From_Polar (3.0, Pi / 2.0);
   D := Compose_From_Polar (5.0, Pi / 2.0);
   X := C + D;

   Show_Complex_Float ("C:", C);
   Show_Complex_Float ("D:", D);
   Show_Complex_Float ("X:", X);
end Show_Use;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Use_Clause_Naming_Conflicts.
 ↪Use_Type_Clause_Complex_Types
MD5: 30b562e2f81ae62912ec4e067150d5cd
```

Build output

```
show_use.adb:21:14: error: "Complex" is not visible
show_use.adb:21:14: error: multiple use clauses cause hiding
show_use.adb:21:14: error: hidden declaration at a-ngcoty.ads:42, instance at line␣
 ↪13
show_use.adb:21:14: error: hidden declaration at a-ngcoty.ads:42, instance at line␣
 ↪8
gprbuild: *** compilation phase failed
```

This example doesn't compile because we have direct visibility to both Com-

plex_Float_Types and Complex_Long_Float_Types packages, and both of them declare the Complex type. In this case, the type declaration becomes hidden, as the compiler cannot decide which declaration of Complex it should take.

Circumventing naming conflicts

As we know, a simple fix for this compilation error is to add the package prefix in the variable declaration:

Listing 74: show_use.adb

```
with Ada.Numerics; use Ada.Numerics;

with Ada.Numerics.Generic_Complex_Types;

with Show_Any_Complex;

procedure Show_Use is
   package Complex_Float_Types is new
     Ada.Numerics.Generic_Complex_Types
       (Real => Float);
   use Complex_Float_Types;

   package Complex_Long_Float_Types is new
     Ada.Numerics.Generic_Complex_Types
       (Real => Long_Float);
   use Complex_Long_Float_Types;

   procedure Show_Complex_Float is new
     Show_Any_Complex (Complex_Float_Types);

   C, D, X : Complex_Float_Types.Complex;
   --        ^ SOLVED: package is now specified.
begin
   C := Compose_From_Polar (3.0, Pi / 2.0);
   D := Compose_From_Polar (5.0, Pi / 2.0);
   X := C + D;

   Show_Complex_Float ("C:", C);
   Show_Complex_Float ("D:", D);
   Show_Complex_Float ("X:", X);
end Show_Use;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Use_Clause_Naming_Conflicts.
 ↪Use_Type_Clause_Complex_Types
MD5: 0b3285364ea0188a678db2fc406741b8
```

Runtime output

```
C: (-1.31134E-07, 3.00000E+00)
D: (-2.18557E-07, 5.00000E+00)
X: (-3.49691E-07, 8.00000E+00)
```

Another possibility is to write a use clause in the form `use all type`:

Listing 75: show_use.adb

```
with Ada.Numerics; use Ada.Numerics;

```

(continues on next page)

(continued from previous page)

```
with Ada.Numerics.Generic_Complex_Types;

with Show_Any_Complex;

procedure Show_Use is
   package Complex_Float_Types is new
     Ada.Numerics.Generic_Complex_Types
       (Real => Float);
   use all type Complex_Float_Types.Complex;

   package Complex_Long_Float_Types is new
     Ada.Numerics.Generic_Complex_Types
       (Real => Long_Float);
   use all type Complex_Long_Float_Types.Complex;

   procedure Show_Complex_Float is new
     Show_Any_Complex (Complex_Float_Types);

   C, D, X : Complex_Float_Types.Complex;
begin
   C := Compose_From_Polar (3.0, Pi / 2.0);
   D := Compose_From_Polar (5.0, Pi / 2.0);
   X := C + D;

   Show_Complex_Float ("C:", C);
   Show_Complex_Float ("D:", D);
   Show_Complex_Float ("X:", X);
end Show_Use;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Use_Clause_Naming_Conflicts.
 ↪Use_Type_Clause_Complex_Types
MD5: 90333ff41e25afb1399f7f94f7e2b566
```

Runtime output

```
C: (-1.31134E-07, 3.00000E+00)
D: (-2.18557E-07, 5.00000E+00)
X: (-3.49691E-07, 8.00000E+00)
```

For the sake of completeness, let's declare and use variables of both Complex types:

Listing 76: show_use.adb

```
with Ada.Numerics; use Ada.Numerics;

with Ada.Numerics.Generic_Complex_Types;

with Show_Any_Complex;

procedure Show_Use is
   package Complex_Float_Types is new
     Ada.Numerics.Generic_Complex_Types
       (Real => Float);
   use all type Complex_Float_Types.Complex;

   package Complex_Long_Float_Types is new
     Ada.Numerics.Generic_Complex_Types
       (Real => Long_Float);
   use all type Complex_Long_Float_Types.Complex;
```

(continues on next page)

(continued from previous page)

```
17
18    procedure Show_Complex_Float is new
19      Show_Any_Complex (Complex_Float_Types);
20
21    procedure Show_Complex_Long_Float is new
22      Show_Any_Complex (Complex_Long_Float_Types);
23
24    C, D, X : Complex_Float_Types.Complex;
25    E, F, Y : Complex_Long_Float_Types.Complex;
26 begin
27    C := Compose_From_Polar (3.0, Pi / 2.0);
28    D := Compose_From_Polar (5.0, Pi / 2.0);
29    X := C + D;
30
31    Show_Complex_Float ("C:", C);
32    Show_Complex_Float ("D:", D);
33    Show_Complex_Float ("X:", X);
34
35    E := Compose_From_Polar (3.0, Pi / 2.0);
36    F := Compose_From_Polar (5.0, Pi / 2.0);
37    Y := E + F;
38
39    Show_Complex_Long_Float ("E:", E);
40    Show_Complex_Long_Float ("F:", F);
41    Show_Complex_Long_Float ("Y:", Y);
42 end Show_Use;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Packages.Use_Clause_Naming_Conflicts.
 ↪Use_Type_Clause_Complex_Types
MD5: 48f31250116f107d3143703debb3107d
```

Runtime output

```
C: (-1.31134E-07, 3.00000E+00)
D: (-2.18557E-07, 5.00000E+00)
X: (-3.49691E-07, 8.00000E+00)
E: ( 1.83697019872103E-16, 3.00000000000000E+00)
F: ( 3.06161699786838E-16, 5.00000000000000E+00)
Y: ( 4.89858719658941E-16, 8.00000000000000E+00)
```

As expected, the code compiles correctly.

27.2 Subprograms and Modularity

27.2.1 Private subprograms

We've seen *previously* (page 696) that we can declare private packages. Because packages and subprograms can both be library units, we can declare private subprograms as well. We do this by using the **private** keyword. For example:

Listing 77: test.ads

```
1 private procedure Test;
```

Listing 78: test.adb

```
procedure Test is
begin
   null;
end Test;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Subprograms_Modularity.Private_
 ↪Subprograms.Private_Test_Procedure
MD5: 2ea1770a5fd5dee40f015b9d33d2f309
```

Such a subprogram as the one above isn't really useful. For example, we cannot write a with clause that refers to the Test procedure, as it's not visible anywhere:

Listing 79: show_test.adb

```
with Test;

procedure Show_Test is
begin
   Test;
end Show_Test;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Subprograms_Modularity.Private_
 ↪Subprograms.Private_Test_Procedure
MD5: 0702378a034f65a69a4c5b5258f7b32e
```

Build output

```
show_test.adb:1:06: error: current unit must also be private descendant of
 ↪"Standard"
gprbuild: *** compilation phase failed
```

As expected, since Test is private, we get a compilation error because this procedure cannot be referenced in the Show_Test procedure.

In the Ada Reference Manual

- 10.1.1 Compilation Units - Library Units[171]
- 10.1.2 Context Clauses - With Clauses[172]

---

[171] http://www.ada-auth.org/standards/22rm/html/RM-10-1-1.html
[172] http://www.ada-auth.org/standards/22rm/html/RM-10-1-2.html

Private subprograms of a package

A more useful example is to declare private subprograms of a package. For example:

Listing 80: data_processing.ads

```
package Data_Processing is

   type Data is private;

   procedure Process (D : in out Data);

private

    type Data is record
       F : Float;
    end record;

end Data_Processing;
```

Listing 81: data_processing.adb

```
with Data_Processing.Calculate;

package body Data_Processing is

   procedure Process (D : in out Data) is
   begin
      Calculate (D);
   end Process;

end Data_Processing;
```

Listing 82: data_processing-calculate.ads

```
private
procedure Data_Processing.Calculate
  (D : in out Data);
```

Listing 83: data_processing-calculate.adb

```
procedure Data_Processing.Calculate
  (D : in out Data)
is
begin
   --  Dummy implementation...
   D.F := 0.0;
end Data_Processing.Calculate;
```

Listing 84: test_data_processing.adb

```
with Data_Processing; use Data_Processing;

procedure Test_Data_Processing is
   D : Data;
begin
   Process (D);
end Test_Data_Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Subprograms_Modularity.Private_
 ↪Subprograms.Private_Package_Procedure
MD5: 0f6af1b02f37e011abac5b2a6dfc482d
```

In this example, we declare `Calculate` as a private procedure of the `Data_Processing` package. Therefore, it's visible in that package (but not in the `Test_Data_Processing` procedure). Also, in the `Calculate` procedure, we're able to initialize the private component `F` of the `D` object because the child subprogram has access to the private part of its parent package.

Private subprograms and private packages

We can also use private subprograms to test private packages. As we know, in most cases, we cannot access private packages in external clients — such as external subprograms. However, by declaring a subprogram private, we're allowed to access private packages. This can be very useful to create applications that we can use to test private packages. (Note that these applications must be library-level parameterless subprograms, because only those can be main programs.)

Let's see an example:

Listing 85: private_data_processing.ads

```
private package Private_Data_Processing is

   type Data is private;

   procedure Process (D : in out Data);

private

    type Data is record
       F : Float;
    end record;

end Private_Data_Processing;
```

Listing 86: private_data_processing.adb

```
package body Private_Data_Processing is

   procedure Process (D : in out Data) is
   begin
      D.F := 0.0;
   end Process;

end Private_Data_Processing;
```

Listing 87: test_private_data_processing.ads

```
private procedure Test_Private_Data_Processing;
```

Listing 88: test_private_data_processing.adb

```
with Private_Data_Processing;
use  Private_Data_Processing;

procedure Test_Private_Data_Processing is
   D : Data;
begin
   Process (D);
end Test_Private_Data_Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Subprograms_Modularity.Private_
 ↪Subprograms.Private_Subprogram_Private_Package
MD5: 3527e54f99eb2cb52317c987b499caaf
```

In this code example, we have the private **Private**_Data_Processing package. In order to test it, we implement the private procedure Test_Private_Data_Processing. The fact that this procedure is private allows us to use the **Private**_Data_Processing package as if it was a non-private package. We then use the private Test_Private_Data_Processing procedure as our main application, so we can run it to test application the private package.

Child subprograms of private packages

We could also implement the Test subprogram that we use to test a private package P as a child subprogram of that package. In other words, we could write a procedure P.Test and use it as our main application. The advantage here is that this allows us to access the private part of the parent package P in the test procedure.

Let's rewrite the Test_Private_Data_Processing procedure from the previous example as the child procedure **Private**_Data_Processing.Test:

Listing 89: private_data_processing.ads

```
private package Private_Data_Processing is

   type Data is private;

   procedure Process (D : in out Data);

private

    type Data is record
       F : Float;
    end record;

end Private_Data_Processing;
```

Listing 90: private_data_processing.adb

```
package body Private_Data_Processing is

   procedure Process (D : in out Data) is
   begin
```

(continues on next page)

(continued from previous page)

```
      null;
   end Process;

end Private_Data_Processing;
```

Listing 91: private_data_processing-test.ads

```
procedure Private_Data_Processing.Test;
```

Listing 92: private_data_processing-test.adb

```
procedure Private_Data_Processing.Test is
   D : Data := (F => 0.0);
begin
   Process (D);
end Private_Data_Processing.Test;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Modular_Prog.Subprograms_Modularity.Private_
↪Subprograms.Private_Package_Child_Subprogram
MD5: 0726f5890a5b3847244d1ae08989e158
```

In this code example, we now implement the `Test` procedure as a child of the **`Private`**`_Data_Processing` package. In this procedure, we're able to initialize the private component `F` of the `D` object. As we know, this initialization of a private component wouldn't be possible if `Test` wasn't a child procedure. (For instance, writing such an initialization in the `Test_Private_Data_Processing` procedure from the previous code example would trigger a compilation error.)

CHAPTER

TWENTYEIGHT

RESOURCE MANAGEMENT

28.1 Access Types

We discussed access types back in the *Introduction to Ada course* (page 95). In this chapter, we discuss further details about access types and techniques when using them. Before we dig into details, however, we're going to make sure we understand the terminology.

28.1.1 Access types: Terminology

In this section, we discuss some of the terminology associated with access types. Usually, the terms used in Ada when discussing references and dynamic memory allocation are different than the ones you might encounter in other languages, so it's necessary you understand what each term means.

Access type, designated subtype and profile

The first term we encounter is (obviously) *access type*, which is a type that provides us access to an object or a subprogram. We declare access types by using the **access** keyword:

Listing 1: show_access_type_declaration.ads

```
1  package Show_Access_Type_Declaration is
2
3     --
4     --  Declaring access types:
5     --
6
7     --  Access-to-object type
8     type Integer_Access is access Integer;
9
10    --  Access-to-subprogram type
11    type Init_Integer_Access is access
12      function return Integer;
13
14 end Show_Access_Type_Declaration;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Terminology.Access_
 ↪Type_Declaration
MD5: 64e4e0847a73a9ed23e29e09798934de
```

Here, we're declaring two access types: the access-to-object type `Integer_Access` and the access-to-subprogram type `Init_Integer_Access`. (We discuss access-to-subprogram types *later on* (page 820)).

In the declaration of an access type, we always specify — after the **access** keyword — the kind of thing we want to designate. In the case of an access-to-object type declaration, we declare a subtype we want to access, which is known as the *designated subtype* of an access type. In the case of an access-to-subprogram type declaration, the subprogram prototype is known as the *designated profile*.

In our previous code example, **Integer** is the designated subtype of the `Integer_Access` type, and **function** `return Integer` is the designated profile of the `Init_Integer_Access` type.

Important

In contrast to other programming languages, an access type is not a pointer, and it doesn't just indicate an address in memory. We discuss more about *addresses* (page 849) later on.

Access object and designated object

We use an access-to-object type by first declaring a variable (or constant) of an access type and then allocating an object. (This is actually just one way of using access types; we discuss other methods later in this chapter.) The actual variable or constant of an access type is called *access object*, while the object we allocate (via **new**) is the *designated object*.

For example:

Listing 2: show_simple_allocation.adb

```
procedure Show_Simple_Allocation is

   --  Access-to-object type
   type Integer_Access is access Integer;

   --  Access object
   I1 : Integer_Access;

begin
   I1 := new Integer;
   --    ^^^^^^^^^^^ allocating an object,
   --                which becomes the designated
   --                object for I1

end Show_Simple_Allocation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Terminology.Simple_
 ↪Allocation
MD5: 32ca8cf523e19b25dabb55da6df1f18d
```

In this example, `I1` is an access object and the object allocated via **new** **Integer** is its designated object.

Access value and designated value

An access object and a designated (allocated) object, both store values. The value of an access object is the *access value* and the value of a designated object is the *designated value*. For example:

Listing 3: show_values.adb

```
procedure Show_Values is

   --  Access-to-object type
   type Integer_Access is access Integer;

   I1, I2, I3 : Integer_Access;

begin
   I1 := new Integer;
   I3 := new Integer;

   --  Copying the access value of I1 to I2
   I2 := I1;

   --  Copying the designated value of I1
   I3.all := I1.all;

end Show_Values;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Terminology.Values
MD5: a152ee813b8ed9fad985cf4e2c25d847
```

In this example, the assignment `I2 := I1` copies the access value of `I1` to `I2`. The assignment `I3.all := I1.all` copies `I1`'s designated value to `I3`'s designated object. (As we already know, `.all` is used to dereference an access object. We discuss this topic again *later in this chapter* (page 766).)

In the Ada Reference Manual

- 3.10 Access Types[173]

28.1.2 Access types: Allocation

Ada makes the distinction between pool-specific and general access types, as we'll discuss in this section. Before doing so, however, let's talk about memory allocation.

In general terms, memory can be allocated dynamically on the heap or statically on the stack. (Strictly speaking, both are dynamic allocations, in that they occur at run-time with amounts not previously specified.) For example:

Listing 4: show_simple_allocation.adb

```
procedure Show_Simple_Allocation is

   --  Declaring access type:
   type Integer_Access is access Integer;

```

(continues on next page)

[173] http://www.ada-auth.org/standards/22rm/html/RM-3-10.html

(continued from previous page)

```
6     --  Declaring access object:
7     A1 : Integer_Access;
8
9  begin
10    --  Allocating an Integer object on the heap
11    A1 := new Integer;
12
13    declare
14       --  Allocating an Integer object on the
15       --  stack
16       I : Integer;
17    begin
18       null;
19    end;
20
21 end Show_Simple_Allocation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_Types_
 ↪Allocation.Simple_Allocation
MD5: 4144feb99e6e0b1a0749fce0b20370a1
```

Build output

```
show_simple_allocation.adb:16:07: warning: variable "I" is never read and never␣
 ↪assigned [-gnatwv]
```

When we allocate an object on the heap via **new**, the allocation happens in a memory pool that is associated with the access type. In our code example, there's a memory pool associated with the `Integer_Access` type, and each **new Integer** allocates a new integer object in that pool. Therefore, access types of this kind are called pool-specific access types. (We discuss *more about these types* (page 740) later.)

It is also possible to access objects that were allocated on the stack. To do that, however, we cannot use pool-specific access types because — as the name suggests — they're only allowed to access objects that were allocated in the specific pool associated with the type. Instead, we have to use general access types in this case:

Listing 5: show_general_access_type.adb

```
1  procedure Show_General_Access_Type is
2
3     --  Declaring general access type:
4     type Integer_Access is access all Integer;
5
6     --  Declaring access object:
7     A1 : Integer_Access;
8
9     --  Allocating an Integer object on the
10    --  stack:
11    I : aliased Integer;
12
13 begin
14    --  Getting access to an Integer object that
15    --  was allocated on the stack
16    A1 := I'Access;
17
18 end Show_General_Access_Type;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_Types_
 ↪Allocation.General_Access_Types
MD5: f166291ad1975396131775d0aff6ad9d
```

In this example, we declare the general access type `Integer_Access` and the access object `A1`. To initialize `A1`, we write `I'Access` to get access to an integer object `I` that was allocated on the stack. (For the moment, don't worry much about these details: we'll talk about general access types again when we introduce the topic of *aliased objects* (page 778) later on.)

For further reading...

Note that it is possible to use general access types to allocate objects on the heap:

Listing 6: show_simple_allocation.adb

```
1  procedure Show_Simple_Allocation is
2
3     --  Declaring general access type:
4     type Integer_Access is access all Integer;
5
6     --  Declaring access object:
7     A1 : Integer_Access;
8
9  begin
10    --
11    --  Allocating an Integer object on the heap
12    --  and initializing an access object of
13    --  the general access type Integer_Access.
14    --
15    A1 := new Integer;
16
17 end Show_Simple_Allocation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_Types_
 ↪Allocation.General_Access_Types_Heap
MD5: 3fa5efeac2f66794f066ab29f26bf7ca
```

Here, we're using a general access type `Integer_Access`, but allocating an integer object on the heap.

Important

In many code examples, we have used the **`Integer`** type as the designated subtype of the access types — by writing **`access Integer`**. Although we have used this specific scalar type, we aren't really limited to those types. In fact, we can use *any type* as the designated subtype, including user-defined types, composite types, task types and protected types.

In the Ada Reference Manual

- 3.10 Access Types[174]

[174] http://www.ada-auth.org/standards/22rm/html/RM-3-10.html

Pool-specific access types

We've already discussed many aspects about pool-specific access types. In this section, we recapitulate some of those aspects, and discuss some new details that haven't seen yet.

As we know, we cannot directly assign an object `Distance_Miles` of type `Miles` to an object `Distance_Meters` of type `Meters`, even if both share a common **`Float`** type ancestor. The assignment is only possible if we perform a type conversion from `Miles` to `Meters`, or vice-versa — e.g.: `Distance_Meters := Meters (Distance_Miles) * Miles_To_Meters_Factor`.

Similarly, in the case of pool-specific access types, a direct assignment between objects of different access types isn't possible. However, even if both access types have the same designated subtype (let's say, they are both declared using **`is access Integer`**), it's still not possible to perform a type conversion between those access types. The only situation when an access type conversion is allowed is when both types have a common ancestor.

Let's see an example:

Listing 7: show_simple_allocation.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Simple_Allocation is

   --  Declaring pool-specific access type:
   type Integer_Access_1 is access Integer;
   type Integer_Access_2 is access Integer;
   type Integer_Access_2B is new Integer_Access_2;

   --  Declaring access object:
   A1  : Integer_Access_1;
   A2  : Integer_Access_2;
   A2B : Integer_Access_2B;

begin
   A1 := new Integer;
   Put_Line ("A1  : " & A1'Image);
   Put_Line ("Pool: " & A1'Storage_Pool'Image);

   A2 := new Integer;
   Put_Line ("A2:   " & A2'Image);
   Put_Line ("Pool: " & A2'Storage_Pool'Image);

   --  ERROR: Cannot directly assign access values
   --         for objects of unrelated access
   --         types; also, cannot convert between
   --         these types.
   --
   --  A1 := A2;
   --  A1 := Integer_Access_1 (A2);

   A2B := Integer_Access_2B (A2);
   Put_Line ("A2B:  " & A2B'Image);
   Put_Line ("Pool: " & A2B'Storage_Pool'Image);

end Show_Simple_Allocation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_Types_
 ↪Allocation.Pool_Specific_Access_Types
MD5: 8984cb9cb9083f09b9b4096da812f805
```

Runtime output

```
A1  : (access ec12a0)
Pool: SYSTEM.POOL_GLOBAL.UNBOUNDED_NO_RECLAIM_POOL'{SYSTEM.STORAGE_POOLS.TROOT_
 ↪STORAGE_POOLC object}
A2:   (access ec1360)
Pool: SYSTEM.POOL_GLOBAL.UNBOUNDED_NO_RECLAIM_POOL'{SYSTEM.STORAGE_POOLS.TROOT_
 ↪STORAGE_POOLC object}
A2B:  (access ec1360)
Pool: SYSTEM.POOL_GLOBAL.UNBOUNDED_NO_RECLAIM_POOL'{SYSTEM.STORAGE_POOLS.TROOT_
 ↪STORAGE_POOLC object}
```

In this example, we declare three access types: `Integer_Access_1`, `Integer_Access_2` and `Integer_Access_2B`. Also, the `Integer_Access_2B` type is derived from the `Integer_Access_2` type. Therefore, we can convert an object of `Integer_Access_2` type to the `Integer_Access_2B` type — we do this in the `A2B := Integer_Access_2B (A2)` assignment. However, we cannot directly assign to or convert between unrelated types such as `Integer_Access_1` and `Integer_Access_2`. (We would get a compilation error if we included the `A1 := A2` or the `A1 := Integer_Access_1 (A2)` assignment.)

Important

Remember that:

- As mentioned in the *Introduction to Ada course* (page 97):
  - an access type can be unconstrained, but the actual object allocation must be constrained;
  - we can use a *qualified expression* (page 332) to allocate an object.
- We can use the `Storage_Size` attribute to limit the size of the memory pool associated with an access type, as discussed previously in the *section about storage size* (page 353).
- When running out of memory while allocating via **new**, we get a `Storage_Error` exception because of the *storage check* (page 673).

For example:

Listing 8: show_array_allocation.adb

```
1  pragma Ada_2022;
2
3  with Ada.Text_IO; use Ada.Text_IO;
4
5  procedure Show_Array_Allocation is
6
7     --  Unconstrained array type:
8     type Integer_Array is
9       array (Positive range <>) of Integer;
10
11    --  Access type with unconstrained
12    --  designated subtype and limited storage
13    --  size.
14    type Integer_Array_Access is
15      access Integer_Array
16        with Storage_Size => 128;
17
```

(continues on next page)

(continued from previous page)

```
   --  An access object:
   A1 : Integer_Array_Access;

   procedure Show_Info
     (IAA : Integer_Array_Access) is
   begin
      Put_Line ("Allocated: " & IAA'Image);
      Put_Line ("Length:    "
                & IAA.all'Length'Image);
      Put_Line ("Values:    "
                & IAA.all'Image);
   end Show_Info;

begin
   --  Allocating an integer array with
   --  constrained range on the heap:
   A1 := new Integer_Array (1 .. 3);
   A1.all := [others => 42];
   Show_Info (A1);

   --  Allocating an integer array on the
   --  heap using a qualified expression:
   A1 := new Integer_Array'(5, 10);
   Show_Info (A1);

   --  A third allocation fails at run time
   --  because of the constrained storage
   --  size:
   A1 := new Integer_Array (1 .. 100);
   Show_Info (A1);

exception
    when Storage_Error =>
       Put_Line ("Out of memory!");

end Show_Array_Allocation;
```

Multiple allocation

Up to now, we have seen examples of allocating a single object on the heap. It's possible to allocate multiple objects *at once* as well — i.e. syntactic sugar is available to simplify the code that performs this allocation. For example:

Listing 9: show_access_array_allocation.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Access_Array_Allocation is

   type Integer_Access is access Integer;

   type Integer_Access_Array is
     array (Positive range <>) of Integer_Access;

   --  An array of access objects:
   Arr : Integer_Access_Array (1 .. 10);
```

(continues on next page)

(continued from previous page)

```
14
15 begin
16    --
17    --  Allocating 10 access objects and
18    --  initializing the corresponding designated
19    --  object with zero:
20    --
21    Arr := (others => new Integer'(0));
22
23    --  Same as:
24    for I in Arr'Range loop
25       Arr (I) := new Integer'(0);
26    end loop;
27
28    Put_Line ("Arr: " & Arr'Image);
29
30    Put_Line ("Arr (designated values): ");
31    for E of Arr loop
32       Put (E.all'Image);
33    end loop;
34
35 end Show_Access_Array_Allocation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_Types_
 ↪Allocation.Integer_Access_Array
MD5: c32af182dc35879d76df989a689ee35c
```

Runtime output

```
Arr:
[(access 12453e0), (access 1245400), (access 1245420), (access 1245440),
 (access 1245460), (access 1245480), (access 12454a0), (access 12454c0),
 (access 12454e0), (access 1245500)]
Arr (designated values):
 0 0 0 0 0 0 0 0 0 0
```

In this example, we have the access type `Integer_Access` and an array type of this access type (`Integer_Access_Array`). We also declare an array `Arr` of `Integer_Access_Array` type. This means that each component of `Arr` is an access object. We allocate all ten components of the `Arr` array by simply writing `Arr := (others => new Integer)`. This *array aggregate* (page 450) is syntactic sugar for a loop over `Arr` that allocates each component. (Note that, by writing `Arr := (others => new Integer'(0))`, we're also initializing the designated objects with zero.)

Let's see another code example, this time with task types:

Listing 10: workers.ads

```
1  package Workers is
2
3     task type Worker is
4        entry Start (Id : Positive);
5        entry Stop;
6     end Worker;
7
8     type Worker_Access is access Worker;
9
10    type Worker_Array is
11      array (Positive range <>) of Worker_Access;
```

(continues on next page)

(continued from previous page)

```
12
13 end Workers;
```

Listing 11: workers.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Workers is
4
5     task body Worker is
6        Id : Positive;
7     begin
8        accept Start (Id : Positive) do
9           Worker.Id := Id;
10       end Start;
11       Put_Line ("Started Worker #"
12                 & Id'Image);
13
14       accept Stop;
15
16       Put_Line ("Stopped Worker #"
17                 & Id'Image);
18    end Worker;
19
20 end Workers;
```

Listing 12: show_workers.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  with Workers; use Workers;
4
5  procedure Show_Workers is
6     Worker_Arr : Worker_Array (1 .. 20);
7  begin
8     --
9     --  Allocating 20 workers at once:
10    --
11    Worker_Arr := (others => new Worker);
12
13    for I in Worker_Arr'Range loop
14       Worker_Arr (I).Start (I);
15    end loop;
16
17    Put_Line ("Some processing...");
18    delay 1.0;
19
20    for W of Worker_Arr loop
21       W.Stop;
22    end loop;
23
24 end Show_Workers;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_Types_
 ↪Allocation.Workers
MD5: d29e3d56585f8d9a63b805c680e5dc54
```

Runtime output

```

Stopped Worker # 10
Stopped Worker # 14
Stopped Worker # 13
Stopped Worker # 19
Stopped Worker # 11
Stopped Worker # 18
Stopped Worker # 20
```

In this example, we declare the task type `Worker`, the access type `Worker_Access` and an array of access to tasks `Worker_Array`. Using this approach, a task is only created when we allocate an individual component of an array of `Worker_Array` type. Thus, when we declare the `Worker_Arr` array in this example, we're only preparing a *container* of 20 workers, but we don't have any actual tasks yet. We bring the 20 tasks into existence by writing `Worker_Arr := (others => new Worker)`.

28.1.3 Discriminants as Access Values

We can use access types when declaring discriminants. Let's see an example:

Listing 13: custom_recs.ads

```
1  package Custom_Recs is
2
3     --  Declaring an access type:
4     type Integer_Access is access Integer;
5
```

(continues on next page)

(continued from previous page)

```
   --  Declaring a discriminant with this
   --  access type:
   type Rec (IA : Integer_Access) is record

      I : Integer := IA.all;
      --            ^^^^^^^^^
      --  Setting I's default to use the
      --  designated value of IA:
   end record;

   procedure Show (R : Rec);

end Custom_Recs;
```

Listing 14: custom_recs.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Custom_Recs is

   procedure Show (R : Rec) is
   begin
      Put_Line ("R.IA = "
                & Integer'Image (R.IA.all));
      Put_Line ("R.I  = "
                & Integer'Image (R.I));
   end Show;

end Custom_Recs;
```

Listing 15: show_discriminants_as_access_values.adb

```
with Custom_Recs; use Custom_Recs;

procedure Show_Discriminants_As_Access_Values is

   IA : constant Integer_Access :=
          new Integer'(10);
   R  : Rec (IA);

begin
   Show (R);

   IA.all := 20;
   R.I    := 30;
   Show (R);

   --  As expected, we cannot change the
   --  discriminant. The following line is
   --  triggers a compilation error:
   --
   --  R.IA := new Integer;

end Show_Discriminants_As_Access_Values;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Discriminants_As_
 ↪Access_Values.Discriminant_Access_Values
MD5: c7850acefd8e5227f4be654faed13055
```

Runtime output

```
R.IA =  10
R.I  =  10
R.IA =  20
R.I  =  30
```

In the Custom_Recs package from this example, we declare the access type Integer_Access. We then use this type to declare the discriminant (IA) of the Rec type. In the Show_Discriminants_As_Access_Values procedure, we see that (as expected) we cannot change the discriminant of an object of Rec type: an assignment such as `R.IA := new Integer` would trigger a compilation error.

Note that we can use a default for the discriminant:

Listing 16: custom_recs.ads

```
package Custom_Recs is

   type Integer_Access is access Integer;

   type Rec (IA : Integer_Access
                  := new Integer'(0)) is
      --             ^^^^^^^^^^^^^^^
      --              default value
   record
      I : Integer := IA.all;
   end record;

   procedure Show (R : Rec);

end Custom_Recs;
```

R.I  =  0
```

(continues on next page)

(continued from previous page)

```
R.IA =  20
R.I  =  20
```

Here, we've changed the declaration of the Rec type to allocate an integer object if the type's discriminant isn't provided — we can see this in the declaration of the R1 object in the Show_Discriminants_As_Access_Values procedure. Also, in this procedure, we're allocating an unnamed integer object in the declaration of R2.

In the Ada Reference Manual

- 3.10 Access Types[175]
- 3.7.1 Discriminant Constraints[176]

Unconstrained type as designated subtype

Notice that we were using a scalar type as the designated subtype of the Integer_Access type. We could have used an unconstrained type as well. In fact, this is often used for the sake of having the effect of an unconstrained discriminant type.

Let's see an example:

Listing 18: persons.ads

```
1  package Persons is
2
3     --  Declaring an access type whose
4     --  designated subtype is unconstrained:
5     type String_Access is access String;
6
7     --  Declaring a discriminant with this
8     --  access type:
9     type Person (Name : String_Access) is record
10       Age : Integer;
11    end record;
12
13    procedure Show (P : Person);
14
15 end Persons;
```

Listing 19: persons.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Persons is
4
5     procedure Show (P : Person) is
6     begin
7        Put_Line ("Name = "
8                  & P.Name.all);
9        Put_Line ("Age  = "
10                 & Integer'Image (P.Age));
11    end Show;
12
13 end Persons;
```

[175] http://www.ada-auth.org/standards/22rm/html/RM-3-10.html
[176] http://www.ada-auth.org/standards/22rm/html/RM-3-7-1.html

Listing 20: show_person.adb

```
with Persons; use Persons;

procedure Show_Person is
   P : Person (new String'("John"));
begin
   P.Age := 30;
   Show (P);
end Show_Person;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Discriminants_As_
 ↪Access_Values.Persons
MD5: 9b1109d076b6f06632c8685a41616210
```

Runtime output

```
Name = John
Age  =  30
```

In this example, the discriminant of the Person type has an unconstrained designated type. In the Show_Person procedure, we declare the P object and specify the constraints of the allocated string object — in this case, a four-character string initialized with the name "John".

For further reading...

In the previous code example, we used an array — actually, a string — to demonstrate the advantage of using discriminants as access values, for we can use an unconstrained type as the designated subtype. In fact, as we discussed *earlier in another chapter* (page 296), we can only use discrete types (or access types) as discriminants. Therefore, you wouldn't be able to use a string, for example, directly as a discriminant without using access types:

Listing 21: persons.ads

```
package Persons is

   --  ERROR: Declaring a discriminant with an
   --         unconstrained type:
   type Person (Name : String) is record
      Age : Integer;
   end record;

end Persons;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Discriminants_As_
 ↪Access_Values.Persons_Error
MD5: 4144852aaf95da62bc4781b1e8dc2717
```

Build output

```
persons.ads:5:24: error: discriminants must have a discrete or access type
gprbuild: *** compilation phase failed
```

As expected, compilation fails for this code because the discriminant of the Person type is indefinite.

However, the advantage of discriminants as access values isn't restricted to being able to

use unconstrained types such as arrays: we could really use any type as the designated subtype! In fact, we can generalized this to:

Listing 22: gen_custom_recs.ads

```
generic
   type T (<>);  --  any type
   type T_Access is access T;
package Gen_Custom_Recs is
   --  Declare a type whose discriminant D can
   --  access any type:
   type T_Rec (D : T_Access) is null record;
end Gen_Custom_Recs;
```

Listing 23: custom_recs.ads

```
with Gen_Custom_Recs;

package Custom_Recs is

    type Incomp;
    --  Incomplete type declaration!

   type Incomp_Access is access Incomp;

   --  Instantiating package using
   --  incomplete type Incomp:
   package Inst is new
     Gen_Custom_Recs
       (T        => Incomp,
        T_Access => Incomp_Access);
   subtype Rec is Inst.T_Rec;

   --  At this point, Rec (Inst.T_Rec) uses
   --  an incomplete type as the designated
   --  subtype of its discriminant type

   procedure Show (R : Rec) is null;

   --  Now, we complete the Incomp type:
   type Incomp (B : Boolean := True) is private;

private
   --  Finally, we have the full view of the
   --  Incomp type:
   type Incomp (B : Boolean := True) is
     null record;

end Custom_Recs;
```

Listing 24: show_rec.adb

```
with Custom_Recs; use Custom_Recs;

procedure Show_Rec is
   R : Rec (new Incomp);
begin
   Show (R);
end Show_Rec;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Discriminants_As_
 ↪Access_Values.Generic_Access
MD5: c65510e8c6a7625cbd08aa9e68f05115
```

In the Gen_Custom_Recs package, we're using **type T** (<>) — which can be any type — for the designated subtype of the access type T_Access, which is the type of T_Rec's discriminant. In the Custom_Recs package, we use the incomplete type Incomp to instantiate the generic package. Only after the instantiation, we declare the complete type.

Later on, we'll discuss discriminants again when we look into *anonymous access discriminants* (page 868), which provide some advantages in terms of *accessibility rules* (page 788).

Whole object assignments

As expected, we cannot change the discriminant value in whole object assignments. If we do that, the Constraint_Error exception is raised at runtime:

Listing 25: show_person.adb

```
with Persons; use Persons;

procedure Show_Person is
   S1 : String_Access := new String'("John");
   S2 : String_Access := new String'("Mark");
   P : Person := (Name => S1,
                  Age  => 30);
begin
   P := (Name => S1, Age => 31);
   --            ^^ OK: we didn't change the
   --                   discriminant.
   Show (P);

   --  We can just repeat the discriminant:
   P := (Name => P.Name, Age => 32);
   --            ^^^^^^ OK: we didn't change the
   --                       discriminant.
   Show (P);

   --  Of course, we can change the string itself:
   S1.all := "Mark";
   Show (P);

   P := (Name => S2, Age => 40);
   --            ^^ ERROR: we changed the
   --                      discriminant!
   Show (P);
end Show_Person;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Discriminants_As_
 ↪Access_Values.Persons
MD5: 96f4742365eb6a07c377a5dec28b5767
```

Runtime output

```
Name = John
Age  =  31
Name = John
Age  =  32
Name = Mark
Age  =  32

raised CONSTRAINT_ERROR : show_person.adb:24 discriminant check failed
```

The first and the second assignments to P are OK because we didn't change the discriminant. However, the last assignment raises the `Constraint_Error` exception at runtime because we're changing the discriminant.

28.1.4 Parameters as Access Values

In addition to *using discriminants as access values* (page 745), we can use access types for subprogram formal parameters. For example, the N parameter of the Show procedure below has an access type:

Listing 26: names.ads

```
1  package Names is
2
3     type Name is access String;
4
5     procedure Show (N : Name);
6
7  end Names;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Parameters_As_
 ↪Access_Values.Names
MD5: 82ce94987dce9026aed54a0deb3cc548
```

This is the complete code example:

Listing 27: names.ads

```
1  package Names is
2
3     type Name is access String;
4
5     procedure Show (N : Name);
6
7  end Names;
```

Listing 28: names.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Names is
```

(continues on next page)

(continued from previous page)

```
4
5     procedure Show (N : Name) is
6     begin
7        Put_Line ("Name: " & N.all);
8     end Show;
9
10 end Names;
```

Listing 29: show_names.adb

```
1  with Names; use Names;
2
3  procedure Show_Names is
4     N : Name := new String'("John");
5  begin
6     Show (N);
7  end Show_Names;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Parameters_As_
 ↪Access_Values.Names
MD5: 526baf1996b4a2970c3fa2e3485dcbad
```

Runtime output

```
Name: John
```

Note that in this example, the Show procedure is basically just displaying the string. Since the procedure isn't doing anything that justifies the need for an access type, we could have implemented it with a *simpler* type:

Listing 30: names.ads

```
1  package Names is
2
3     type Name is access String;
4
5     procedure Show (N : String);
6
7  end Names;
```

Listing 31: names.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Names is
4
5     procedure Show (N : String) is
6     begin
7        Put_Line ("Name: " & N);
8     end Show;
9
10 end Names;
```

Listing 32: show_names.adb

```
1  with Names; use Names;
2
3  procedure Show_Names is
```

(continues on next page)

(continued from previous page)

```
   N : Name := new String'("John");
begin
   Show (N.all);
end Show_Names;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Parameters_As_
 ↪Access_Values.Names_String
MD5: 097ec1ff781fda9deed1de23cae39ae5
```

Runtime output

```
Name: John
```

It's important to highlight the difference between passing an access value to a subprogram and passing an object by reference. In both versions of this code example, the compiler will make use of a reference for the actual parameter of the N parameter of the Show procedure. However, the difference between these two cases is that:

- `N : Name` is a reference to an object (because it's an access value) that is passed by value, and
- `N : String` is an object passed by reference.

Changing the referenced object

Since the Name type gives us access to an object in the Show procedure, we could actually change this object inside the procedure. To illustrate this, let's change the Show procedure to lower each character of the string before displaying it (and rename the procedure to Lower_And_Show):

Listing 33: names.ads

```
package Names is

   type Name is access String;

   procedure Lower_And_Show (N : Name);

end Names;
```

Listing 34: names.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Ada.Characters.Handling;
use  Ada.Characters.Handling;

package body Names is

   procedure Lower_And_Show (N : Name) is
   begin
      for I in N'Range loop
         N (I) := To_Lower (N (I));
      end loop;
      Put_Line ("Name: " & N.all);
   end Lower_And_Show;

end Names;
```

Listing 35: show_changed_names.adb

```
with Names; use Names;

procedure Show_Changed_Names is
   N : Name := new String'("John");
begin
   Lower_And_Show (N);
end Show_Changed_Names;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Parameters_As_
 ↪Access_Values.Changed_Names
MD5: 063a507284f5e7ffa669db2c8fdd3d6f
```

Runtime output

```
Name: john
```

Notice that, again, we could have implemented the Lower_And_Show procedure without using an access type:

Listing 36: names.ads

```
package Names is

   type Name is access String;

   procedure Lower_And_Show (N : in out String);

end Names;
```

Listing 37: names.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Ada.Characters.Handling;
use  Ada.Characters.Handling;

package body Names is

   procedure Lower_And_Show (N : in out String) is
   begin
      for I in N'Range loop
         N (I) := To_Lower (N (I));
      end loop;
      Put_Line ("Name: " & N);
   end Lower_And_Show;

end Names;
```

Listing 38: show_changed_names.adb

```
with Names; use Names;

procedure Show_Changed_Names is
   N : Name := new String'("John");
begin
   Lower_And_Show (N.all);
end Show_Changed_Names;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Parameters_As_
 ↪Access_Values.Changed_Names_String
MD5: 783ea8c45ed8ad3e0007524c11b6bcc4
```

Runtime output

```
Name: john
```

Replace the access value

Instead of changing the object in the Lower_And_Show procedure, we could replace the access value by another one — for example, by allocating a new string inside the procedure. In this case, we have to pass the access value by reference using the **in out** parameter mode:

Listing 39: names.ads

```
package Names is

   type Name is access String;

   procedure Lower_And_Show (N : in out Name);

end Names;
```

Listing 40: names.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Ada.Characters.Handling;
use  Ada.Characters.Handling;

package body Names is

   procedure Lower_And_Show (N : in out Name) is
   begin
      N := new String'(To_Lower (N.all));
      Put_Line ("Name: " & N.all);
   end Lower_And_Show;

end Names;
```

Listing 41: show_changed_names.adb

```
with Names; use Names;

procedure Show_Changed_Names is
   N : Name := new String'("John");
begin
   Lower_And_Show (N);
end Show_Changed_Names;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Parameters_As_
 ↪Access_Values.Replaced_Names
MD5: a4abfe6fdb1e5029e8eea17641cd960b
```

Runtime output

```
Name: john
```

Now, instead of changing the object referenced by N, we're actually replacing it with a new object that we allocate inside the Lower_And_Show procedure.

As expected, contrary to the previous examples, we cannot implement this code by relying on parameter modes to replace the object. In fact, we have to use access types for this kind of operations.

Note that this implementation creates a memory leak. In a proper implementation, we should make sure to *deallocate the object* (page 800), as explained later on.

Side-effects on designated objects

In previous code examples from this section, we've seen that passing a parameter by reference using the **in** or **in out** parameter modes is an alternative to using access values as parameters. Let's focus on the subprogram declarations of those code examples and their parameter modes:

Subprogram	Parameter type	Parameter mode
Show	Name	**in**
Show	**String**	**in**
Lower_And_Show	Name	**in**
Lower_And_Show	**String**	**in out**

When we analyze the information from this table, we see that in the case of using strings with different parameter modes, we have a clear indication whether the subprogram might change the object or not. For example, we know that a call to Show (N : **String**) won't change the string object that we're passing as the actual parameter.

In the case of passing an access value, we cannot know whether the designated object is going to be altered by a call to the subprogram. In fact, in both Show and Lower_And_Show procedures, the parameter is the same: N : Name — in other words, the parameter mode is **in** in both cases. Here, there's no clear indication about the effects of a subprogram call on the designated object.

The simplest way to ensure that the object isn't changed in the subprogram is by using *access-to-constant types* (page 780), which we discuss later on. In this case, we're basically saying that the object we're accessing in Show is constant, so we cannot possibly change it:

Listing 42: names.ads

```
1  package Names is
2
3     type Name is access String;
4
5     type Constant_Name is access constant String;
6
7     procedure Show (N : Constant_Name);
8
9  end Names;
```

Listing 43: names.adb

```
with Ada.Text_IO; use Ada.Text_IO;

--  with Ada.Characters.Handling;
--  use  Ada.Characters.Handling;

package body Names is

   procedure Show (N : Constant_Name) is
   begin
      --  for I in N'Range loop
      --     N (I) := To_Lower (N (I));
      --  end loop;
      Put_Line ("Name: " & N.all);
   end Show;

end Names;
```

Listing 44: show_names.adb

```
with Names; use Names;

procedure Show_Names is
   N : Name := new String'("John");
begin
   Show (Constant_Name (N));
end Show_Names;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Parameters_As_
 ↪Access_Values.Names_Constant
MD5: 77526e0a159bf1bcbef08a21be250f3c
```

Runtime output

```
Name: John
```

In this case, the `Constant_Name` type ensures that the `N` parameter won't be changed in the `Show` procedure. Note that we need to convert from `Name` to `Constant_Name` to be able to call the `Show` procedure (in the `Show_Names` procedure). Although using `in String` is still a simpler solution, this approach works fine.

(Feel free to uncomment the call to `To_Lower` in the `Show` procedure and the corresponding with- and use-clauses to see that the compilation fails when trying to change the constant object.)

We could also mitigate the problem by using contracts. For example:

Listing 45: names.ads

```
package Names is

   type Name is access String;

   procedure Show (N : Name)
     with Post => N.all'Old = N.all;
   --             ^^^^^^^^^^^^^^^^^
   --     we promise that we won't change
   --     the object

end Names;
```

Listing 46: names.adb

```
with Ada.Text_IO; use Ada.Text_IO;

--  with Ada.Characters.Handling;
--  use  Ada.Characters.Handling;

package body Names is

   procedure Show (N : Name) is
   begin
      --  for I in N'Range loop
      --     N (I) := To_Lower (N (I));
      --  end loop;
      Put_Line ("Name: " & N.all);
   end Show;

end Names;
```

Listing 47: show_names.adb

```
with Names; use Names;

procedure Show_Names is
   N : Name := new String'("John");
begin
   Show (N);
end Show_Names;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Parameters_As_
 ↪Access_Values.Names_Postcondition
MD5: 2a70993232baca9d58d36e537a6fd32b
```

Runtime output

```
Name: John
```

Although a bit more verbose than a simple `in String`, the information in the specification of Show at least gives us an indication that the object won't be affected by the call to this subprogram. Note that this code actually compiles if we try to modify `N.all` in the Show procedure, but the post-condition fails at runtime when we do that.

(By uncommentating and building the code again, you'll see an exception being raised at runtime when trying to change the object.)

In the postcondition above, we're using `'Old` to refer to the original object before the subprogram call. Unfortunately, we cannot use this attribute when dealing with *limited private types* (page 928) — or limited types in general. For example, let's change the declaration of Name and have it as a limited private type instead:

Listing 48: names.ads

```
package Names is

   type Name is limited private;

   function Init (S : String) return Name;

   function Equal (N1, N2 : Name)
```

(continues on next page)

(continued from previous page)

```
                    return Boolean;

   procedure Show (N : Name)
     with Post => Equal (N'Old = N);

private

   type Name is access String;

   function Init (S : String) return Name is
     (new String'(S));

   function Equal (N1, N2 : Name)
                    return Boolean is
     (N1.all = N2.all);

end Names;
```

Listing 49: names.adb

```
with Ada.Text_IO; use Ada.Text_IO;

--  with Ada.Characters.Handling;
--  use  Ada.Characters.Handling;

package body Names is

   procedure Show (N : Name) is
   begin
      --  for I in N'Range loop
      --     N (I) := To_Lower (N (I));
      --  end loop;
      Put_Line ("Name: " & N.all);
   end Show;

end Names;
```

Listing 50: show_names.adb

```
with Names; use Names;

procedure Show_Names is
   N : Name := Init ("John");
begin
   Show (N);
end Show_Names;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Parameters_As_
 ↪Access_Values.Names_Limited_Private
MD5: 39691394d7a934869dc569eb72d1bf3a
```

Build output

```
names.ads:11:26: error: attribute "Old" cannot apply to limited objects
gprbuild: *** compilation phase failed
```

In this case, we have no means to indicate that a call to Show won't change the internal state of the actual parameter.

For further reading...

As an alternative, we could declare a new `Constant_Name` type that is also limited private. If we use this type in `Show` procedure, we're at least indicating (in the type name) that the type is supposed to be constant — even though we're not directly providing means to actually ensure that no modifications occur in a call to the procedure. However, the fact that we declare this type as an access-to-constant (in the private part of the specification) makes it clear that a call to `Show` won't change the designated object.

Let's look at the adapted code:

Listing 51: names.ads

```
package Names is

   type Name is limited private;

   type Constant_Name is limited private;

   function Init (S : String) return Name;

   function To_Constant_Name
     (N : Name)
      return Constant_Name;

   procedure Show (N : Constant_Name);

private

   type Name is
     access String;

   type Constant_Name is
     access constant String;

   function Init (S : String) return Name is
     (new String'(S));

   function To_Constant_Name
     (N : Name)
      return Constant_Name is
        (Constant_Name (N));

end Names;
```

Listing 52: names.adb

```
with Ada.Text_IO; use Ada.Text_IO;

```

Runtime output

```
Name: John
```

In this version of the source code, the Show procedure doesn't have any side-effects, as we cannot modify N inside the procedure.

Having the information about the effects of a subprogram call to an object is very important: we can use this information to set expectations — and avoid unexpected changes to an object. Also, this information can be used to prove that a program works as expected. Therefore, whenever possible, we should avoid access values as parameters. Instead, we can rely on appropriate parameter modes and pass an object by reference.

There are cases, however, where the design of our application doesn't permit replacing the access type with simple parameter modes. Whenever we have an abstract data type encapsulated as a limited private type — such as in the last code example —, we might have no means to avoid access values as parameters. In this case, using the access type is of course justifiable. We'll see such a case in the *next section* (page 762).

28.1.5 Self-reference

As we've discussed in the section about incomplete types <Adv_Ada_Incomplete_Types>, we can use incomplete types to create a recursive, self-referencing type. Let's revisit a code example from that section:

Listing 54: linked_list_example.ads

```
1  package Linked_List_Example is
2
3     type Integer_List;
4
5     type Next is access Integer_List;
6
7     type Integer_List is record
8        I : Integer;
9        N : Next;
10    end record;
11
12 end Linked_List_Example;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Self_Reference.
 ↪Linked_List_Example
MD5: b2d3a048473d498bbe691bc6e38ca1e9
```

Here, we're using the incomplete type `Integer_List` in the declaration of the `Next` type, which we then use in the complete declaration of the `Integer_List` type.

Self-references are useful, for example, to create unbounded containers — such as the linked lists mentioned in the example above. Let's extend this code example and partially implement a generic package for linked lists:

Listing 55: linked_lists.ads

```
generic
   type T is private;
package Linked_Lists is

   type List is limited private;

   procedure Append_Front
      (L : in out List;
       E :        T);

   procedure Append_Rear
      (L : in out List;
       E :        T);

   procedure Show (L : List);

private

   --  Incomplete type declaration:
   type Component;

   --  Using incomplete type:
   type List is access Component;

   type Component is record
      Value : T;
      Next  : List;
      --      ^^^^
      --   Self-reference via access type
   end record;

end Linked_Lists;
```

Listing 56: linked_lists.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

package body Linked_Lists is

   procedure Append_Front
      (L : in out List;
       E :        T)
   is
      New_First : constant List := new
        Component'(Value => E,
```

(continues on next page)

(continued from previous page)

```
                    Next  => L);
   begin
      L := New_First;
   end Append_Front;

   procedure Append_Rear
      (L : in out List;
       E :        T)
   is
      New_Last : constant List := new
        Component'(Value => E,
                   Next  => null);
   begin
      if L = null then
         L := New_Last;
      else
         declare
            Last : List := L;
         begin
            while Last.Next /= null loop
               Last := Last.Next;
            end loop;
            Last.Next := New_Last;
         end;
      end if;
   end Append_Rear;

   procedure Show (L : List) is
      Curr : List := L;
   begin
      if L = null then
         Put_Line ("[ ]");
      else
         Put ("[");
         loop
            Put (Curr.Value'Image);
            Put (" ");
            exit when Curr.Next = null;
            Curr := Curr.Next;
         end loop;
         Put_Line ("]");
      end if;
   end Show;

end Linked_Lists;
```

Listing 57: test_linked_list.adb

```
with Linked_Lists;

procedure Test_Linked_List is
    package Integer_Lists is new
      Linked_Lists (T => Integer);
    use Integer_Lists;

    L : List;
begin
    Append_Front (L, 3);
    Append_Rear (L, 4);
    Append_Rear (L, 5);
    Append_Front (L, 2);
```

(continues on next page)

(continued from previous page)

```
14     Append_Front (L, 1);
15     Append_Rear (L, 6);
16     Append_Rear (L, 7);
17
18     Show (L);
19  end Test_Linked_List;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Self_Reference.
 ↪Linked_List_Example

```

Runtime output

```
[ 1  2  3  4  5  6  7 ]
```

In this example, we declare an incomplete type `Component` in the private part of the generic `Linked_Lists` package. We use this incomplete type to declare the access type `List`, which is then used as a self-reference in the `Next` component of the `Component` type.

Note that we're using the `List` type *as a parameter* (page 752) for the `Append_Front`, `Append_Rear` and `Show` procedures.

In the Ada Reference Manual

- 3.10.1 Incomplete Type Declarations[177]

28.1.6 Mutually dependent types using access types

In the section on *mutually dependent types* (page 418), we've seen a code example where each type depends on the other one. We could rewrite that code example using access types:

Listing 58: mutually_dependent.ads

```
1  package Mutually_Dependent is
2
3     type T2;
4     type T2_Access is access T2;
5
6     type T1 is record
7        B : T2_Access;
8     end record;
9
10    type T1_Access is access T1;
11
12    type T2 is record
13       A : T1_Access;
14    end record;
15
16 end Mutually_Dependent;
```

Code block metadata

[177] http://www.ada-auth.org/standards/22rm/html/RM-3-10-1.html

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Mutually_Dependent_
 ↪Access_Types.Example
MD5: b21ffc4cdfe3db939dfc841cf8434344
```

In this example, T1 and T2 are mutually dependent types via the access types T1_Access and T2_Access — we're using those access types in the declaration of the B and A components.

28.1.7 Dereferencing

In the *Introduction to Ada course* (page 98), we discussed the **.all** syntax to dereference access values:

Listing 59: show_dereferencing.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Dereferencing is
4
5     --  Declaring access type:
6     type Integer_Access is access Integer;
7
8     --  Declaring access object:
9     A1 : Integer_Access;
10
11 begin
12    A1 := new Integer;
13
14    --  Dereferencing access value:
15    A1.all := 22;
16
17    Put_Line ("A1: " & Integer'Image (A1.all));
18 end Show_Dereferencing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Dereferencing.
 ↪Simple_Dereferencing
MD5: 65655768c17a02991ffeda9a853b6ffb
```

Runtime output

```
A1:  22
```

In this example, we declare A1 as an access object, which allows us to access objects of **Integer** type. We dereference A1 by writing A1.**all**.

Here's another example, this time with an array:

Listing 60: show_dereferencing.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Dereferencing is
4
5     type Integer_Array is
6       array (Positive range <>) of Integer;
7
8     type Integer_Array_Access is
9       access Integer_Array;
```

(continues on next page)

(continued from previous page)

```
10
11    Arr : constant Integer_Array_Access :=
12                     new Integer_Array (1 .. 6);
13 begin
14    Arr.all := (1, 2, 3, 5, 8, 13);
15
16    for I in Arr'Range loop
17       Put_Line ("Arr (: "
18                 & Integer'Image (I) & "): "
19                 & Integer'Image (Arr.all (I)));
20    end loop;
21 end Show_Dereferencing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Dereferencing.Array_
 ↪Dereferencing
MD5: 0e533dfd8ec1a74af17c99633c292e95
```

Runtime output

```
Arr (:  1):  1
Arr (:  2):  2
Arr (:  3):  3
Arr (:  4):  5
Arr (:  5):  8
Arr (:  6):  13
```

In this example, we dereference the access value by writing `Arr.all`. We then assign an array aggregate to it — this becomes `Arr.all := (..., ...);`. Similarly, in the loop, we write `Arr.all (I)` to access the `I` component of the array.

In the Ada Reference Manual

- 4.1 Names[178]

Implicit Dereferencing

Implicit dereferencing allows us to omit the `.all` suffix without getting a compilation error. In this case, the compiler *knows* that the dereferenced object is implied, not the access value.

Ada supports implicit dereferencing in these use cases:

- when accessing components of a record or an array — including array slices.
- when accessing subprograms that have at least one parameter (we discuss this topic later in this chapter);
- when accessing some attributes — such as some array and task attributes.

[178] http://www.ada-auth.org/standards/22rm/html/RM-4-1.html

Arrays

Let's start by looking into an example of implicit dereferencing of arrays. We can take the previous code example and replace `Arr.all (I)` by `Arr (I)`:

Listing 61: show_dereferencing.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Dereferencing is

   type Integer_Array is
     array (Positive range <>) of Integer;

   type Integer_Array_Access is
     access Integer_Array;

   Arr : constant Integer_Array_Access :=
                    new Integer_Array (1 .. 6);
begin
   Arr.all := (1, 2, 3, 5, 8, 13);

   Arr (1 .. 6) := (1, 2, 3, 5, 8, 13);

   for I in Arr'Range loop
      Put_Line
        ("Arr (: "
         & Integer'Image (I) & "): "
         & Integer'Image (Arr (I)));
      --                       ^ .all is implicit.
   end loop;
end Show_Dereferencing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Dereferencing.Array_
 ↪Implicit_Dereferencing
MD5: ade602a9e6976018e0c00f930a2399f1
```

Runtime output

```
Arr (:  1):  1
Arr (:  2):  2
Arr (:  3):  3
Arr (:  4):  5
Arr (:  5):  8
Arr (:  6):  13
```

Both forms — `Arr.all (I)` and `Arr (I)` — are equivalent. Note, however, that there's no implicit dereferencing when we want to access the whole array. (Therefore, we cannot write `Arr := (1, 2, 3, 5, 8, 13);`.) However, as slices are implicitly dereferenced, we can write `Arr (1 .. 6) := (1, 2, 3, 5, 8, 13);` instead of `Arr.all (1 .. 6) := (1, 2, 3, 5, 8, 13);`. Alternatively, we can assign to the array components individually and use implicit dereferencing for each component:

```
Arr (1) := 1;
Arr (2) := 2;
Arr (3) := 3;
Arr (4) := 5;
Arr (5) := 8;
Arr (6) := 13;
```

Implicit dereferencing isn't available for the whole array because we have to distinguish between assigning to access objects and assigning to actual arrays. For example:

Listing 62: show_array_assignments.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Array_Assignments is

   type Integer_Array is
     array (Positive range <>) of Integer;

   type Integer_Array_Access is
     access Integer_Array;

   procedure Show_Array
     (Name : String;
      Arr  : Integer_Array_Access) is
   begin
      Put (Name);
      for E of Arr.all loop
         Put (Integer'Image (E));
      end loop;
      New_Line;
   end Show_Array;

   Arr_1 : constant Integer_Array_Access :=
                      new Integer_Array (1 .. 6);
   Arr_2 :          Integer_Array_Access :=
                      new Integer_Array (1 .. 6);
begin
   Arr_1.all := (1,   2,  3,  5,   8,  13);
   Arr_2.all := (21, 34, 55, 89, 144, 233);

   --  Array assignment
   Arr_2.all := Arr_1.all;

   Show_Array ("Arr_2", Arr_2);

   --  Access value assignment
   Arr_2 := Arr_1;

   Arr_1.all := (377, 610, 987, 1597, 2584, 4181);

   Show_Array ("Arr_2", Arr_2);
end Show_Array_Assignments;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Dereferencing.Array_
 ↪Assignments
MD5: 9b1f99af081000c28a6bf9b033127ea3
```

Runtime output

```
Arr_2 1 2 3 5 8 13
Arr_2 377 610 987 1597 2584 4181
```

Here, `Arr_2.all := Arr_1.all` is an array assignment, while `Arr_2 := Arr_1` is an access value assignment. By forcing the usage of the `.all` suffix, the distinction is clear. Implicit dereferencing, however, could be confusing here. (For example, the `.all` suffix in `Arr_2 := Arr_1.all` is an oversight by the programmer when the intention actually was to use access values on both sides.) Therefore, implicit dereferencing is only supported in those

cases where there's no risk of ambiguities or oversights.

Records

Let's see an example of implicit dereferencing of a record:

Listing 63: show_dereferencing.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Dereferencing is

   type Rec is record
      I : Integer;
      F : Float;
   end record;

   type Rec_Access is access Rec;

   R : constant Rec_Access := new Rec;
begin
   R.all := (I => 1, F => 5.0);

   Put_Line ("R.I: "
             & Integer'Image (R.I));
   Put_Line ("R.F: "
             & Float'Image (R.F));
end Show_Dereferencing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Dereferencing.
 ↪Record_Implicit_Dereferencing
MD5: 9af72502d04f128785f77dcc829d5d48
```

Runtime output

```
R.I:  1
R.F:  5.00000E+00
```

Again, we can replace `R.all.I` by `R.I`, as record components are implicitly dereferenced. Also, we could use implicit dereference when assigning to record components individually:

```
R.I := 1;
R.F := 5.0;
```

However, we have to write `R.all` when assigning to the whole record R.

Attributes

Finally, let's see an example of implicit dereference when using attributes:

Listing 64: show_dereferencing.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Dereferencing is

   type Integer_Array is
```

(continues on next page)

(continued from previous page)

```
6       array (Positive range <>) of Integer;
7
8    type Integer_Array_Access is
9       access Integer_Array;
10
11   Arr : constant Integer_Array_Access :=
12                    new Integer_Array (1 .. 6);
13 begin
14    Put_Line
15      ("Arr'First: "
16       & Integer'Image (Arr'First));
17    Put_Line
18      ("Arr'Last: "
19       & Integer'Image (Arr'Last));
20
21    Put_Line
22      ("Arr'Component_Size: "
23       & Integer'Image (Arr'Component_Size));
24    Put_Line
25      ("Arr.all'Component_Size: "
26       & Integer'Image (Arr.all'Component_Size));
27
28    Put_Line
29      ("Arr'Size: "
30       & Integer'Image (Arr'Size));
31    Put_Line
32      ("Arr.all'Size: "
33       & Integer'Image (Arr.all'Size));
34 end Show_Dereferencing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Dereferencing.Array_
 ↪Implicit_Dereferencing
MD5: 5730e18c8d2ed5e26a4d7d325a46a7e9
```

Runtime output

```
Arr'First:  1
Arr'Last:  6
Arr'Component_Size:  32
Arr.all'Component_Size:  32
Arr'Size:  128
Arr.all'Size:  192
```

Here, we can write `Arr'First` and `Arr'Last` instead of `Arr.all'First` and `Arr.all'Last`, respectively, because `Arr` is implicitly dereferenced. The same applies to `Arr'Component_Size`. Note that we can write both `Arr'Size` and `Arr.all'Size`, but they have different meanings:

- `Arr'Size` is the size of the access object; while
- `Arr.all'Size` indicates the size of the actual array `Arr`.

In other words, the `Size` attribute is *not* implicitly dereferenced. In fact, any attribute that could potentially be ambiguous is not implicitly dereferenced. Therefore, in those cases, we must explicitly indicate (by using `.all` or not) how we want to use the attribute.

Summary

The following table summarizes all instances where implicit dereferencing is supported:

Entities	Standard Usage	Implicit Dereference
Array components	Arr.all (I)	Arr (I)
Array slices	Arr.all (F .. L)	Arr (F .. L)
Record components	Rec.all.C	Rec.C
Array attributes	Arr.all'First	Arr'First
	Arr.all'First (N)	Arr'First (N)
	Arr.all'Last	Arr'Last
	Arr.all'Last (N)	Arr'Last (N)
	Arr.all'Range	Arr'Range
	Arr.all'Range (N)	Arr'Range (N)
	Arr.all'Length	Arr'Length
	Arr.all'Length (N)	Arr'Length (N)
	Arr.all'Component_Size	Arr'Component_Size
Task attributes	T.all'Identity	T'Identity
	T.all'Storage_Size	T'Storage_Size
	T.all'Terminated	T'Terminated
	T.all'Callable	T'Callable
Tagged type attributes	X.all'Tag	X'Tag
Other attributes	X.all'Valid	X'Valid
	X.all'Old	X'Old
	A.all'Constrained	A'Constrained

- 4.1.3 Selected Components[182]
- 4.1.4 Attributes[183]

28.1.8 Ragged arrays

Ragged arrays — also known as jagged arrays — are non-uniform, multidimensional arrays. They can be useful to implement tables with varying number of coefficients, as we discuss as an example in this section.

[179] http://www.ada-auth.org/standards/22rm/html/RM-4-1.html
[180] http://www.ada-auth.org/standards/22rm/html/RM-4-1-1.html
[181] http://www.ada-auth.org/standards/22rm/html/RM-4-1-2.html
[182] http://www.ada-auth.org/standards/22rm/html/RM-4-1-3.html
[183] http://www.ada-auth.org/standards/22rm/html/RM-4-1-4.html

Uniform multidimensional arrays

Consider an algorithm that processes data based on coefficients that depends on a selected quality level:

Quality level	Number of coefficients	#1	#2	#3	#4	#5
Simplified	1	0.15				
Better	3	0.02	0.16	0.27		
Best	5	0.01	0.08	0.12	0.20	0.34

(Note that this is just a bogus table with no real purpose, as we're not trying to implement any actual algorithm.)

We can implement this table as a two-dimensional array (`Calc_Table`), where each quality level has an associated array:

Listing 65: data_processing.ads

```
package Data_Processing is

   type Quality_Level is
     (Simplified, Better, Best);

private

   Calc_Table : constant array
     (Quality_Level, 1 .. 5) of Float :=
       (Simplified =>
            (0.15, 0.00, 0.00, 0.00, 0.00),
        Better     =>
            (0.02, 0.16, 0.27, 0.00, 0.00),
        Best       =>
            (0.01, 0.08, 0.12, 0.20, 0.34));

   Last : constant array
     (Quality_Level) of Positive :=
       (Simplified => 1,
        Better     => 3,
        Best       => 5);

end Data_Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Ragged_Arrays.
 ↪Uniform_Table
MD5: befa8d2b684ee20495f2dd6907dc44d4
```

Note that, in this implementation, we have a separate table `Last` that indicates the actual number of coefficients of each quality level.

Alternatively, we could use a record (`Table_Coefficient`) that stores the number of coefficients and the actual coefficients:

Listing 66: data_processing.ads

```
package Data_Processing is

   type Quality_Level is
     (Simplified, Better, Best);
```

(continues on next page)

(continued from previous page)

```
5
6     type Data is
7       array (Positive range <>) of Float;
8
9  private
10
11    type Table_Coefficient is record
12       Last : Positive;
13       Coef : Data (1 .. 5);
14    end record;
15
16    Calc_Table : constant array
17      (Quality_Level) of Table_Coefficient :=
18        (Simplified =>
19             (1, (0.15, 0.00, 0.00, 0.00, 0.00)),
20         Better     =>
21             (3, (0.02, 0.16, 0.27, 0.00, 0.00)),
22         Best       =>
23             (5, (0.01, 0.08, 0.12, 0.20, 0.34)));
24

 ↪Uniform_Table
MD5: 4c8602f6ecede0ac1231838c0a0a54b7
```

In this case, we have a unidimensional array where each component (of Table_Coefficient type) contains an array (Coef) with the coefficients.

This is an example of a Process procedure that references the Calc_Table:

Listing 67: data_processing-operations.ads

```
1  package Data_Processing.Operations is
2
3    procedure Process (D : in out Data;
4                       Q :        Quality_Level);
5
6  end Data_Processing.Operations;
```

Listing 68: data_processing-operations.adb

```
1  package body Data_Processing.Operations is
2
3     procedure Process (D : in out Data;
4                        Q :        Quality_Level) is
5     begin
6        for I in D'Range loop
7           for J in 1 .. Calc_Table (Q).Last loop
8             --  ... * Calc_Table (Q).Coef (J)
9             null;
10          end loop;
11          --  D (I) := ...
12          null;
13       end loop;
14    end Process;
15
16 end Data_Processing.Operations;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Ragged_Arrays.
 ↪Uniform_Table
MD5: 2b0d2cee265509e64e507cfa6289bdcc
```

Note that, to loop over the coefficients, we're using `for J in 1 .. Calc_Table (Q).Last loop` instead of `for J in Calc_Table (Q)'Range loop`. As we're trying to make a non-uniform array fit in a uniform array, we cannot simply loop over all elements using the `Range` attribute, but must be careful to use the correct number of elements in the loop instead.

Also, note that `Calc_Table` has 15 coefficients in total. Out of those coefficients, 6 coefficients (or 40 percent of the table) aren't being used. Naturally, this is wasted memory space. We can improve this by using ragged arrays.

Non-uniform multidimensional array

Ragged arrays are declared by using an access type to an array. By doing that, each array can be declared with a different size, thereby creating a non-uniform multidimensional array.

For example, we can declare a constant array `Table` as a ragged array:

Listing 69: data_processing.ads

```
package Data_Processing is

   type Integer_Array is
     array (Positive range <>) of Integer;

private

   type Integer_Array_Access is
     access constant Integer_Array;

   Table : constant array (1 .. 3) of
             Integer_Array_Access :=
     (1 => new Integer_Array'(1 => 15),
      2 => new Integer_Array'(1 => 12,
                              2 => 15,
                              3 => 20),
      3 => new Integer_Array'(1 => 12,
                              2 => 15,
                              3 => 20,
                              4 => 20,
                              5 => 25,
                              6 => 30));

end Data_Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Ragged_Arrays.
 ↪Simple_Ragged_Array
MD5: 28e044a43bf45585a0268c60d63c629e
```

Here, each component of `Table` is an access to another array. As each array is allocated via `new`, those arrays may have different sizes.

We can rewrite the example from the previous subsection using a ragged array for the `Calc_Table`:

Listing 70: data_processing.ads

```
package Data_Processing is

   type Quality_Level is
     (Simplified, Better, Best);

   type Data is
     array (Positive range <>) of Float;

private

   type Coefficients is access constant Data;

   Calc_Table : constant array (Quality_Level) of
                  Coefficients :=
     (Simplified =>
          new Data'(1 => 0.15),
      Better     =>
          new Data'(0.02, 0.16, 0.27),
      Best       =>
          new Data'(0.01, 0.08, 0.12,
                    0.20, 0.34));

end Data_Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Ragged_Arrays.
 ↪Ragged_Table
MD5: 0781b27cba27dbd1e74da54e425a1f4b
```

Now, we aren't wasting memory space because each data component has the right size that is required for each quality level. Also, we don't need to store the number of coefficients, as this information is automatically available from the array initialization — via the allocation of the `Data` array for the `Coefficients` type.

Note that the `Coefficients` type is defined as **`access constant`**. We discuss *access-to-constant types* (page 780) in more details later on.

This is the adapted `Process` procedure:

Listing 71: data_processing-operations.ads

```
package Data_Processing.Operations is

  procedure Process (D : in out Data;
                     Q :        Quality_Level);

end Data_Processing.Operations;
```

Listing 72: data_processing-operations.adb

```
package body Data_Processing.Operations is

   procedure Process (D : in out Data;
                      Q :        Quality_Level) is
   begin
      for I in D'Range loop
         for J in Calc_Table (Q)'Range loop
           --  ... * Calc_Table (Q).Coef (J)
           null;
```

(continues on next page)

(continued from previous page)

```
         end loop;
         --  D (I) := ...
         null;
      end loop;
   end Process;

end Data_Processing.Operations;
```

Now, we can simply loop over the coefficients by writing `for J in Calc_Table (Q)'Range loop`, as each element of `Calc_Table` automatically has the correct range.

28.1.9 Aliasing

The term aliasing[184] refers to objects in memory that we can access using more than a single reference. In Ada, if we allocate an object via `new`, we have a potentially aliased object. We can then have multiple references to this object:

Listing 73: show_aliasing.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Aliasing is
   type Integer_Access is access Integer;

   A1, A2 : Integer_Access;
begin
   A1 := new Integer;
   A2 := A1;

   A1.all := 22;
   Put_Line ("A1: " & Integer'Image (A1.all));
   Put_Line ("A2: " & Integer'Image (A2.all));

   A2.all := 24;
   Put_Line ("A1: " & Integer'Image (A1.all));
   Put_Line ("A2: " & Integer'Image (A2.all));
end Show_Aliasing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Aliasing.Aliasing_
 ↪Via_Access
MD5: 2fde6073cec9823a1a9d93aec82384e1
```

Runtime output

```
A1:  22
A2:  22
A1:  24
A2:  24
```

In this example, we access the object allocated via `new` by using either A1 or A2, as both refer to the same *aliased* object. In other words, A1 or A2 allow us to access the same object in memory.

Important

[184] https://en.wikipedia.org/wiki/Aliasing_(computing)

Note that aliasing is unrelated to renaming. For example, we could use renaming to write a program that looks similar to the one above:

Listing 74: show_renaming.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Renaming is
   A1 : Integer;
   A2 : Integer renames A1;
begin
   A1 := 22;
   Put_Line ("A1: " & Integer'Image (A1));
   Put_Line ("A2: " & Integer'Image (A2));

   A2 := 24;
   Put_Line ("A1: " & Integer'Image (A1));
   Put_Line ("A2: " & Integer'Image (A2));
end Show_Renaming;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Aliasing.Renaming
MD5: 99a47d02000b91f7464dffe994fd8ee6
```

Runtime output

```
A1:  22
A2:  22
A1:  24
A2:  24
```

Here, A1 or A2 are two different names for the same object. However, the object itself isn't aliased.

In the Ada Reference Manual

- 3.10 Access Types[185]

Aliased objects

As we discussed *previously* (page 737), we use **new** to create aliased objects on the heap. We can also use general access types to access objects that were created on the stack.

By default, objects created on the stack aren't aliased. Therefore, we have to indicate that an object is aliased by using the **aliased** keyword in the object's declaration: `Obj : aliased Integer;`.

Let's see an example:

Listing 75: show_aliased_obj.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Aliased_Obj is
   type Integer_Access is access all Integer;

```

(continues on next page)

[185] http://www.ada-auth.org/standards/22rm/html/RM-3-10.html

(continued from previous page)

```
   I_Var : aliased Integer;
   A1    : Integer_Access;
begin
   A1 := I_Var'Access;

   A1.all := 22;
   Put_Line ("A1: " & Integer'Image (A1.all));
end Show_Aliased_Obj;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Aliasing.Access_
 ↪Aliased_Obj
MD5: 98c8e47d7c2b5df8075918b239a8d476
```

Runtime output

```
A1:  22
```

Here, we declare `I_Var` as an aliased integer variable and get a reference to it, which we assign to `A1`. Naturally, we could also have two accesses `A1` and `A2`:

Listing 76: show_aliased_obj.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Aliased_Obj is
   type Integer_Access is access all Integer;

   I_Var  : aliased Integer;
   A1, A2 : Integer_Access;
begin
   A1 := I_Var'Access;
   A2 := A1;

   A1.all := 22;
   Put_Line ("A1: " & Integer'Image (A1.all));
   Put_Line ("A2: " & Integer'Image (A2.all));

   A2.all := 24;
   Put_Line ("A1: " & Integer'Image (A1.all));
   Put_Line ("A2: " & Integer'Image (A2.all));

end Show_Aliased_Obj;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Aliasing.Access_
 ↪Aliased_Obj
MD5: ac331285456462f05abe7e1fd5e3ca2b
```

Runtime output

```
A1:  22
A2:  22
A1:  24
A2:  24
```

In this example, both `A1` and `A2` refer to the `I_Var` variable.

Note that these examples make use of these two features:

1. The declaration of a general access type (`Integer_Access`) using **`access all`**.
2. The retrieval of a reference to `I_Var` using the **`Access`** attribute.

In the next sections, we discuss these features in more details.

In the Ada Reference Manual

- 3.3.1 Object Declarations[186]
- 3.10 Access Types[187]

General access modifiers

Let's now discuss how to declare general access types. In addition to the *standard* (pool-specific) access type declarations, Ada provides two access modifiers:

Type	Declaration
Access-to-variable	`type T_Acc is access all T`
Access-to-constant	`type T_Acc is access constant T`

Let's look at an example:

Listing 77: integer_access_types.ads

```
package Integer_Access_Types is

   type Integer_Access is
     access Integer;

   type Integer_Access_All is
     access all Integer;

   type Integer_Access_Const is
     access constant Integer;

end Integer_Access_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Aliasing.Show_
 ↪Access_Modifiers
MD5: 98ccaa703194ae88222ccc5a4400e967
```

As we've seen previously, we can use a type such as `Integer_Access` to allocate objects dynamically. However, we cannot use this type to refer to declared objects, for example. In this case, we have to use an access-to-variable type such as `Integer_Access_All`. Also, if we want to access constants — or access objects that we want to treat as constants —, we use a type such as `Integer_Access_Const`.

[186] http://www.ada-auth.org/standards/22rm/html/RM-3-3-1.html
[187] http://www.ada-auth.org/standards/22rm/html/RM-3-10.html

Access attribute

To get access to a variable or a constant, we make use of the **Access** attribute. For example, `I_Var'Access` gives us access to the `I_Var` object.

Let's look at an example of how to use the integer access types from the previous code snippet:

Listing 78: integer_access_types.ads

```
package Integer_Access_Types is

   type Integer_Access is
     access Integer;

   type Integer_Access_All is
     access all Integer;

   type Integer_Access_Const is
     access constant Integer;

   procedure Show;

end Integer_Access_Types;
```

Listing 79: integer_access_types.adb

```
with Ada.Text_IO;          use Ada.Text_IO;

package body Integer_Access_Types is

   I_Var : aliased          Integer :=  0;
   Fact  : aliased constant Integer := 42;

   Dyn_Ptr     : constant Integer_Access
                    := new Integer'(30);
   I_Var_Ptr   : constant Integer_Access_All
                    := I_Var'Access;
   I_Var_C_Ptr : constant Integer_Access_Const
                    := I_Var'Access;
   Fact_Ptr    : constant Integer_Access_Const
                    := Fact'Access;

   procedure Show is
   begin
      Put_Line ("Dyn_Ptr:     "
                & Integer'Image (Dyn_Ptr.all));
      Put_Line ("I_Var_Ptr:   "
                & Integer'Image (I_Var_Ptr.all));
      Put_Line ("I_Var_C_Ptr: "
                & Integer'Image
                    (I_Var_C_Ptr.all));
      Put_Line ("Fact_Ptr:    "
                & Integer'Image (Fact_Ptr.all));
   end Show;

end Integer_Access_Types;
```

Listing 80: show_access_modifiers.adb

```
with Integer_Access_Types;
```

(continues on next page)

(continued from previous page)

```
2
3  procedure Show_Access_Modifiers is
4  begin
5     Integer_Access_Types.Show;
6  end Show_Access_Modifiers;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Aliasing.Show_
 ↪Access_Modifiers
MD5: c9036f060859207ea14354b26dc8b981
```

Runtime output

```
Dyn_Ptr:      30
I_Var_Ptr:    0
I_Var_C_Ptr:  0
Fact_Ptr:     42
```

In this example, `Dyn_Ptr` refers to a dynamically allocated object, `I_Var_Ptr` refers to the `I_Var` variable, and `Fact_Ptr` refers to the `Fact` constant. We get access to the variable and the constant objects by using the **`Access`** attribute.

Also, we declare `I_Var_C_Ptr` as an access-to-constant, but we get access to the `I_Var` variable. This simply means the object `I_Var_C_Ptr` refers to is treated as a constant. Therefore, we can write `I_Var := 22;`, but we cannot write `I_Var_C_Ptr.all := 22;`.

In the Ada Reference Manual

- 3.10.2 Operations of Access Types[188]

Non-aliased objects

As mentioned earlier, by default, declared objects — which are allocated on the stack — aren't aliased. Therefore, we cannot get a reference to those objects. For example:

Listing 81: show_access_error.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_Access_Error is
4     type Integer_Access is access all Integer;
5     I_Var : Integer;
6     A1    : Integer_Access;
7  begin
8     A1 := I_Var'Access;
9
10    A1.all := 22;
11    Put_Line ("A1: " & Integer'Image (A1.all));
12 end Show_Access_Error;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Aliasing.Access_Non_
 ↪Aliased_Obj
MD5: 2a9904062eea96ae6dc209493d6f20d4
```

[188] http://www.ada-auth.org/standards/22rm/html/RM-3-10-2.html

Build output

```
show_access_error.adb:8:10: error: prefix of "Access" attribute must be aliased
gprbuild: *** compilation phase failed
```

In this example, the compiler complains that we cannot get a reference to `I_Var` because `I_Var` is not aliased.

Ragged arrays using aliased objects

We can use aliased objects to declare *ragged arrays* (page 772). For example, we can rewrite a previous program using aliased constant objects:

Listing 82: data_processing.ads

```
1  package Data_Processing is
2
3     type Integer_Array is
4       array (Positive range <>) of Integer;
5
6  private
7
8     type Integer_Array_Access is
9       access constant Integer_Array;
10
11    Tab_1 : aliased constant Integer_Array
12              := (1 => 15);
13    Tab_2 : aliased constant Integer_Array
14              := (12, 15, 20);
15    Tab_3 : aliased constant Integer_Array
16              := (12, 15, 20,
17                  20, 25, 30);
18
19    Table : constant array (1 .. 3) of
20              Integer_Array_Access :=
21      (1 => Tab_1'Access,
22       2 => Tab_2'Access,
23       3 => Tab_3'Access);
24
25 end Data_Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Aliasing.Ragged_
 ↪Array_Aliased_Objs
MD5: 7e284560c447c02628e34bac982d4ad5
```

Here, instead of allocating the constant arrays dynamically via **new**, we declare three aliased arrays (Tab_1, Tab_2 and Tab_3) and get a reference to them in the declaration of `Table`.

Aliased access objects

It's interesting to mention that access objects can be aliased themselves. Consider this example where we declare the `Integer_Access_Access` type to refer to an access object:

Listing 83: show_aliased_access_obj.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Aliased_Access_Obj is

   type Integer_Access        is
     access all Integer;
   type Integer_Access_Access is
     access all Integer_Access;

   I_Var : aliased Integer;
   A     : aliased Integer_Access;
   B     : Integer_Access_Access;
begin
   A := I_Var'Access;
   B := A'Access;

   B.all.all := 22;
   Put_Line ("A: " & Integer'Image (A.all));
   Put_Line ("B: " & Integer'Image (B.all.all));
end Show_Aliased_Access_Obj;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Aliasing.Aliased_
 ↪Access
MD5: 77e9be5e29cfb99aef9409728202ba9d
```

Runtime output

```
A:  22
B:  22
```

After the assignments in this example, `B` refers to `A`, which in turn refers to `I_Var`. Note that this code only compiles because we declare `A` as an aliased (access) object.

Aliased components

Components of an array or a record can be aliased. This allows us to get access to those components:

Listing 84: show_aliased_components.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Aliased_Components is

   type Integer_Access is access all Integer;

   type Rec is record
      I_Var_1 :         Integer;
      I_Var_2 : aliased Integer;
   end record;

```

(continues on next page)

(continued from previous page)

```
12    type Integer_Array is
13      array (Positive range <>) of aliased Integer;
14
15    R   : Rec := (22, 24);
16    Arr : Integer_Array (1 .. 3) := (others => 42);
17    A   : Integer_Access;
18 begin
19    --  A := R.I_Var_1'Access;
20    --                 ^ ERROR: cannot access
21    --                          non-aliased
22    --                          component
23
24    A := R.I_Var_2'Access;
25    Put_Line ("A: " & Integer'Image (A.all));
26
27    A := Arr (2)'Access;
28    Put_Line ("A: " & Integer'Image (A.all));
29 end Show_Aliased_Components;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Aliasing.Aliased_
 ↪Components
MD5: 5dfaa248caf8e37a4a3a1e1a24973777
```

Runtime output

```
A:  24
A:  42
```

In this example, we get access to the `I_Var_2` component of record R. (Note that trying to access the `I_Var_1` component would gives us a compilation error, as this component is not aliased.) Similarly, we get access to the second component of array `Arr`.

Declaring components with the **aliased** keyword allows us to specify that those are accessible via other paths besides the component name. Therefore, the compiler won't store them in registers. This can be essential when doing low-level programming — for example, when accessing memory-mapped registers. In this case, we want to ensure that the compiler uses the memory address we're specifying (instead of assigning registers for those components).

In the Ada Reference Manual

- 3.6 Array Types[189]

Aliased parameters

In addition to aliased objects and components, we can declare *aliased parameters* (page 625), as we already discussed in an earlier chapter. As we mentioned there, aliased parameters are always passed by reference, independently of the type we're using.

The parameter mode indicates which type we must use for the access type:

[189] http://www.ada-auth.org/standards/22rm/html/RM-3-6.html

Parameter mode	Type
aliased in	Access-to-constant
aliased out	Access-to-variable
aliased in out	Access-to-variable

Using aliased parameters in a subprogram allows us to get access to those parameters in the body of that subprogram. Let's see an example:

Listing 85: data_processing.ads

```
package Data_Processing is

   procedure Proc (I : aliased in out Integer);

end Data_Processing;
```

Listing 86: data_processing.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Data_Processing is

   procedure Show (I : aliased Integer) is
      --               ^ equivalent to
      --                 "aliased in Integer"

      type Integer_Constant_Access is
        access constant Integer;

      A : constant Integer_Constant_Access
            := I'Access;
   begin
      Put_Line ("Value : I "
                & Integer'Image (A.all));
   end Show;

   procedure Set_One (I : aliased out Integer) is

      type Integer_Access is access all Integer;

      procedure Local_Set_One (A : Integer_Access)
      is
      begin
         A.all := 1;
      end Local_Set_One;

   begin
      Local_Set_One (I'Access);
   end Set_One;

   procedure Proc (I : aliased in out Integer) is

      type Integer_Access is access all Integer;

      procedure Add_One (A : Integer_Access) is
      begin
         A.all := A.all + 1;
      end Add_One;

```

(continues on next page)

(continued from previous page)

```
   begin
      Show (I);
      Add_One (I'Access);
      Show (I);
   end Proc;

end Data_Processing;
```

Listing 87: show_aliased_param.adb

```
with Data_Processing; use Data_Processing;

procedure Show_Aliased_Param is
   I : aliased Integer := 22;
begin
   Proc (I);
end Show_Aliased_Param;
```

Code block metadata

```

Runtime output

```
Value : I  22
Value : I  23
```

Here, `Proc` has an **`aliased in out`** parameter. In `Proc`'s body, we declare the `Integer_Access` type as an **`access all`** type. We use the same approach in body of the `Set_One` procedure, which has an **`aliased out`** parameter. Finally, the `Show` procedure has an **`aliased in`** parameter. Therefore, we declare the `Integer_Constant_Access` as an **`access constant`** type.

Note that parameter aliasing has an influence on how arguments are passed to a subprogram when the parameter is of scalar type. When a scalar parameter is declared as aliased, the corresponding argument is passed by reference. For example, if we had declared **`procedure Show (I : Integer)`**, the argument for `I` would be passed by value. However, since we're declaring it as **`aliased Integer`**, it is passed by reference.

28.1.10 Accessibility Levels and Rules: An Introduction

This section provides an introduction to accessibility levels and accessibility rules. This topic can be very complicated, and by no means do we intend to cover all the details here. (In fact, discussing all the details about accessibility levels and rules could be a long chapter on its own. If you're interested in them, please refer to the Ada Reference Manual.) In any case, the goal of this section is to present the intention behind the accessibility rules and build intuition on how to best use access types in your code.

In the Ada Reference Manual

- 3.10.2 Operations of Access Types[193]

Lifetime of objects

First, let's talk a bit about lifetime of objects[194]. We assume you understand the concept, so this section is very short.

In very simple terms, the lifetime of an object indicates when an object still has relevant information. For example, if a variable V gets out of scope, we say that its lifetime has ended. From this moment on, V no longer exists.

For example:

Listing 88: show_lifetime.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Lifetime is
   I_Var_1 : Integer := 22;
begin

   Inner_Block : declare
      I_Var_2 : Integer := 42;
   begin
      Put_Line ("I_Var_1: "
                & Integer'Image (I_Var_1));
      Put_Line ("I_Var_2: "
                & Integer'Image (I_Var_2));

      --  I_Var_2 will get out of scope
      --  when the block finishes.
   end Inner_Block;

   --  I_Var_2 is now out of scope...

   Put_Line ("I_Var_1: "
             & Integer'Image (I_Var_1));
   Put_Line ("I_Var_2: "
             & Integer'Image (I_Var_2));
   --                        ^^^^^^^
   --  ERROR: lifetime of I_Var_2 has ended!
end Show_Lifetime;
```

Code block metadata

[193] http://www.ada-auth.org/standards/22rm/html/RM-3-10-2.html
[194] https://en.wikipedia.org/wiki/Variable_(computer_science)#Scope_and_extent

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Accessibility_
 ↪Levels_Rules_Introduction.Lifetime
MD5: ebe36f12c832ecfe71399b89801808d4
```

Build output

```
show_lifetime.adb:24:31: error: "I_Var_2" is undefined
gprbuild: *** compilation phase failed
```

In this example, we declare `I_Var_1` in the `Show_Lifetime` procedure, and `I_Var_2` in its `Inner_Block`.

This example doesn't compile because we're trying to use `I_Var_2` after its lifetime has ended. However, if such a code could compile and run, the last call to `Put_Line` would potentially display garbage to the user. (In fact, the actual behavior would be undefined.)

Accessibility Levels

In basic terms, accessibility levels are a mechanism to assess the lifetime of objects (as we've just discussed). The starting point is the library level: this is the base level, and no level can be deeper than that. We start "moving" to deeper levels when we use a library in a subprogram or call other subprograms for example.

Suppose we have a procedure `Proc` that makes use of a package `Pkg`, and there's a block in the `Proc` procedure:

```
package Pkg is

   --  Library level

end Pkg;

with Pkg; use Pkg;

procedure Proc is

   --  One level deeper than
   --  library level

begin

   declare
      --  Two levels deeper than
      --  library level
  begin
      null;
   end;

end Proc;
```

For this code, we can say that:

- the specification of `Pkg` is at library level;
- the declarative part of `Proc` is one level deeper than the library level; and
- the block is two levels deeper than the library level.

(Note that this is still a very simplified overview of accessibility levels. Things start getting more complicated when we use information from `Pkg` in `Proc`. Those details will become more clear in the next sections.)

The levels themselves are not visible to the programmer. For example, there's no Access_Level attribute that returns an integer value indicating the level. Also, you cannot write a user message that displays the level at a certain point. In this sense, accessibility levels are assessed relatively to each other: we can only say that a specific operation is at the same or at a deeper level than another one.

Accessibility Rules

The accessibility rules determine whether a specific use of access types or objects is legal (or not). Actually, accessibility rules exist to prevent *dangling references* (page 795), which we discuss later. Also, they are based on the *accessibility levels* (page 789) we discussed earlier.

Code example

As mentioned earlier, the accessibility level at a specific point isn't visible to the programmer. However, to illustrate which level we have at each point in the following code example, we use a prefix (L0, L1, and L2) to indicate whether we're at the library level (L0) or at a deeper level.

Let's now look at the complete code example:

Listing 89: library_level.ads

```
package Library_Level is

   type L0_Integer_Access is
     access all Integer;

   L0_IA  : L0_Integer_Access;

   L0_Var : aliased Integer;

end Library_Level;
```

Listing 90: show_library_level.adb

```
with Library_Level; use Library_Level;

procedure Show_Library_Level is
   type L1_Integer_Access is
     access all Integer;

   L0_IA_2 : L0_Integer_Access;
   L1_IA   : L1_Integer_Access;

   L1_Var : aliased Integer;

   procedure Test is
      type L2_Integer_Access is
        access all Integer;

      L2_IA  : L2_Integer_Access;

      L2_Var : aliased Integer;
   begin
      L1_IA := L2_Var'Access;
      --       ^^^^^^
```

(continues on next page)

(continued from previous page)

```
      --       ILLEGAL: L2 object to
      --                L1 access object

      L2_IA := L2_Var'Access;
      --       ^^^^^^
      --       LEGAL: L2 object to
      --              L2 access object
   end Test;

begin
   L0_IA := new Integer'(22);
   --       ^^^^^^^^^^^
   --       LEGAL: L0 object to
   --              L0 access object

   L0_IA_2 := new Integer'(22);
   --         ^^^^^^^^^^^
   --         LEGAL: L0 object to
   --                L0 access object

   L0_IA := L1_Var'Access;
   --       ^^^^^^
   --       ILLEGAL: L1 object to
   --                L0 access object

   L0_IA_2 := L1_Var'Access;
   --         ^^^^^^
   --         ILLEGAL: L1 object to
   --                  L0 access object

   L1_IA := L0_Var'Access;
   --       ^^^^^^
   --       LEGAL: L0 object to
   --              L1 access object

   L1_IA := L1_Var'Access;
   --       ^^^^^^
   --       LEGAL: L1 object to
   --              L1 access object

   L0_IA := L1_IA;
   --       ^^^^^
   --       ILLEGAL: type mismatch

   L0_IA := L0_Integer_Access (L1_IA);
   --       ^^^^^^^^^^^^^^^^^
   --       ILLEGAL: cannot convert
   --                L1 access object to
   --                L0 access object

   Test;
end Show_Library_Level;
```

 ↪line 4
show_library_level.adb:66:32: error: cannot convert local pointer to non-local␣
 ↪access type
gprbuild: *** compilation phase failed
```

In this example, we declare

- in the `Library_Level` package: the `L0_Integer_Access` type, the `L0_IA` access object, and the `L0_Var` aliased variable;
- in the `Show_Library_Level` procedure: the `L1_Integer_Access` type, the `L0_IA_2` and `L1_IA` access objects, and the `L1_Var` aliased variable;
- in the nested `Test` procedure: the `L2_Integer_Access` type, the `L2_IA`, and the `L2_Var` aliased variable.

As mentioned earlier, the `Ln` prefix indicates the level of each type or object. Here, the `n` value is zero at library level. We then increment the `n` value each time we refer to a deeper level.

For instance:

- when we declare the `L1_Integer_Access` type in the `Show_Library_Level` procedure, that declaration is one level deeper than the level of the `Library_Level` package — so it has the `L1` prefix.
- when we declare the `L2_Integer_Access` type in the `Test` procedure, that declaration is one level deeper than the level of the `Show_Library_Level` procedure — so it has the `L2` prefix.

Types and Accessibility Levels

It's very important to highlight the fact that:

- types themselves also have an associated level, and
- objects have the same accessibility level as their types.

When we declare the `L0_IA_2` object in the code example, its accessibility level is at library level because its type (the `L0_Integer_Access` type) is at library level. Even though this declaration is in the `Show_Library_Level` procedure — whose declarative part is one level deeper than the library level —, the object itself has the same accessibility level as its type.

Now that we've discussed the accessibility levels of this code example, let's see how the accessibility rules use those levels.

Operations on Access Types

In very simple terms, the accessibility rules say that:

- operations on access types at the same accessibility level are legal;
- assigning or converting to a deeper level is legal;

Otherwise, operations targeting objects at a *less-deep* level are illegal.

For example, `L0_IA := new Integer'(22)` and `L1_IA := L1_Var'Access` are legal because we're operating at the same accessibility level. Also, `L1_IA := L0_Var'Access` is legal because `L1_IA` is at a deeper level than `L0_Var'Access`.

However, many operations in the code example are illegal. For instance, `L0_IA := L1_Var'Access` and `L0_IA_2 := L1_Var'Access` are illegal because the target objects in the assignment are *less* deep.

Note that the `L0_IA := L1_IA` assignment is mainly illegal because the access types don't match. (Of course, in addition to that, assigning `L1_Var'Access` to `L0_IA` is also illegal in terms of accessibility rules.)

Conversion between Access Types

The same rules apply to the conversion between access types. In the code example, the `L0_Integer_Access (L1_IA)` conversion is illegal because the resulting object is less deep. That being said, conversions on the same level are fine:

Listing 91: show_same_level_conversion.adb

```
procedure Show_Same_Level_Conversion is
   type L1_Integer_Access is
     access all Integer;

   type L1_B_Integer_Access is
     access all Integer;

   L1_IA   : L1_Integer_Access;
   L1_B_IA : L1_B_Integer_Access;

   L1_Var  : aliased Integer;
begin
   L1_IA := L1_Var'Access;

   L1_B_IA := L1_B_Integer_Access (L1_IA);
   --         ^^^^^^^^^^^^^^^^^^^
   --         LEGAL: conversion from
   --                L1 access object to
   --                L1 access object
end Show_Same_Level_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Accessibility_
↪Levels_Rules_Introduction.Same_Level_Conversion
MD5: 7276a06e9f5b634d4f5a10a892071d87
```

Here, we're converting from the `L1_Integer_Access` type to the `L1_B_Integer_Access`, which are both at the same level.

Accessibility rules on parameters

Note that the accessibility rules also apply to access values as subprogram parameters. For example, compilation fails for this example:

Listing 92: names.ads

```
package Names is

   type Name is access all String;

   type Constant_Name is
     access constant String;

   procedure Show (N : Constant_Name);

end Names;
```

Listing 93: names.adb

```
with Ada.Text_IO; use Ada.Text_IO;

--  with Ada.Characters.Handling;
--  use  Ada.Characters.Handling;

package body Names is

   procedure Show (N : Constant_Name) is
   begin
      --  for I in N'Range loop
      --     N (I) := To_Lower (N (I));
      --  end loop;
      Put_Line ("Name: " & N.all);
   end Show;

end Names;
```

Listing 94: show_names.adb

```
with Names; use Names;

procedure Show_Names is
   S : aliased String := "John";
begin
   Show (S'Access);
end Show_Names;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Accessibility_
 ↪Levels_Rules_Introduction.Accessibility_Checks_Parameters
MD5: 6b8bf2799caa32f55d216ac0b58fcd39
```

Build output

```
show_names.adb:6:10: error: non-local pointer cannot point to local object
gprbuild: *** compilation phase failed
```

In this case, the `S'Access` cannot be used as the actual parameter for the `N` parameter of the Show procedure because it's in a deeper level. If we allocate the string via **new**, however, the code compiles as expected:

Listing 95: show_names.adb

```
with Names; use Names;

procedure Show_Names is
   S : Name := new String'("John");
begin
   Show (Constant_Name (S));
end Show_Names;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Accessibility_
 ↪Levels_Rules_Introduction.Accessibility_Checks_Parameters
MD5: 30237c83426db758804b802e1953d5d9
```

Runtime output

```
Name: John
```

This version of the code works because both object and access object have the same level.

Dangling References

An access value that points to a non-existent object is called a dangling reference. Later on, we'll discuss how dangling references may occur using *unchecked deallocation* (page 803).

Dangling references are created when we have an access value pointing to an object whose lifetime has ended, so it becomes a non-existent object. This could occur, for example, when an access value still points to an object X that has gone out of scope.

As mentioned in the previous section, the accessibility rules of the Ada language ensure that such situations never happen! In fact, whenever possible, the compiler applies those rules to detect potential dangling references at compile time. When this detection isn't possible at compile time, the compiler introduces an *accessibility check* (page 669). If this check fails at runtime, it raises a `Program_Error` exception — thereby preventing that a dangling reference gets used.

Let's see an example of how dangling references could occur:

Listing 96: show_dangling_reference.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Dangling_Reference is

   type Integer_Access is
     access all Integer;

   I_Var_1 : aliased Integer := 22;

   A1    : Integer_Access;
begin
   A1 := I_Var_1'Access;
   Put_Line ("A1.all: "
             & Integer'Image (A1.all));

   Put_Line ("Inner_Block will start now!");

   Inner_Block : declare
```

(continues on next page)

(continued from previous page)

```
      --
      --  I_Var_2 only exists in Inner_Block
      --
      I_Var_2 : aliased Integer := 42;

      --
      --  A2 only exists in Inner_Block
      --
      A2      : Integer_Access;
   begin
      A2 := I_Var_1'Access;
      Put_Line ("A2.all: "
                & Integer'Image (A2.all));

      A1 := I_Var_2'Access;
      --   PROBLEM: A1 and Integer_Access type
      --            have longer lifetime than
      --            I_Var_2

      Put_Line ("A1.all: "
                & Integer'Image (A1.all));

      A2 := I_Var_2'Access;
      --   PROBLEM: A2 has the same lifetime as
      --            I_Var_2, but Integer_Access
      --            type has a longer lifetime.

      Put_Line ("A2.all: "
                & Integer'Image (A2.all));
   end Inner_Block;

   Put_Line ("Inner_Block has ended!");
   Put_Line ("A1.all: "
             & Integer'Image (A1.all));

end Show_Dangling_Reference;
```

gprbuild: *** compilation phase failed
```

Here, we declare the access objects A1 and A2 of Integer_Access type, and the I_Var_1 and I_Var_2 objects. Moreover, A1 and I_Var_1 are declared in the scope of the Show_Dangling_Reference procedure, while A2 and I_Var_2 are declared in the Inner_Block.

When we try to compile this code, we get two compilation errors due to violation of accessibility rules. Let's now discuss these accessibility rules in terms of lifetime, and see which problems they are preventing in each case.

1. In the A1 := I_Var_2'Access assignment, the main problem is that A1 has a longer lifetime than I_Var_2. After the Inner_Block finishes — when I_Var_2 gets out of

scope and its lifetime has ended —, A1 would still be pointing to an object that does not longer exist.

2. In the A2 := I_Var_2'Access assignment, however, both A2 and I_Var_2 have the same lifetime. In that sense, the assignment may actually look pretty much OK.
   - However, as mentioned in the previous section, Ada also cares about the lifetime of access types. In fact, since the Integer_Access type is declared outside of the Inner_Block, it has a longer lifetime than A2 and I_Var_2.
   - To be more precise, the accessibility rules detect that A2 is an access object of a type that has a longer lifetime than I_Var_2.

At first glance, this last accessibility rule may seem too strict, as both A2 and I_Var_2 have the same lifetime — so nothing bad could occur when dereferencing A2. However, consider the following change to the code:

```
A2 := I_Var_2'Access;

A1 := A2;
--    PROBLEM: A1 will still be referring
--             to I_Var_2 after the
--             Inner_Block, i.e. when the
--             lifetime of I_Var_2 has
--             ended!
```

Here, we're introducing the A1 := A2 assignment. The problem with this is that I_Var_2's lifetime ends when the Inner_Block finishes, but A1 would continue to refer to an I_Var_2 object that doesn't exist anymore — thereby creating a dangling reference.

Even though we're actually not assigning A2 to A1 in the original code, we could have done it. The accessibility rules ensure that such an error is never introduced into the program.

For further reading...

In the original code, we can consider the A2 := I_Var_2'Access assignment to be safe, as we're not using the A1 := A2 assignment there. Since we're confident that no error could ever occur in the Inner_Block due to the assignment to A2, we could replace it with A2 := I_Var_2'Unchecked_Access, so that the compiler accepts it. We discuss more about the unchecked access attribute *later in this chapter* (page 798).

Alternatively, we could have solved the compilation issue that we see in the A2 := I_Var_2'Access assignment by declaring another access type locally in the Inner_Block:

```
Inner_Block : declare
   type Integer_Local_Access is
     access all Integer;

   I_Var_2 : aliased Integer := 42;

   A2      : Integer_Local_Access;
begin
   A2 := I_Var_2'Access;
   --   This assignment is fine because
   --   the Integer_Local_Access type has
   --   the same lifetime as I_Var_2.
end Inner_Block;
```

With this change, A2 becomes an access object of a type that has the same lifetime as I_Var_2, so that the assignment doesn't violate the rules anymore.

(Note that in the Inner_Block, we could have simply named the local access type Integer_Access instead of Integer_Local_Access, thereby masking the Integer_Access

type of the outer block.)

We discuss the effects of dereferencing dangling references *later in this chapter* (page 805).

28.1.11 Unchecked Access

In this section, we discuss the Unchecked_Access attribute, which we can use to circumvent accessibility issues for objects in specific cases. (Note that this attribute only exists for objects, not for subprograms.)

We've seen *previously* (page 788) that the accessibility levels verify the lifetime of access types. Let's see a simplified version of a code example from that section:

Listing 97: integers.ads

```
package Integers is

   type Integer_Access is access all Integer;

end Integers;
```

Listing 98: show_access_issue.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Integers; use Integers;

procedure Show_Access_Issue is
   I_Var : aliased Integer := 42;

   A     : Integer_Access;
begin
   A := I_Var'Access;
   --   PROBLEM: A has the same lifetime as I_Var,
   --            but Integer_Access type has a
   --            longer lifetime.

   Put_Line ("A.all: " & Integer'Image (A.all));
end Show_Access_Issue;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Unchecked_Access.
↪Dangling_Reference_Rules
MD5: 646acabf3f388b52809349463d20d314
```

Build output

```
show_access_issue.adb:10:09: error: non-local pointer cannot point to local object
gprbuild: *** compilation phase failed
```

Here, the compiler complains about the `A := I_Var'Access` assignment because the `Integer_Access` type has a longer lifetime than `A`. However, we know that this assignment to `A` — and further uses of `A` in the code — won't cause dangling references to be created. Therefore, we can assume that assigning the access to `I_Var` to `A` is safe.

When we're sure that an access assignment cannot possibly generate dangling references, we can the use Unchecked_Access attribute. For instance, we can use this attribute to circumvent the compilation error in the previous code example, since we know that the assignment is actually safe:

Listing 99: integers.ads

```
package Integers is

   type Integer_Access is access all Integer;

end Integers;
```

Listing 100: show_access_issue.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Integers; use Integers;

procedure Show_Access_Issue is
   I_Var : aliased Integer := 42;

   A     : Integer_Access;
begin
   A := I_Var'Unchecked_Access;
   --   OK: assignment is now accepted.

   Put_Line ("A.all: " & Integer'Image (A.all));
end Show_Access_Issue;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Unchecked_Access.
 ↪Dangling_Reference_Rules
MD5: a71b9076d9e2983ffb9811183afdf6c1
```

Runtime output

```
A.all:  42
```

When we use the Unchecked_Access attribute, most rules still apply. The only difference to the standard **Access** attribute is that unchecked access applies the rules as if the object we're getting access to was being declared at library level. (For the code example we've just seen, the check would be performed as if I_Var was declared in the Integers package instead of being declared in the procedure.)

It is strongly recommended to avoid unchecked access in general. You should only use it when you can safely assume that the access object will be discarded before the object we had access to gets out of scope. Therefore, if this situation isn't clear enough, it's best to avoid unchecked access. (Later in this chapter, we'll see some of the nasty issues that arrive from creating dangling references.) Instead, you should work on improving the software design of your application by considering alternatives such as using containers or encapsulating access types in well-designed abstract data types.

In the Ada Reference Manual

- Unchecked Access Value Creation[195]

[195] http://www.ada-auth.org/standards/22rm/html/RM-13-10.html

28.1.12 Unchecked Deallocation

So far, we've seen multiple examples of using `new` to allocate objects. In this section, we discuss how to manually deallocate objects.

Our starting point to manually deallocate an object is the generic `Ada.Unchecked_Deallocation` procedure. We first instantiate this procedure for an access type whose objects we want to be able to deallocate. For example, let's instantiate it for the `Integer_Access` type:

Listing 101: integer_types.ads

```
with Ada.Unchecked_Deallocation;

package Integer_Types is

   type Integer_Access is access Integer;

   --
   --  Instantiation of Ada.Unchecked_Deallocation
   --  for the Integer_Access type:
   --
   procedure Free is
     new Ada.Unchecked_Deallocation
       (Object => Integer,
        Name   => Integer_Access);
end Integer_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Unchecked_
↪Deallocation.Simple_Unchecked_Deallocation
MD5: 328b244cf406853e87494c381c9c4c9e
```

Here, we declare the `Free` procedure, which we can then use to deallocate objects that were allocated for the `Integer_Access` type.

`Ada.Unchecked_Deallocation` is a generic procedure that we can instantiate for access types. When declaring an instance of `Ada.Unchecked_Deallocation`, we have to specify arguments for:

- the formal `Object` parameter, which indicates the type of actual objects that we want to deallocate; and
- the formal `Name` parameter, which indicates the access type.

In a type declaration such as `type Integer_Access is access Integer`, `Integer` denotes the `Object`, while `Integer_Access` denotes the `Name`.

Because each instance of `Ada.Unchecked_Deallocation` is bound to a specific access type, we cannot use it for another access type, even if the type we use for the `Object` parameter is the same:

Listing 102: integer_types.ads

```
with Ada.Unchecked_Deallocation;

package Integer_Types is

   type Integer_Access is access Integer;

   procedure Free is
     new Ada.Unchecked_Deallocation
```

(continues on next page)

(continued from previous page)

```
      (Object => Integer,
       Name   => Integer_Access);

   type Another_Integer_Access is access Integer;

   procedure Free is
     new Ada.Unchecked_Deallocation
       (Object => Integer,
        Name   => Another_Integer_Access);
end Integer_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Unchecked_
 ↪Deallocation.Simple_Unchecked_Deallocation
MD5: b9bc58ff60632287237e2e322fcbc63e
```

Here, we're declaring two `Free` procedures: one for the `Integer_Access` type, another for the `Another_Integer_Access`. We cannot use the `Free` procedure for the `Integer_Access` type when deallocating objects associated with the `Another_Integer_Access` type, even though both types are declared as **`access Integer`**.

Note that we can use any name when instantiating the `Ada.Unchecked_Deallocation` procedure. However, naming it `Free` is very common.

Now, let's see a complete example that includes object allocation and deallocation:

Listing 103: integer_types.ads

```
with Ada.Unchecked_Deallocation;

package Integer_Types is

   type Integer_Access is access Integer;

   procedure Free is
     new Ada.Unchecked_Deallocation
       (Object => Integer,
        Name   => Integer_Access);

   procedure Show_Is_Null (I : Integer_Access);

end Integer_Types;
```

Listing 104: integer_types.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Integer_Types is

   procedure Show_Is_Null (I : Integer_Access) is
   begin
      if I = null then
         Put_Line ("access value is null.");
      else
         Put_Line ("access value is NOT null.");
      end if;
   end Show_Is_Null;

end Integer_Types;
```

Listing 105: show_unchecked_deallocation.adb

```
with Ada.Text_IO;   use Ada.Text_IO;
with Integer_Types; use Integer_Types;

procedure Show_Unchecked_Deallocation is

   I : Integer_Access;

begin
   Put ("We haven't called new yet... ");
   Show_Is_Null (I);

   Put ("Calling new... ");
   I := new Integer;
   Show_Is_Null (I);

   Put ("Calling Free... ");
   Free (I);
   Show_Is_Null (I);
end Show_Unchecked_Deallocation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Unchecked_
 ↪Deallocation.Unchecked_Deallocation
MD5: a9f2df04e2fe0d5ee8c17249b4ae315a
```

Runtime output

```
We haven't called new yet... access value is null.
Calling new... access value is NOT null.
Calling Free... access value is null.
```

In the `Show_Unchecked_Deallocation` procedure, we first allocate an object for `I` and then call `Free (I)` to deallocate it. Also, we call the `Show_Is_Null` procedure at three different points: before any allocation takes place, after allocating an object for `I`, and after deallocating that object.

When we deallocate an object via a call to `Free`, the corresponding access value — which was previously pointing to an existing object — is set to **`null`**. Therefore, `I = null` after the call to `Free`, which is exactly what we see when running this example code.

Note that it is OK to call `Free` multiple times for the same access object:

Listing 106: show_unchecked_deallocation.adb

```
with Integer_Types; use Integer_Types;

procedure Show_Unchecked_Deallocation is

   I : Integer_Access;

begin
   I := new Integer;

   Free (I);
   Free (I);
   Free (I);
end Show_Unchecked_Deallocation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Unchecked_
 ↪Deallocation.Unchecked_Deallocation
MD5: ce7f4f912f12d723ca673ca36a478765
```

The multiple calls to Free for the same access object don't cause any issues. Because the access value is null after the first call to Free (I), we're actually just passing **null** as an argument in the second and third calls to Free. However, any attempt to deallocate an access value of null is ignored in the Free procedure, so the second and third calls to Free don't have any effect.

In the Ada Reference Manual

- 4.8 Allocators[196]
- 13.11.2 Unchecked Storage Deallocation[197]

Unchecked Deallocation and Dangling References

We've discussed *dangling references* (page 795) before. In this section, we discuss how unchecked deallocation can create dangling references and the issues of having them in an application.

Let's reuse the last example and introduce I_2, which will point to the same object as I:

Listing 107: show_unchecked_deallocation.adb

```
1  with Integer_Types; use Integer_Types;
2
3  procedure Show_Unchecked_Deallocation is
4
5     I, I_2 : Integer_Access;
6
7  begin
8     I := new Integer;
9
10    I_2 := I;
11
12    --  NOTE: I_2 points to the same
13    --        object as I.
14
15    --
16    --  Use I and I_2...
17    --
18    --  ... then deallocate memory...
19    --
20
21    Free (I);
22
23    --  NOTE: at this point, I_2 is a
24    --        dangling reference!
25
26    --  Further calls to Free (I)
27    --  are OK!
28
29    Free (I);
30    Free (I);
```

(continues on next page)

[196] http://www.ada-auth.org/standards/22rm/html/RM-4-8.html
[197] http://www.ada-auth.org/standards/22rm/html/RM-13-11-2.html

(continued from previous page)

```
31
32       --  A call to Free (I_2) is
33       --  NOT OK:
34
35       Free (I_2);
36    end Show_Unchecked_Deallocation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Unchecked_
 ↪Deallocation.Unchecked_Deallocation
MD5: ee5c20209a113a6c1bc7895b8ebdb174
```

Runtime output

```
free(): double free detected in tcache 2

raised PROGRAM_ERROR : unhandled signal
```

As we've seen before, we can have multiple calls to `Free (I)`. However, the call to `Free (I_2)` is bad because `I_2` is not null. In fact, it is a dangling reference — i.e. `I_2` points to an object that doesn't exist anymore. Also, the first call to `Free (I)` will reclaim the storage that was allocated for the object that `I` originally referred to. The call to `Free (I_2)` will then try to reclaim the previously-reclaimed object, but it'll fail in an undefined manner.

Because of these potential errors, you should be very careful when using unchecked deallocation: it is the programmer's responsibility to avoid creating dangling references!

For the example we've just seen, we could avoid creating a dangling reference by explicitly assigning **null** to `I_2` to indicate that it doesn't point to any specific object:

Listing 108: show_unchecked_deallocation.adb

```
1   with Integer_Types; use Integer_Types;
2
3   procedure Show_Unchecked_Deallocation is
4
5      I, I_2 : Integer_Access;
6
7   begin
8      I := new Integer;
9
10     I_2 := I;
11
12     --  NOTE: I_2 points to the same
13     --        object as I.
14
15     --
16     --  Use I and I_2...
17     --
18     --  ... then deallocate memory...
19     --
20
21     I_2 := null;
22
23     --  NOTE: now, I_2 doesn't point to
24     --        any object, so calling
25     --        Free (I_2) is OK.
26
27     Free (I);
28     Free (I_2);
29  end Show_Unchecked_Deallocation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Unchecked_
 ↪Deallocation.Unchecked_Deallocation
MD5: 3381ba594cbbc0f1547e3f819bae0f97
```

Now, calling `Free (I_2)` doesn't cause any issues because it doesn't point to any object.

Note, however, that this code example is just meant to illustrate the issues of dangling pointers and how we could circumvent them. We're not suggesting to use this approach when designing an implementation. In fact, it's not practical for the programmer to make every possible dangling reference become null if the calls to `Free` are strewn throughout the code.

The suggested design is to not use `Free` in the client code, but instead hide its use within bigger abstractions. In that way, all the occurrences of the calls to `Free` are in one package, and the programmer of that package can then prevent dangling references. We'll discuss these *design strategies* (page 812) later on.

Dereferencing dangling references

Of course, you shouldn't try to dereference a dangling reference because your program becomes erroneous, as we discuss in this section. Let's see an example:

Listing 109: show_unchecked_deallocation.adb

```
1  with Ada.Text_IO;   use Ada.Text_IO;
2  with Integer_Types; use Integer_Types;
3
4  procedure Show_Unchecked_Deallocation is
5
6     I_1, I_2 : Integer_Access;
7
8  begin
9     I_1 := new Integer'(42);
10    I_2 := I_1;
11
12    Put_Line ("I_1.all = "
13              & Integer'Image (I_1.all));
14    Put_Line ("I_2.all = "
15              & Integer'Image (I_2.all));
16
17    Put_Line ("Freeing I_1");
18    Free (I_1);
19
20    if I_1 /= null then
21       Put_Line ("I_1.all = "
22                 & Integer'Image (I_1.all));
23    end if;
24
25    if I_2 /= null then
26       Put_Line ("I_2.all = "
27                 & Integer'Image (I_2.all));
28    end if;
29 end Show_Unchecked_Deallocation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Unchecked_
 ↪Deallocation.Unchecked_Deallocation
MD5: 8536190aa5bbafa715ad8153aaeb4889
```

Runtime output

```
I_1.all =  42
I_2.all =  42
Freeing I_1
I_2.all =  7670
```

In this example, we allocate an object for `I_1` and make `I_2` point to the same object. Then, we call `Free (I)`, which has the following consequences:

- The call to `Free (I_1)` will try to reclaim the storage for the original object (`I_1.all`), so it may be reused for other allocations.
- `I_1 = null` after the call to `Free (I_1)`.
- `I_2` becomes a dangling reference by the call to `Free (I_1)`.
  - In other words, `I_2` is still non-null, and what it points to is now undefined.

In principle, we could check for `null` before trying to dereference the access value. (Remember that when deallocating an object via a call to `Free`, the corresponding access value is set to `null`.) In fact, this strategy works fine for `I_1`, but it doesn't work for `I_2` because the access value is not `null`. As a consequence, the application tries to dereference `I_2`.

Dereferencing a dangling reference is erroneous: the behavior is undefined in this case. For the example we've just seen,

- `I_2.all` might make the application crash;
- `I_2.all` might give us a different value than before;
- `I_2.all` might even give us the same value as before (42) if the original object is still available.

Because the effect is unpredictable, it might be really difficult to debug the application and identify the cause.

Having dangling pointers in an application should be avoided at all costs! Again, it is the programmer's responsibility to be very careful when using unchecked deallocation: avoid creating dangling references!

In the Ada Reference Manual

- 13.9.1 Data Validity[198]
- 13.11.2 Unchecked Storage Deallocation[199]

Restrictions for `Ada.Unchecked_Deallocation`

There are two unsurprising restrictions for `Ada.Unchecked_Deallocation`:

1. It cannot be instantiated for access-to-constant types; and
2. It cannot be used when the `Storage_Size` aspect of a type is zero (i.e. when its storage pool is empty).

(Note that this last restriction also applies to the allocation via `new`.)

Let's see an example of these restrictions:

[198] http://www.ada-auth.org/standards/22rm/html/RM-13-9-1.html
[199] http://www.ada-auth.org/standards/22rm/html/RM-13-11-2.html

Listing 110: show_unchecked_deallocation_errors.adb

```
with Ada.Unchecked_Deallocation;

procedure Show_Unchecked_Deallocation_Errors is

   type Integer_Access_Zero is access Integer
     with Storage_Size => 0;

   procedure Free is
     new Ada.Unchecked_Deallocation
       (Object => Integer,
        Name   => Integer_Access_Zero);

   type Constant_Integer_Access is
     access constant Integer;

   --  ERROR: Cannot use access-to-constant type
   --         for Name
   procedure Free is
     new Ada.Unchecked_Deallocation
       (Object => Integer,
        Name   => Constant_Integer_Access);

   I : Integer_Access_Zero;

begin
   --  ERROR: Cannot allocate objects from
   --         empty storage pool
   I := new Integer;

   --  ERROR: Cannot deallocate objects from
   --         empty storage pool
   Free (I);
end Show_Unchecked_Deallocation_Errors;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Unchecked_
 ↪Deallocation.Unchecked_Deallocation_Error
MD5: 5032d13b2eb6b7ca1979282ddd6df98a
```

Build output

```
show_unchecked_deallocation_errors.adb:21:19: error: actual type must be access-to-
 ↪variable type
show_unchecked_deallocation_errors.adb:21:19: error: instantiation abandoned
show_unchecked_deallocation_errors.adb:28:09: error: allocation from empty storage␣
 ↪pool
show_unchecked_deallocation_errors.adb:32:04: error: deallocation from empty␣
 ↪storage pool
gprbuild: *** compilation phase failed
```

Here, we see that trying to instantiate Ada.Unchecked_Deallocation for the Constant_Integer_Access type is rejected by the compiler. Similarly, we cannot allocate or deallocate an object for the Integer_Access_Zero type because its storage pool is empty.

28.1.13 Null & Not Null Access

Note: This section was originally written by Robert A. Duff and published as Gem #23: Null Considered Harmful[200] and Gem #24[201].

Ada, like many languages, defines a special **null** value for access types. All values of an access type designate some object of the designated type, except for **null**, which does not designate any object. The null value can be used as a special flag. For example, a singly-linked list can be null-terminated. A Lookup function can return **null** to mean "not found", presuming the result is of an access type:

Listing 111: show_null_return.ads

```
package Show_Null_Return is

   type Ref_Element is access all Element;

   Not_Found : constant Ref_Element := null;

   function Lookup (T : Table) return Ref_Element;
   --  Returns Not_Found if not found.
end Show_Null_Return;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Null_And_Not_Null_
 ↪Access.Null_Return
MD5: 6c4eed750d42685198ec9495805e3e23
```

An alternative design for Lookup would be to raise an exception:

Listing 112: show_not_found_exception.ads

```
package Show_Not_Found_Exception is
   Not_Found : exception;

   function Lookup (T : Table) return Ref_Element;
   --  Raises Not_Found if not found.
   --  Never returns null.
end Show_Not_Found_Exception;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Null_And_Not_Null_
 ↪Access.Not_Found_Exception
MD5: 6ef47b32d4923838ffc28f43e5db323c
```

Neither design is better in all situations; it depends in part on whether we consider the "not found" situation to be exceptional.

Clearly, the client calling Lookup needs to know whether it can return **null**, and if so, what that means. In general, it's a good idea to document whether things can be null or not, especially for formal parameters and function results. Prior to Ada 2005, we would do that with comments. Since Ada 2005, we can use the **not null** syntax:

[200] https://www.adacore.com/gems/ada-gem-23
[201] https://www.adacore.com/gems/ada-gem-24

Listing 113: show_not_null_return.ads

```
package Show_Not_Null_Return is
   type Ref_Element is access all Element;

   Not_Found : constant Ref_Element := null;

   function Lookup (T : Table)
                    return not null Ref_Element;
   --  Possible since Ada 2005.
end Show_Not_Null_Return;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Null_And_Not_Null_
 ↪Access.Not_Null_Return
MD5: 4c0bb95da3b5a7c555a763c4951f7e21
```

This is a complete package for the code snippets above:

Listing 114: example.ads

```
package Example is

   type Element is limited private;
   type Ref_Element is access all Element;

   type Table is limited private;

   Not_Found : constant Ref_Element := null;
   function Lookup (T : Table)
                    return Ref_Element;
   --  Returns Not_Found if not found.

   Not_Found_2 : exception;
   function Lookup_2 (T : Table)
                      return not null Ref_Element;
   --  Raises Not_Found_2 if not found.

   procedure P (X : not null Ref_Element);

   procedure Q (X : not null Ref_Element);

private
   type Element is limited
      record
         Component : Integer;
      end record;
   type Table is limited null record;
end Example;
```

Listing 115: example.adb

```
package body Example is

   An_Element : aliased Element;

   function Lookup (T : Table)
                    return Ref_Element is
      pragma Unreferenced (T);
   begin
```

(continues on next page)

(continued from previous page)

```
9        --  ...
10       return Not_Found;
11    end Lookup;

```

In general, it's better to use the language proper for documentation, when possible, rather than comments, because compile-time and/or run-time checks can help ensure that the "documentation" is actually true. With comments, there's a greater danger that the comment will become false during maintenance, and false documentation is obviously a menace.

In many, perhaps most cases, **null** is just a tripping hazard. It's a good idea to put in **not null** when possible. In fact, a good argument can be made that **not null** should be the default, with extra syntax required when **null** is wanted. This is the way Standard ML[202] works, for example — you don't get any special null-like value unless you ask for it. Of course, because Ada 2005 needs to be compatible with previous versions of the language, **not null** cannot be the default for Ada.

One word of caution: access objects are default-initialized to **null**, so if you have a **not null** object (or component) you had better initialize it explicitly, or you will get `Constraint_Error`. **not null** is more often useful on parameters and function results, for this reason.

[202] https://en.wikipedia.org/wiki/Standard_ML

Another advantage of `not null` over comments is for efficiency. Consider procedures P and Q in this example:

Listing 116: example-processing.ads

```
package Example.Processing is

   procedure P (X : not null Ref_Element);

   procedure Q (X : not null Ref_Element);

end Example.Processing;
```

Listing 117: example-processing.adb

```
package body Example.Processing is

   procedure P (X : not null Ref_Element) is
   begin
      X.all.Component := X.all.Component + 1;
   end P;

   procedure Q (X : not null Ref_Element) is
   begin
      for I in 1 .. 1000 loop
         P (X);
      end loop;
   end Q;

end Example.Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Null_And_Not_Null_
 ↪Access.Complete_Null_Return
MD5: dc34b1a27737d57c041be6260dd577fd
```

Without `not null`, the generated code for P will do a check that X `/= null`, which may be costly on some systems. P is called in a loop, so this check will likely occur many times. With `not null`, the check is pushed to the call site. Pushing checks to the call site is usually beneficial because

1. the check might be hoisted out of a loop by the optimizer, or
2. the check might be eliminated altogether, as in the example above, where the compiler knows that `An_Element'Access` cannot be `null`.

This is analogous to the situation with other run-time checks, such as array bounds checks:

Listing 118: show_process_array.ads

```
package Show_Process_Array is

   type My_Index is range 1 .. 10;
   type My_Array is array (My_Index) of Integer;

   procedure Process_Array
     (X     : in out My_Array;
      Index :        My_Index);

end Show_Process_Array;
```

Listing 119: show_process_array.adb

```
package body Show_Process_Array is

   procedure Process_Array
     (X     : in out My_Array;
      Index :        My_Index) is
   begin
      X (Index) := X (Index) + 1;
   end Process_Array;

end Show_Process_Array;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Null_And_Not_Null_
 ↪Access.Process_Array
MD5: 32424432f5b2e3013292680f92a04320
```

If `X (Index)` occurs inside `Process_Array`, there is no need to check that `Index` is in range, because the check is pushed to the caller.

28.1.14 Design strategies for access types

Previously, we learned about *dangling references* (page 795) and discussed the effects of *dereferencing them* (page 805). Also, we've seen the relationship between *unchecked deallocation and dangling references* (page 803). Ensuring that all calls to `Free` for a specific access type will never cause dangling references can become an arduous task — if not impossible — if those calls are located in different parts of the source code.

Although we used access types directly in the main application in many of the previous code examples from this chapter, this approach was in fact selected just for illustration purposes — i.e. to make the code look simpler. In general, however, we should avoid this approach. Instead, our recommendation is to encapsulate the access types in some form of abstraction. In this section, we discuss design strategies for access types that take this recommendation into account.

Abstract data type for access types

The simplest form of abstraction is of course an abstract data type. For example, we could declare a limited private type, which allows us to hide the access type and to avoid copies of references that could potentially become dangling references. (We discuss limited private types later *in another chapter* (page 928).)

Let's see an example:

Listing 120: access_type_abstraction.ads

```
package Access_Type_Abstraction is

   type Info is limited private;

   function To_Info (S : String) return Info;

   function To_String (Obj : Info)
                       return String;

   function Copy (Obj : Info) return Info;
```

(continues on next page)

(continued from previous page)

```
11
12    procedure Copy (To   : in out Info;
13                    From :        Info);
14
15    procedure Append (Obj : in out Info;
16                      S   : String);
17
18    procedure Reset (Obj : in out Info);
19
20    procedure Destroy (Obj : in out Info);
21
22 private
23
24    type Info is access String;
25
26 end Access_Type_Abstraction;
```

Listing 121: access_type_abstraction.adb

```
1  with Ada.Unchecked_Deallocation;
2
3  package body Access_Type_Abstraction is
4
5     function To_Info (S : String) return Info is
6       (new String'(S));
7
8     function To_String (Obj : Info)
9                         return String is
10      (if Obj /= null then Obj.all else "");
11
12    function Copy (Obj : Info) return Info is
13      (To_Info (Obj.all));
14
15    procedure Copy (To   : in out Info;
16                    From :        Info) is
17    begin
18       Destroy (To);
19       To := To_Info (From.all);
20    end Copy;
21
22    procedure Append (Obj : in out Info;
23                      S   : String) is
24       New_Info : constant Info :=
25                     To_Info (To_String (Obj) & S);
26    begin
27       Destroy (Obj);
28       Obj := New_Info;
29    end Append;
30
31    procedure Reset (Obj : in out Info) is

Obj_1 : hello world
Obj_2 : hello world
----------
DESTROY
Obj_1 :
Obj_2 :
----------
APPEND
Obj_1 : hey
----------
APPEND
Obj_1 : hey there
```

In this example, we hide an access type in the `Info` type — a limited private type. We allocate an object of this type in the `To_Info` function and deallocate it in the `Destroy` procedure. Also, we make sure that the reference isn't copied in the `Copy` function — we only copy the designated value in this function. This strategy eliminates the possibility of dangling references, as each reference is encapsulated in an object of `Info` type.

Controlled type for access types

In the previous code example, the `Destroy` procedure had to be called to deallocate the hidden access object. We could make sure that this deallocation happens automatically by using a controlled (or limited controlled) type. (We discuss *controlled types* (page 1815) in another chapter.)

Let's adapt the previous example and declare `Info` as a limited controlled type:

Listing 123: access_type_abstraction.ads

```

Of course, because we're using the `Limited_Controlled` type from the `Ada.Finalization` package, we had to adapt the prototype of the subprograms from the `Access_Type_Abstraction`. In this version of the code, we only have the allocation taking place in the `To_Info` procedure, but we don't have a `Destroy` procedure for deallocation: this call was moved to the `Finalize` procedure.

Since objects of the `Info` type — such as `Obj_1` in the `Show_Access_Type_Abstraction` procedure — are now controlled, the `Finalize` procedure is automatically called when they go out of scope. In this procedure, which we override for the `Info` type, we perform the deallocation of the internal access object `Str_A`. (You may uncomment the calls to `Put_Line` in the body of the `Initialize` and `Finalize` subprograms to confirm that these subprograms are called in the background.)

28.1.15 Access to subprograms

So far in this chapter, we focused mainly on access-to-objects. However, we can use access types to subprograms. This is the topic of this section.

Static vs. dynamic calls

In a typical subprogram call, we indicate the subprogram we want to call statically. For example, let's say we've implemented a procedure `Proc` that calls a procedure `P`:

Listing 126: p.ads

```
1 procedure P (I : in out Integer);
```

Listing 127: p.adb

```
1 procedure P (I : in out Integer) is
2 begin
3    null;
4 end P;
```

Listing 128: proc.adb

```
1 with P;
2
3 procedure Proc is
4    I : Integer := 0;
5 begin
6    P (I);
7 end Proc;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Subprogram_Call
MD5: 0e9547e53d0d02d39920f4d1d6787af6
```

The call to P is statically dispatched: every time Proc runs and calls P, that call is always to the same procedure. In other words, we can determine at compilation time which procedure is called.

In contrast, an access to a subprogram allows us to dynamically indicate which subprogram we want to call. For example, if we change Proc in the code above to receive the access to a subprogram P as a parameter, the actual procedure that would be called when running Proc would be determined at run time, and it might be different for every call to Proc. In this case, we wouldn't be able to determine at compilation time which procedure would be called in every case. (In some cases, however, it could still be possible to determine which procedure is called by analyzing the argument that is passed to Proc.)

Access to subprogram declaration

We declare an access to a subprogram as a type by writing **access procedure** or **access function** and the corresponding prototype:

Listing 129: access_to_subprogram_types.ads

```
package Access_To_Subprogram_Types is

   type Access_To_Procedure is
     access procedure (I : in out Integer);

   type Access_To_Function is
     access function (I : Integer) return Integer;

end Access_To_Subprogram_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Access_To_Subprogram_Types
MD5: 5f834c1b2044ba5ea7d4835c3ebdedb1
```

In the designated profile of the access type declarations, we list all the parameters that we expect in the subprogram.

We can use those types to declare access to subprograms — as subprogram parameters, for example:

Listing 130: access_to_subprogram_params.ads

```
with Access_To_Subprogram_Types;
use  Access_To_Subprogram_Types;

package Access_To_Subprogram_Params is

   procedure Proc (P : Access_To_Procedure);

end Access_To_Subprogram_Params;
```

Listing 131: access_to_subprogram_params.adb

```
package body Access_To_Subprogram_Params is

   procedure Proc (P : Access_To_Procedure) is
      I : Integer := 0;
   begin
      P (I);
      --  P.all (I);
   end Proc;

end Access_To_Subprogram_Params;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Access_To_Subprogram_Types
MD5: 17c1a07f48d9fb0efef37aa4c5ec8a51
```

In the implementation of the Proc procedure of the code example, we call the P procedure by simply passing I as a parameter. In this case, P is automatically dereferenced. We may, however, explicitly dereference P by writing P.**all** (I).

Before we use this package, let's implement a simple procedure that we'll use later on:

Listing 132: add_ten.ads

```
procedure Add_Ten (I : in out Integer);
```

Listing 133: add_ten.adb

```
procedure Add_Ten (I : in out Integer) is
begin
   I := I + 10;
end Add_Ten;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Access_To_Subprogram_Types
MD5: 8553ad7329bf1ed727147b47b7355a70
```

Now, we can get access to a subprogram by using the **Access** attribute and pass it as an actual parameter:

Listing 134: show_access_to_subprograms.adb

```
with Access_To_Subprogram_Params;
use  Access_To_Subprogram_Params;

with Add_Ten;

procedure Show_Access_To_Subprograms is
begin
   Proc (Add_Ten'Access);
   --             ^ Getting access to Add_Ten
   --               procedure and passing it
   --               to Proc
end Show_Access_To_Subprograms;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
↪Subprograms.Access_To_Subprogram_Types
MD5: 599e9d1306da48e3c532692b34c02a1d
```

Here, we get access to the Add_Ten procedure and pass it to the Proc procedure.

In the Ada Reference Manual

- 3.10 Access Types[203]

Objects of access-to-subprogram type

In the previous example, the Proc procedure had a parameter of access-to-subprogram type. In addition to parameters, we can of course declare *objects* of access-to-subprogram types as well. For example, we can extend our previous test application and declare an object P of access-to-subprogram type. Before we do so, however, let's implement another small procedure that we'll use later on:

Listing 135: add_twenty.ads

```
procedure Add_Twenty (I : in out Integer);
```

Listing 136: add_twenty.adb

```
procedure Add_Twenty (I : in out Integer) is
begin
   I := I + 20;
end Add_Twenty;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
↪Subprograms.Access_To_Subprogram_Types
MD5: 697959b806f6f2bfba248ec15c47883b
```

In addition to Add_Ten, we've implemented the Add_Twenty procedure, which we use in our extended test application:

Listing 137: show_access_to_subprograms.adb

```
with Access_To_Subprogram_Types;
use  Access_To_Subprogram_Types;

with Access_To_Subprogram_Params;
use  Access_To_Subprogram_Params;

with Add_Ten;
with Add_Twenty;

procedure Show_Access_To_Subprograms is
   P        : Access_To_Procedure;
   Some_Int : Integer := 0;
begin
   P := Add_Ten'Access;
   --           ^ Getting access to Add_Ten
   --             procedure and assigning it
```

(continues on next page)

[203] http://www.ada-auth.org/standards/22rm/html/RM-3-10.html

(continued from previous page)

```
   --             to P

   Proc (P);
   --    ^ Passing access-to-subprogram as an
   --      actual parameter

   P (Some_Int);
   --  ^ Using access-to-subprogram object in a
   --    subprogram call

   P := Add_Twenty'Access;
   --               ^ Getting access to Add_Twenty
   --                 procedure and assigning it
   --                 to P

   Proc (P);
   P (Some_Int);
end Show_Access_To_Subprograms;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Access_To_Subprogram_Types
MD5: 7b4ea19187806e88ba65847876cafb4f
```

In the Show_Access_To_Subprograms procedure, we see the declaration of our access-to-subprogram object P (of Access_To_Procedure type). We get access to the Add_Ten procedure and assign it to P, and we then do the same for the Add_Twenty procedure.

We can use an access-to-subprogram object either as the actual parameter of a subprogram call, or in a subprogram call. In the code example, we're passing P as the actual parameter of the Proc procedure in the Proc (P) calls. Also, we're calling the subprogram assigned to (designated by the current value of) P in the P (Some_Int) calls.

Components of access-to-subprogram type

In addition to declaring subprogram parameters and objects of access-to-subprogram types, we can declare components of these types. For example:

Listing 138: access_to_subprogram_types.ads

```
package Access_To_Subprogram_Types is

   type Access_To_Procedure is
     access procedure (I : in out Integer);

   type Access_To_Function is
     access function (I : Integer) return Integer;

   type Access_To_Procedure_Array is
     array (Positive range <>) of
       Access_To_Procedure;

   type Access_To_Function_Array is
     array (Positive range <>) of
       Access_To_Function;

   type Rec_Access_To_Procedure is record
      AP : Access_To_Procedure;
```

(continues on next page)

(continued from previous page)

```
   end record;

   type Rec_Access_To_Function is record
      AF : Access_To_Function;
   end record;

end Access_To_Subprogram_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Access_To_Subprogram_Types
MD5: 32203838b97af66ef6ca3f6b1ce646a5
```

Here, the access-to-procedure type `Access_To_Procedure` is used as a component of the array type `Access_To_Procedure_Array` and the record type `Rec_Access_To_Procedure`. Similarly, the access-to-function type `Access_To_Function` type is used as a component of the array type `Access_To_Function_Array` and the record type `Rec_Access_To_Function`.

Let's see two test applications using these types. First, let's use the `Access_To_Procedure_Array` array type in a test application:

Listing 139: show_access_to_subprograms.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Access_To_Subprogram_Types;
use  Access_To_Subprogram_Types;

with Add_Ten;
with Add_Twenty;

procedure Show_Access_To_Subprograms is
   PA : constant
          Access_To_Procedure_Array (1 .. 2) :=
            (Add_Ten'Access,
             Add_Twenty'Access);

   Some_Int : Integer := 0;
begin
   Put_Line ("Some_Int: " & Some_Int'Image);

   for I in PA'Range loop
      PA (I) (Some_Int);
      Put_Line ("Some_Int: " & Some_Int'Image);
   end loop;
end Show_Access_To_Subprograms;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Access_To_Subprogram_Types
MD5: f1d10056b4b3424bd30d954f34caa255
```

Runtime output

```
Some_Int:  0
Some_Int:  10
Some_Int:  30
```

Here, we declare the PA array and use the access to the `Add_Ten` and `Add_Twenty` procedures as its components. We can call any of these procedures by simply specifying the

index of the component, e.g. `PA (2)`. Once we specify the procedure we want to use, we simply pass the parameters, e.g.: `PA (2) (Some_Int)`.

Now, let's use the `Rec_Access_To_Procedure` record type in a test application:

Listing 140: show_access_to_subprograms.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Access_To_Subprogram_Types;
use  Access_To_Subprogram_Types;

with Add_Ten;
with Add_Twenty;

procedure Show_Access_To_Subprograms is
   RA       : Rec_Access_To_Procedure;
   Some_Int : Integer := 0;
begin
   Put_Line ("Some_Int: " & Some_Int'Image);

   RA := (AP => Add_Ten'Access);
   RA.AP (Some_Int);
   Put_Line ("Some_Int: " & Some_Int'Image);

   RA := (AP => Add_Twenty'Access);
   RA.AP (Some_Int);
   Put_Line ("Some_Int: " & Some_Int'Image);
end Show_Access_To_Subprograms;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Access_To_Subprogram_Types
MD5: 4b23b5f6a8c252a1a014a2b54fa32c1a
```

Runtime output

```
Some_Int:  0
Some_Int:  10
Some_Int:  30
```

Here, we declare two record aggregates where we specify the AP component, e.g.: `(AP => Add_Ten'Access)`, which indicates the access-to-subprogram we want to use. We can call the subprogram by simply accessing the AP component, i.e.: `RA.AP`.

Access-to-subprogram as discriminant types

As you might expect, we can use access-to-subprogram types when declaring discriminants. In fact, when we were talking about *discriminants as access values* (page 745) earlier on, we used access-to-object types in our code examples, but we could have used access-to-subprogram types as well. For example:

Listing 141: custom_processing.ads

```
package Custom_Processing is

   --  Declaring an access type:
   type Integer_Processing is
     access procedure (I : in out Integer);

```

(continues on next page)

(continued from previous page)

```
   --  Declaring a discriminant with this
   --  access type:
   type Rec (IP : Integer_Processing) is
     private;

   procedure Init (R     : in out Rec;
                   Value :        Integer);

   procedure Process (R : in out Rec);

   procedure Show (R : Rec);

private

   type Rec (IP : Integer_Processing) is
   record
      I : Integer := 0;
   end record;

end Custom_Processing;
```

Listing 142: custom_processing.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Custom_Processing is

   procedure Init (R     : in out Rec;
                   Value :        Integer) is
   begin
      R.I := Value;
   end Init;

   procedure Process (R : in out Rec) is
   begin
      R.IP (R.I);
      --  ^^^^^^
      --  Calling procedure that we specified as
      --  the record's discriminant
   end Process;

   procedure Show (R : Rec) is
   begin
      Put_Line ("R.I = "
                & Integer'Image (R.I));
   end Show;

end Custom_Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
↪Subprograms.Access_To_Subprogram_Types
MD5: 02fc0c51722c321c4ec6115de68d1c06
```

In this example, we declare the access-to-subprogram type `Integer_Processing`, which we use as the `IP` discriminant of the `Rec` type. In the `Process` procedure, we call the `IP` procedure that we specified as the record's discriminant (`R.IP (R.I)`).

Before we look at a test application for this package, let's implement another small procedure:

Listing 143: mult_two.ads

```
procedure Mult_Two (I : in out Integer);
```

Listing 144: mult_two.adb

```
procedure Mult_Two (I : in out Integer) is
begin
   I := I * 2;
end Mult_Two;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Access_To_Subprogram_Types
MD5: cd43fa39dac9a1c9182f69d32eab1d26
```

Now, let's look at the test application:

Listing 145: show_access_to_subprogram_discriminants.adb

```
with Ada.Text_IO;       use Ada.Text_IO;

with Custom_Processing; use Custom_Processing;

with Add_Ten;
with Mult_Two;

procedure Show_Access_To_Subprogram_Discriminants
is

   R_Add_Ten  : Rec (IP => Add_Ten'Access);
   --                ^^^^^^^^^^^^^^^^^^^^
   --       Using access-to-subprogram as a
   --       discriminant

   R_Mult_Two : Rec (IP => Mult_Two'Access);
   --                ^^^^^^^^^^^^^^^^^^^^
   --       Using access-to-subprogram as a
   --       discriminant

begin
   Init (R_Add_Ten,  1);
   Init (R_Mult_Two, 2);

   Put_Line ("---- R_Add_Ten ----");
   Show (R_Add_Ten);

   Put_Line ("Calling Process procedure...");
   Process (R_Add_Ten);
   Show (R_Add_Ten);

   Put_Line ("---- R_Mult_Two ----");
   Show (R_Mult_Two);

   Put_Line ("Calling Process procedure...");
   Process (R_Mult_Two);
   Show (R_Mult_Two);
end Show_Access_To_Subprogram_Discriminants;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Access_To_Subprogram_Types
MD5: 544c224f8bc8e6ba2db4914c2a3dcff4
```

Runtime output

```
---- R_Add_Ten ----
R.I =  1
Calling Process procedure...
R.I =  11
---- R_Mult_Two ----
R.I =  2
Calling Process procedure...
R.I =  4
```

In this procedure, we declare the `R_Add_Ten` and `R_Mult_Two` of `Rec` type and specify the access to `Add_Ten` and `Mult_Two`, respectively, as the `IP` discriminant. The procedure we specified here is then called inside a call to the `Process` procedure.

Access-to-subprograms as formal parameters

We can use access-to-subprograms types when declaring formal parameters. For example, let's revisit the `Custom_Processing` package from the previous section and convert it into a generic package.

Listing 146: gen_custom_processing.ads

```
generic
   type T is private;

   --
   --  Declaring formal access-to-subprogram
   --  type:
   --
   type T_Processing is
     access procedure (Element : in out T);

   --
   --  Declaring formal access-to-subprogram
   --  parameter:
   --
   Proc : T_Processing;

   with function Image_T (Element : T)
                          return String;
package Gen_Custom_Processing is

   type Rec is private;

   procedure Init (R     : in out Rec;
                   Value :        T);

   procedure Process (R : in out Rec);

   procedure Show (R : Rec);

private

   type Rec is record
      Comp : T;
```

(continues on next page)

(continued from previous page)

```
   end record;

end Gen_Custom_Processing;
```

Listing 147: gen_custom_processing.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Gen_Custom_Processing is

   procedure Init (R     : in out Rec;
                   Value :        T) is
   begin
      R.Comp := Value;
   end Init;

   procedure Process (R : in out Rec) is
   begin
      Proc (R.Comp);
   end Process;

   procedure Show (R : Rec) is
   begin
      Put_Line ("R.Comp = "
                & Image_T (R.Comp));
   end Show;

end Gen_Custom_Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Access_To_Subprogram_Types
MD5: 6f06e066bafa5f02abb3ee1b33ea0831
```

In this version of the procedure, instead of declaring `Proc` as a discriminant of the `Rec` record, we're declaring it as a formal parameter of the `Gen_Custom_Processing` package. Also, we're declaring an access-to-subprogram type (`T_Processing`) as a formal parameter. (Note that, in contrast to these two parameters that we've just mentioned, `Image_T` is not a formal access-to-subprogram parameter: it's actually just a formal subprogram.)

We then instantiate the `Gen_Custom_Processing` package in our test application:

Listing 148: show_access_to_subprogram_as_formal_parameter.adb

```
with Gen_Custom_Processing;

with Add_Ten;

with Ada.Text_IO; use Ada.Text_IO;

procedure
  Show_Access_To_Subprogram_As_Formal_Parameter
is
   type Integer_Processing is
     access procedure (I : in out Integer);

   package Custom_Processing is new
     Gen_Custom_Processing
       (T            => Integer,
        T_Processing => Integer_Processing,
```

(continues on next page)

(continued from previous page)

```
17          --                  ^^^^^^^^^^^^^^^^^^
18          --                  access-to-subprogram type
19          Proc         => Add_Ten'Access,
20          --                  ^^^^^^^^^^^^^^^^^^^
21          --                  access-to-subprogram
22          Image_T      => Integer'Image);
23       use Custom_Processing;
24
25       R_Add_Ten  : Rec;
26
27    begin
28       Init (R_Add_Ten,  1);
29
30       Put_Line ("---- R_Add_Ten ----");
31       Show (R_Add_Ten);
32
33       Put_Line ("Calling Process procedure...");
34       Process (R_Add_Ten);
35       Show (R_Add_Ten);
36    end Show_Access_To_Subprogram_As_Formal_Parameter;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Access_To_Subprogram_Types
MD5: 6ae27ebd59e5307551e9a38f3b94c70c
```

Runtime output

```
---- R_Add_Ten ----
R.Comp =  1
Calling Process procedure...
R.Comp =  11
```

Here, we instantiate the `Gen_Custom_Processing` package as `Custom_Processing` and specify the access-to-subprogram type and the access-to-subprogram.

Selecting subprograms

A practical application of access to subprograms is that it enables us to dynamically select a subprogram and pass it to another subprogram, where it can then be called.

For example, we may have a `Process` procedure that receives a logging procedure as a parameter (`Log_Proc`). Also, this parameter may be **`null`** by default — so that no procedure is called if the parameter isn't specified:

Listing 149: data_processing.ads

```
1  package Data_Processing is
2
3     type Data_Container is
4       array (Positive range <>) of Float;
5
6     type Log_Procedure is
7       access procedure (D : Data_Container);
8
9     procedure Process
10      (D        : in out Data_Container;
11       Log_Proc :        Log_Procedure := null);
```

(continues on next page)

(continued from previous page)

```
12
13 end Data_Processing;
```

Listing 150: data_processing.adb

```
1  package body Data_Processing is
2
3     procedure Process
4       (D        : in out Data_Container;
5        Log_Proc :        Log_Procedure := null) is
6     begin
7        --  missing processing part...
8
9        if Log_Proc /= null then
10          Log_Proc (D);
11       end if;
12    end Process;
13
14 end Data_Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Log_Procedure
MD5: 59399e0809deb476f608faab7e4398bd
```

In the implementation of Process, we check whether Log_Proc is null or not. (If it's not null, we call the procedure. Otherwise, we just skip the call.)

Now, let's implement two logging procedures that match the expected form of the Log_Procedure type:

Listing 151: log_element_per_line.adb

```
1  with Ada.Text_IO;      use Ada.Text_IO;
2  with Data_Processing; use Data_Processing;
3
4  procedure Log_Element_Per_Line
5    (D : Data_Container) is
6  begin
7     Put_Line ("Elements: ");
8     for V of D loop
9        Put_Line (V'Image);
10    end loop;
11    Put_Line ("------");
12 end Log_Element_Per_Line;
```

Listing 152: log_csv.adb

```
1  with Ada.Text_IO;      use Ada.Text_IO;
2  with Data_Processing; use Data_Processing;
3
4  procedure Log_Csv (D : Data_Container) is
5  begin
6     for I in D'First .. D'Last - 1 loop
7        Put (D (I)'Image & ", ");
8     end loop;
9     Put (D (D'Last)'Image);
10    New_Line;
11 end Log_Csv;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Log_Procedure
MD5: 468789f7331ffcd16f754f7116b076d7
```

Finally, we implement a test application that selects each of the logging procedures that we've just implemented:

Listing 153: show_access_to_subprograms.adb

```
with Ada.Text_IO;     use Ada.Text_IO;
with Data_Processing; use Data_Processing;

with Log_Element_Per_Line;
with Log_Csv;

procedure Show_Access_To_Subprograms is
   D : Data_Container (1 .. 5) := (others => 1.0);
begin
   Put_Line ("==== Log_Element_Per_Line ====");
   Process (D, Log_Element_Per_Line'Access);

   Put_Line ("==== Log_Csv ====");
   Process (D, Log_Csv'Access);

   Put_Line ("==== None ====");
   Process (D);
end Show_Access_To_Subprograms;
```

Code block metadata

Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Log_Procedure
MD5: 134aa682cea1999efa0ea97052f315c8
```

Runtime output

```
==== Log_Element_Per_Line ====
Elements:
 1.00000E+00
 1.00000E+00
 1.00000E+00
 1.00000E+00
 1.00000E+00
------
==== Log_Csv ====
 1.00000E+00,  1.00000E+00,  1.00000E+00,  1.00000E+00,  1.00000E+00
==== None ====
```

Here, we use the **Access** attribute to get access to the Log_Element_Per_Line and Log_Csv procedures. Also, in the third call, we don't pass any access as an argument, which is then **null** by default.

Null exclusion

We can use null exclusion when declaring an access to subprograms. By doing so, we ensure that a subprogram must be specified — either as a parameter or when initializing an access object. Otherwise, an exception is raised. Let's adapt the previous example and introduce the `Init_Function` type:

Listing 154: data_processing.ads

```
package Data_Processing is

   type Data_Container is
     array (Positive range <>) of Float;

   type Init_Function is
     not null access function return Float;

   procedure Process
     (D         : in out Data_Container;
      Init_Func :        Init_Function);

end Data_Processing;
```

Listing 155: data_processing.adb

```
package body Data_Processing is

   procedure Process
     (D         : in out Data_Container;
      Init_Func :        Init_Function) is
   begin
      for I in D'Range loop
         D (I) := Init_Func.all;
      end loop;
   end Process;

end Data_Processing;
```

In this case, we specify that `Init_Function` is **`not null access`** because we want to always be able to call this function in the `Process` procedure (i.e. without raising an exception).

When an access to a subprogram doesn't have parameters — which is the case for the subprograms of `Init_Function` type — we need to explicitly dereference it by writing **`.all`**. (In this case, **`.all`** isn't optional.) Therefore, we have to write `Init_Func.`**`all`** in the implementation of the `Process` procedure of the code example.

Now, let's declare two simple functions — `Init_Zero` and `Init_One` — that return 0.0 and 1.0, respectively:

Listing 156: init_zero.ads

```
function Init_Zero return Float;
```

Listing 157: init_one.ads

```
function Init_One return Float;
```

Listing 158: init_zero.adb

```
function Init_Zero return Float is
begin
```

(continues on next page)

(continued from previous page)

```
   return 0.0;
end Init_Zero;
```

Listing 159: init_one.adb

```
function Init_One return Float is
begin
   return 1.0;
end Init_One;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Access_Init_Function
MD5: 444110d50ddb430fd5be31cf1b417fc8
```

Finally, let's see a test application where we select each of the init functions we've just implemented:

Listing 160: log_element_per_line.adb

```
with Ada.Text_IO;      use Ada.Text_IO;
with Data_Processing; use Data_Processing;

procedure Log_Element_Per_Line
  (D : Data_Container) is
begin
   Put_Line ("Elements: ");
   for V of D loop
      Put_Line (V'Image);
   end loop;
   Put_Line ("------");
end Log_Element_Per_Line;
```

Listing 161: show_access_to_subprograms.adb

```
with Ada.Text_IO;      use Ada.Text_IO;
with Data_Processing; use Data_Processing;

with Init_Zero;
with Init_One;

with Log_Element_Per_Line;

procedure Show_Access_To_Subprograms is
   D : Data_Container (1 .. 5) := (others => 1.0);
begin
   Put_Line ("==== Init_Zero ====");
   Process (D, Init_Zero'Access);
   Log_Element_Per_Line (D);

   Put_Line ("==== Init_One ====");
   Process (D, Init_One'Access);
   Log_Element_Per_Line (D);

   --  Put_Line ("==== None ====");
   --  Process (D, null);
   --  Log_Element_Per_Line (D);
end Show_Access_To_Subprograms;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Access_Init_Function
MD5: ae0e3fd58e9bb83061248967c709190a
```

Runtime output

```
==== Init_Zero ====
Elements:
 0.00000E+00
 0.00000E+00
 0.00000E+00
 0.00000E+00
 0.00000E+00
------
==== Init_One ====
Elements:
 1.00000E+00
 1.00000E+00
 1.00000E+00
 1.00000E+00
 1.00000E+00
------
```

Here, we use the **Access** attribute to get access to the `Init_Zero` and `Init_One` functions. Also, if we uncomment the call to `Process` with **null** as an argument for the init function, we see that the `Constraint_Error` exception is raised at run time — as the argument cannot be **null** due to the null exclusion.

For further reading...

Note: This example was originally written by Robert A. Duff and was part of the Gem #24[204].

Here's another example, first with **null**:

Listing 162: show_null_procedure.ads

```
1  package Show_Null_Procedure is
2     type Element is limited null record;
3     --  Not implemented yet
4
5     type Ref_Element is access all Element;
6
7     type Table is limited null record;
8     --  Not implemented yet
9
10    type Iterate_Action is
11      access procedure
12        (X : not null Ref_Element);
13
14    procedure Iterate
15      (T      : Table;
16       Action : Iterate_Action := null);
17    --  If Action is null, do nothing.
18
19 end Show_Null_Procedure;
```

Code block metadata

[204] https://www.adacore.com/gems/ada-gem-24

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Null_Procedure
MD5: ac21dd76ed9fb7f26839c24210cf4425
```

and without **null**:

Listing 163: show_null_procedure.ads

```
package Show_Null_Procedure is
   type Element is limited null record;
   --  Not implemented yet

   type Ref_Element is access all Element;

   type Table is limited null record;
   --  Not implemented yet

   procedure Do_Nothing
     (X : not null Ref_Element) is null;

   type Iterate_Action is
     access procedure
       (X : not null Ref_Element);

   procedure Iterate
     (T      : Table;
      Action : not null Iterate_Action
                  := Do_Nothing'Access);

end Show_Null_Procedure;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Null_Procedure
MD5: 7341d8f23cd4efe45698481be452a9e8
```

The style of the second `Iterate` is clearly better because it makes use of the syntax to indicate that a procedure is expected. This is a complete package that includes both versions of the `Iterate` procedure:

Listing 164: example.ads

```
package Example is

   type Element is limited private;
   type Ref_Element is access all Element;

   type Table is limited private;

   type Iterate_Action is
     access procedure
       (X : not null Ref_Element);

   procedure Iterate
     (T : Table;
      Action : Iterate_Action := null);
   --  If Action is null, do nothing.

   procedure Do_Nothing
     (X : not null Ref_Element) is null;
   procedure Iterate_2
```

(continues on next page)

(continued from previous page)

```
     (T : Table;
      Action : not null Iterate_Action
                  := Do_Nothing'Access);

private
   type Element is limited
      record
         Component : Integer;
      end record;
   type Table is limited null record;
end Example;
```

Listing 165: example.adb

```
package body Example is

   An_Element : aliased Element;

   procedure Iterate
     (T : Table;
      Action : Iterate_Action := null)
   is
   begin
      if Action /= null then
         Action (An_Element'Access);
         --  In a real program, this would do
         --  something more sensible.
      end if;
   end Iterate;

   procedure Iterate_2
     (T : Table;
      Action : not null Iterate_Action
                  := Do_Nothing'Access)
   is
   begin
      Action (An_Element'Access);
      --  In a real program, this would do
      --  something more sensible.
   end Iterate_2;

end Example;
```

Listing 166: show_example.adb

```
with Example; use Example;

procedure Show_Example is
   T : Table;
begin
   Iterate_2 (T);
end Show_Example;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Complete_Not_Null_Procedure
MD5: ab0a41e0d39a8a16b0b69f8c6b2a43fd
```

Writing **not null** Iterate_Action might look a bit more complicated, but it's worthwhile, and anyway, as mentioned earlier, the compatibility requirement requires that the **not null**

be explicit, rather than the other way around.

Access to protected subprograms

Up to this point, we've discussed access to *normal* Ada subprograms. In some situations, however, we might want to have access to protected subprograms. To do this, we can simply declare a type using **access protected**:

Listing 167: simple_protected_access.ads

```
package Simple_Protected_Access is

   type Access_Proc is
     access protected procedure;

   protected Obj is

      procedure Do_Something;

   end Obj;

   Acc : Access_Proc := Obj.Do_Something'Access;

end Simple_Protected_Access;
```

Listing 168: simple_protected_access.adb

```
package body Simple_Protected_Access is

   protected body Obj is

      procedure Do_Something is
      begin
         --  Not doing anything
         --  for the moment...
         null;
      end Do_Something;

   end Obj;

end Simple_Protected_Access;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Simple_Protected_Access
MD5: d82f7c90355e9810bd1e35f65e278626
```

Here, we declare the `Access_Proc` type as an access type to protected procedures. Then, we declare the variable `Acc` and assign to it the access to the `Do_Something` procedure (of the protected object `Obj`).

Now, let's discuss a more useful example: a simple system that allows us to register protected procedures and execute them. This is implemented in `Work_Registry` package:

Listing 169: work_registry.ads

```
package Work_Registry is

```

(continues on next page)

(continued from previous page)

```
   type Work_Id is tagged limited private;

   type Work_Handler is
     access protected procedure (T : Work_Id);

   subtype Valid_Work_Handler is
     not null Work_Handler;

   type Work_Handlers is
     array (Positive range <>) of Work_Handler;

   protected type Work_Handler_Registry
     (Last : Positive)
   is

      procedure Register (T : Valid_Work_Handler);

      procedure Reset;

      procedure Process_All;

   private

      D    : Work_Handlers (1 .. Last);
      Curr : Natural := 0;

   end Work_Handler_Registry;

private

   type Work_Id is tagged limited null record;

end Work_Registry;
```

Listing 170: work_registry.adb

```
package body Work_Registry is

   protected body Work_Handler_Registry is

      procedure Register (T : Valid_Work_Handler)
      is
      begin
         if Curr < Last then
            Curr := Curr + 1;
            D (Curr) := T;
         end if;
      end Register;

      procedure Reset is
      begin
         Curr := 0;
      end Reset;

      procedure Process_All is
         Dummy_ID : Work_Id;
      begin
         for I in D'First .. Curr loop
            D (I).all (Dummy_ID);
         end loop;
      end Process_All;
```

(continues on next page)

(continued from previous page)

```
26
27    end Work_Handler_Registry;
28
29 end Work_Registry;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Protected_Access_Init_Function
MD5: 5dfa8ab098900ab4f6b7575e1cde5e53
```

Here, we declare the protected `Work_Handler_Registry` type with the following subprograms:

- `Register`, which we can use to register a protected procedure;
- `Reset`, which we can use to reset the system; and
- `Process_All`, which we can use to call all procedures that were registered in the system.

`Work_Handler` is our access to protected subprogram type. Also, we declare the `Valid_Work_Handler` subtype, which excludes **`null`**. By doing so, we can ensure that only valid procedures are passed to the `Register` procedure. In the protected `Work_Handler_Registry` type, we store the procedures in an array (of `Work_Handlers` type).

Important

Note that, in the type declaration `Work_Handler`, we say that the protected procedure must have a parameter of `Work_Id` type. In this example, this parameter is just used to *bind* the procedure to the `Work_Handler_Registry` type. The `Work_Id` type itself is actually declared as a null record (in the private part of the package), and it isn't really useful on its own.

If we had declared **`type Work_Handler is access protected procedure`**; instead, we would be able to register *any* protected procedure into the system, even the ones that might not be suitable for the system. By using a parameter of `Work_Id` type, however, we make use of strong typing to ensure that only procedures that were designed for the system can be registered.

In the next part of the code, we declare the `Integer_Storage` type, which is a simple protected type that we use to store an integer value:

Listing 171: integer_storage_system.ads

```
1  with Work_Registry;
2
3  package Integer_Storage_System is
4
5     protected type Integer_Storage is
6
7        procedure Set (V : Integer);
8
9        procedure Show (T : Work_Registry.Work_Id);
10
11    private
12
13       I : Integer := 0;
14
15    end Integer_Storage;
```

(continues on next page)

(continued from previous page)

```
16
17    type Integer_Storage_Access is
18      access Integer_Storage;
19
20    type Integer_Storage_Array is
21      array (Positive range <>) of
22        Integer_Storage_Access;
23
24 end Integer_Storage_System;
```

Listing 172: integer_storage_system.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Integer_Storage_System is
4
5     protected body Integer_Storage is
6
7        procedure Set (V : Integer) is
8        begin
9           I := V;
10       end Set;
11
12       procedure Show (T : Work_Registry.Work_Id)
13       is
14          pragma Unreferenced (T);
15       begin
16          Put_Line ("Value: " & Integer'Image (I));
17       end Show;
18
19    end Integer_Storage;
20
21 end Integer_Storage_System;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Protected_Access_Init_Function
MD5: a388d792bc85709785d324c914d9d236
```

For the `Integer_Storage` type, we declare two procedures:

- Set, which we use to assign a value to the (protected) integer value; and
- Show, which we use to show the integer value that is stored in the protected object.

The Show procedure has a parameter of `Work_Id` type, which indicates that this procedure was designed to be registered in the system of `Work_Handler_Registry` type.

Finally, we have a test application in which we declare a registry (`WHR`) and an array of "protected integer objects" (`Int_Stor`):

Listing 173: show_access_to_protected_subprograms.adb

```
1  with Work_Registry;
2  use  Work_Registry;
3
4  with Integer_Storage_System;
5  use  Integer_Storage_System;
6
7  procedure Show_Access_To_Protected_Subprograms is
8
```

(continues on next page)

(continued from previous page)

```
   WHR      : Work_Handler_Registry (5);
   Int_Stor : Integer_Storage_Array (1 .. 3);

begin
   --  Allocate and initialize integer storage
   --
   --  (For the initialization, we're just
   --  assigning the index here, but we could
   --  really have used any integer value.)

   for I in Int_Stor'Range loop
      Int_Stor (I) := new Integer_Storage;
      Int_Stor (I).Set (I);
   end loop;

   --  Register handlers

   for I in Int_Stor'Range loop
      WHR.Register (Int_Stor (I).all.Show'Access);
   end loop;

   --  Now, use Process_All to call the handlers
   --  (in this case, the Show procedure for
   --  each protected object from Int_Stor).

   WHR.Process_All;

end Show_Access_To_Protected_Subprograms;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Protected_Access_Init_Function
MD5: 44c24ef07333e1d31844cc2ea6d91ab6
```

Runtime output

```
Value:  1
Value:  2
Value:  3
```

The work handler registry (`WHR`) has a maximum capacity of five procedures, whereas the `Int_Stor` array has a capacity of three elements. By calling `WHR.Register` and passing `Int_Stor (I).all.Show'Access`, we register the Show procedure of each protected object from `Int_Stor`.

Important

Note that the components of the `Int_Stor` array are of `Integer_Storage_Access` type, which is declared as an access to `Integer_Storage` objects. Therefore, we have to dereference the object (by writing `Int_Stor (I).all`) before getting access to the Show procedure (by writing `.Show'Access`).

We have to use an access type here because we cannot pass the access (to the Show procedure) of a local object in the call to the `Register` procedure. Therefore, the protected objects (of `Integer_Storage` type) cannot be local.

This issue becomes evident if we replace the declaration of `Int_Stor` with a local array (and then adapt the remaining code). If we do this, we get a compilation error in the call to `Register`:

Listing 174: show_access_to_protected_subprograms.adb

```
with Work_Registry;
use  Work_Registry;

with Integer_Storage_System;
use  Integer_Storage_System;

procedure Show_Access_To_Protected_Subprograms
is
   WHR      : Work_Handler_Registry (5);

   Int_Stor : array (1 .. 3) of Integer_Storage;

begin
   --  Allocate and initialize integer storage
   --
   --  (For the initialization, we're just
   --  assigning the index here, but we could
   --  really have used any integer value.)

   for I in Int_Stor'Range loop
      --  Int_Stor (I) := new Integer_Storage;
      Int_Stor (I).Set (I);
   end loop;

   --  Register handlers

   for I in Int_Stor'Range loop
      WHR.Register (Int_Stor (I).Show'Access);
      --            ^ ERROR!
   end loop;

   --  Now, call the handlers
   --  (i.e. the Show procedure of each
   --   protected object).

   WHR.Process_All;

end Show_Access_To_Protected_Subprograms;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_To_
 ↪Subprograms.Protected_Access_Init_Function
MD5: 359241c84cd30313fe2d7701b55f303e
```

Build output

```
show_access_to_protected_subprograms.adb:28:21: error: non-local pointer cannot␣
 ↪point to local object
gprbuild: *** compilation phase failed
```

As we've just discussed, this error is due to the fact that `Int_Stor` is now a "local" protected object, and the accessibility rules don't allow mixing it with non-local accesses in order to prevent the possibility of dangling references.

When we call `WHR.Process_All`, the registry system calls each procedure that has been registered with the system. When looking at the values displayed by the test application, we may notice that each call to Show is referring to a different protected object. In fact, even though we're passing just the access to a protected *procedure* in the call to `Register`,

that access is also associated to a specific protected object. (This is different from access to non-protected subprograms we've discussed previously: in that case, there's no object associated.) If we replace the argument to `Register` by `Int_Stor (2).all.Show'Access`, for example, the three Show procedures registered in the system will now refer to the same protected object (stored at `Int_Stor (2)`).

Also, even though we have registered the same procedure (`Show`) of the same type (`Integer_Storage`) in all calls to `Register`, we could have used a different protected procedure — and of a different protected type. As an exercise, we could, for example, create a new type called `Float_Storage` (based on the code that we used for the `Integer_Storage` type) and register some objects of `Float_Storage` type into the system (with a couple of additional calls to `Register`). If we then call `WHR.Process_All`, we'd see that the system is able to cope with objects of both `Integer_Storage` and `Float_Storage` types. In fact, the system implemented with the `Work_Handler_Registry` can be seen as "type agnostic," as it doesn't care about which type the protected objects have — as long as the subprograms we want to register are conformant to the `Valid_Work_Handler` type.

28.1.16 Accessibility Rules and Access-To-Subprograms

In general, the accessibility rules that we discussed *previously for access-to-objects* (page 788) also apply to access-to-subprograms. In this section, we discuss minor differences when applying those rules to access-to-subprograms.

In our discussion about accessibility rules, we've looked into *accessibility levels* (page 789) and the *accessibility rules* (page 790) that are based on those levels. The same accessibility rules apply to access-to-subprograms. *As we said previously* (page 793), operations targeting objects at a *less-deep* level are illegal, as it's the case for subprograms as well:

Listing 175: access_to_subprogram_types.ads

```
package Access_To_Subprogram_Types is

   type Access_To_Procedure is
     access procedure (I : in out Integer);

   type Access_To_Function is
     access function (I : Integer) return Integer;

end Access_To_Subprogram_Types;
```

Listing 176: show_access_to_subprogram_error.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Access_To_Subprogram_Types;
use  Access_To_Subprogram_Types;

procedure Show_Access_To_Subprogram_Error is
   Func : Access_To_Function;

   Value : Integer := 0;
begin
   declare
      function Add_One (I : Integer)
                        return Integer is
        (I + 1);
   begin
      Func := Add_One'Access;
      --  This assignment is illegal because the
```

(continues on next page)

(continued from previous page)

```
      --  Access_To_Function type is less deep
      --  than Add_One.
   end;

   Put_Line ("Value: " & Value'Image);
   Value := Func (Value);
   Put_Line ("Value: " & Value'Image);
end Show_Access_To_Subprogram_Error;
```

Code block metadata

```

 ↪Access_To_Subprograms.Access_To_Subprogram_Accessibility_Error_Less_Deep
MD5: 2a068732606a1fee156e82515febe9c4
```

Build output

```
show_access_to_subprogram_error.adb:16:15: error: subprogram must not be deeper␣
 ↪than access type
gprbuild: *** compilation phase failed
```

Obviously, we can correct this error by putting the Add_One function at the same level as the Access_To_Function type, i.e. at library level:

Listing 177: access_to_subprogram_types.ads

```
package Access_To_Subprogram_Types is

   type Access_To_Procedure is
     access procedure (I : in out Integer);

   type Access_To_Function is
     access function (I : Integer) return Integer;

end Access_To_Subprogram_Types;
```

Listing 178: add_one.ads

```
function Add_One (I : Integer) return Integer;
```

Listing 179: add_one.adb

```
function Add_One (I : Integer) return Integer is
begin
   return I + 1;
end Add_One;
```

Listing 180: show_access_to_subprogram_error.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Access_To_Subprogram_Types;
use  Access_To_Subprogram_Types;

with Add_One;

procedure Show_Access_To_Subprogram_Error is
   Func : Access_To_Function;

   Value : Integer := 0;
```

(continues on next page)

(continued from previous page)

```
begin
   Func := Add_One'Access;

   Put_Line ("Value: " & Value'Image);
   Value := Func (Value);
   Put_Line ("Value: " & Value'Image);
end Show_Access_To_Subprogram_Error;
```

Code block metadata

```

Runtime output

```
Value:  0
Value:  1
```

As a recommendation, resolving accessibility issues in the case of access-to-subprograms is best done by refactoring the subprograms of your source code — for example, moving subprograms to a different level.

Unchecked Access

Previously, we discussed about the *Unchecked_Access attribute* (page 798), which we can use to circumvent accessibility issues in specific cases for access-to-objects. We also said in that section that this attribute only exists for objects, not for subprograms. We can use the previous example to illustrate this limitation:

Listing 181: access_to_subprogram_types.ads

```
package Access_To_Subprogram_Types is

   type Access_To_Procedure is
     access procedure (I : in out Integer);

   type Access_To_Function is
     access function (I : Integer) return Integer;

end Access_To_Subprogram_Types;
```

Listing 182: show_access_to_subprogram_error.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Access_To_Subprogram_Types;
use  Access_To_Subprogram_Types;

procedure Show_Access_To_Subprogram_Error is
   Func : Access_To_Function;

   function Add_One (I : Integer)
            return Integer is
     (I + 1);

   Value : Integer := 0;
begin
   Func := Add_One'Access;
```

(continues on next page)

(continued from previous page)

```
16
17    Put_Line ("Value: " & Value'Image);
18    Value := Func (Value);
19    Put_Line ("Value: " & Value'Image);
20 end Show_Access_To_Subprogram_Error;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Accessibility_Rules_
 ↪Access_To_Subprograms.Access_To_Subprogram_Accessibility_Error_Same_Lifetime
MD5: c1ee1946f0c979eb30fbf2c72c426f50
```

Build output

```
show_access_to_subprogram_error.adb:15:12: error: subprogram must not be deeper␣
 ↪than access type
gprbuild: *** compilation phase failed
```

When we analyze the Show_Access_To_Subprogram_Error procedure, we see that the Func object and the Add_One function have the same lifetime. Therefore, in this very specific case, we could safely assign Add_One'Access to Func and call Func for Value. Due to the accessibility rules, however, this assignment is illegal. (Obviously, the accessibility issue here is that the Access_To_Function type has a potentially longer lifetime.)

In the case of access-to-objects, we could use Unchecked_Access to enforce assignments that we consider safe after careful analysis. However, because this attribute isn't available for access-to-subprograms, the best solution is to move the subprogram to a level that allows the assignment to be legal, as we said before.

In the GNAT toolchain

GNAT offers an equivalent for Unchecked_Access that can be used for subprograms: the Unrestricted_Access attribute. Note, however, that this attribute is not portable.

Listing 183: access_to_subprogram_types.ads

```
1  package Access_To_Subprogram_Types is
2
3     type Access_To_Procedure is
4       access procedure (I : in out Integer);
5
6     type Access_To_Function is
7       access function (I : Integer) return Integer;
8
9  end Access_To_Subprogram_Types;
```

Listing 184: show_access_to_subprogram_error.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  with Access_To_Subprogram_Types;
4  use  Access_To_Subprogram_Types;
5
6  procedure Show_Access_To_Subprogram_Error is
7     Func : Access_To_Function;
8
9     function Add_One (I : Integer)
10             return Integer is
11       (I + 1);
12
```

(continues on next page)

(continued from previous page)

```
13    Value : Integer := 0;
14 begin
15    Func := Add_One'Unrestricted_Access;
16    --              ^^^^^^^^^^^^^^^^^^^
17    --       Allowing access to local function
18
19    Put_Line ("Value: " & Value'Image);
20    Value := Func (Value);
21    Put_Line ("Value: " & Value'Image);
22 end Show_Access_To_Subprogram_Error;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Accessibility_Rules_
 ↪Access_To_Subprograms.Unrestricted_Access
MD5: 90e2c57c01463cbe6efee6e093d01e5b
```

Runtime output

```
Value:  0
Value:  1
```

As we can see, the `Unrestricted_Access` attribute can be safely used in this specific case to circumvent the accessibility rule limitation.

28.1.17 Access and Address

As we know, an access type is not a pointer, and it doesn't just indicate an address in memory. In fact, to represent an address in Ada, we use *the Address type* (page 401). Also, as we discussed earlier, we can use operators such as `<`, `>`, `+` and `-` for addresses. In contrast to that, those operators aren't available for access types — except, of course, for `=` and `/=`.

In certain situations, however, we might need to convert between access types and addresses. In this section, we discuss how to do so.

In the Ada Reference Manual

- 13.3 Operational and Representation Attributes[205]
- 13.7 The Package System[206]

Address and access conversion

The generic `System.Address_To_Access_Conversions` package allows us to convert between access types and addresses. This might be useful for specific low-level operations. Let's see an example:

[205] http://www.ada-auth.org/standards/22rm/html/RM-13-3.html
[206] http://www.ada-auth.org/standards/22rm/html/RM-13-7.html

Listing 185: show_address_conversion.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with System.Address_To_Access_Conversions;
with System.Address_Image;

procedure Show_Address_Conversion is

   package Integer_AAC is
     new System.Address_To_Access_Conversions
       (Object => Integer);
   use Integer_AAC;

   subtype Integer_Access is
     Integer_AAC.Object_Pointer;
   --  This is similar to:
   --
   --  type Integer_Access is access all Integer;

   I  : aliased Integer := 5;
   AI : Integer_Access  := I'Access;
begin
   Put_Line ("I'Address : "
             & System.Address_Image (I'Address));

   Put_Line ("AI.all'Address : "
             & System.Address_Image
                 (AI.all'Address));

   Put_Line ("To_Address (AI) : "
             & System.Address_Image
                 (To_Address (AI)));
end Show_Address_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_Address.
↪Address_Conversion
MD5: 717532026247044a667b60f6c1e1c7da
```

Runtime output

```
I'Address : 00007FFC6DB64054
AI.all'Address : 00007FFC6DB64054
To_Address (AI) : 00007FFC6DB64054
```

In this example, we instantiate the generic `System.Address_To_Access_Conversions` package using **`Integer`** as our target object type. This new package (`Integer_AAC`) has an `Object_Pointer` type, which is equivalent to a declaration such as **`type Integer_Access is access all Integer`**. (In this example, we declare `Integer_Access` as a subtype of `Integer_AAC.Object_Pointer` to illustrate that.)

The `Integer_AAC` package also includes the `To_Address` function, which converts an access object to an address. If the actual parameter is not null, `To_Address` returns the same information as if we were using the **`Address`** attribute for the designated object. In other words, `To_Address (AI) = AI.all'Address` when `AI /= null`.

If the access value is null, `To_Address` returns `Null_Address`, while `.all'Address` makes the *access check* (page 662) fail because we have to dereference the access object (via `.all`) before retrieving its address (via the **`Address`** attribute).

In addition to the `To_Address` function, the `To_Pointer` function is available to convert

from an address to an object of access type. For example:

Listing 186: show_address_conversion.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with System;      use System;

with System.Address_To_Access_Conversions;
with System.Address_Image;

procedure Show_Address_Conversion is

   package Integer_AAC is
     new System.Address_To_Access_Conversions
       (Object => Integer);
   use Integer_AAC;

   subtype Integer_Access is
     Integer_AAC.Object_Pointer;

   I          : aliased Integer := 5;
   AI_1, AI_2 : Integer_Access;
   A          : Address;
begin
   AI_1 := I'Access;
   A    := To_Address (AI_1);
   AI_2 := To_Pointer (A);

   Put_Line ("AI_1.all'Address : "
             & System.Address_Image
                 (AI_1.all'Address));
   Put_Line ("AI_2.all'Address : "
             & System.Address_Image
                 (AI_2.all'Address));

   if AI_1 = AI_2 then
      Put_Line ("AI_1 = AI_2");
   else
      Put_Line ("AI_1 /= AI_2");
   end if;
end Show_Address_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_Address.
 ↪Address_Conversion
MD5: 5c6fc19ca1aa227feba97ea610dd9218
```

Runtime output

```
AI_1.all'Address : 00007FFF064581CC
AI_2.all'Address : 00007FFF064581CC
AI_1 = AI_2
```

Here, we convert the A address back to an access value by calling `To_Pointer (A)`. (When running this object, we see that `AI_1` and `AI_2` have the same access value.)

Conversion of unbounded designated types

Note that the conversions might not work in all cases. For instance, when the designated type — indicated by the formal `Object` parameter of the generic `Address_To_Access_Conversions` package — is unbounded, the result of a call to `To_Pointer` may not have bounds.

Let's adapt the previous code example and replace the **`Integer`** type by the (unbounded) **`String`** type:

Listing 187: show_address_conversion.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with System;      use System;

with System.Address_To_Access_Conversions;
with System.Address_Image;

procedure Show_Address_Conversion is

   package String_AAC is
     new System.Address_To_Access_Conversions
       (Object => String);
   use String_AAC;

   subtype Integer_Access is
     String_AAC.Object_Pointer;

   S          : aliased String := "Hello";
   AI_1, AI_2 : Integer_Access;
   A          : Address;
begin
   AI_1 := S'Access;
   A    := To_Address (AI_1);

   AI_2 := To_Pointer (A);
   --      ^^^^^^^^^^^^^^
   --   WARNING: Result might not have bounds

   Put_Line ("AI_1.all'Address : "
             & System.Address_Image
                 (AI_1.all'Address));
   Put_Line ("AI_2.all'Address : "
             & System.Address_Image
                 (AI_2.all'Address));

   if AI_1 = AI_2 then
      Put_Line ("AI_1 = AI_2");
   else
      Put_Line ("AI_1 /= AI_2");
   end if;

   Put_Line ("AI_1: " & AI_1.all);
   Put_Line ("AI_2: " & AI_2.all);
   --                   ^^^^^^^^^^
   --   WARNING: As AI_2 might not have bounds
   --            due to the call to To_Pointer
   --            the behavior of this call to
   --            the "&" operator is
   --            unpredictable.
end Show_Address_Conversion;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Access_Address.
 ↪Address_Conversion
MD5: b1adcaa1f2cb4dfbd157aebf7893bd72
```

Build output

```
show_address_conversion.adb:9:04: warning: in instantiation at s-atacco.ads:43␣
 ↪[enabled by default]
show_address_conversion.adb:9:04: warning: Object is unconstrained array type␣
 ↪[enabled by default]
show_address_conversion.adb:9:04: warning: To_Pointer results may not have bounds␣
 ↪[enabled by default]
```

Runtime output

```
AI_1.all'Address : 00007FFE7BECD388
AI_2.all'Address : 00007FFE7BECD388
AI_1 = AI_2
AI_1: Hello
AI_2: Hello
```

In this case, the call to `To_Pointer (A)` might not have bounds, so any operation on `AI_2` might lead to unpredictable results.

In the Ada Reference Manual

- 13.7.2 The Package System.Address_To_Access_Conversions[207]

28.2 Anonymous Access Types

28.2.1 Named and Anonymous Access Types

The previous chapter dealt with access type declarations such as this one:

```
type Integer_Access is access all Integer;

procedure Add_One (A : Integer_Access);
```

In addition to named access type declarations such as the one in this example, Ada also supports anonymous access types, which, as the name implies, don't have an actual type declaration.

To declare an access object of anonymous type, we just specify the subtype of the object or subprogram we want to have access to. For example:

```
procedure Add_One (A : access Integer);
```

When we compare this example with the previous one, we see that the declaration `A : Integer_Access` becomes `A : access Integer`. Here, `access Integer` is the anonymous access type declaration, and `A` is an access object of this anonymous type.

To be more precise, `A : access Integer` is an *access parameter* (page 877) and it's specifying an *anonymous access-to-object type* (page 858). Another flavor of anonymous access types are *anonymous access-to-subprograms* (page 901). We discuss all these topics in more details later.

[207] http://www.ada-auth.org/standards/22rm/html/RM-13-7-2.html

Let's see a complete example:

Listing 188: show_anonymous_access_types.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Anonymous_Access_Types is
   I_Var : aliased Integer;

   A     : access Integer;
   --      ^ Anonymous access type
begin
   A := I_Var'Access;
   --   ^ Assignment to object of
   --     anonymous access type.

   A.all := 22;

   Put_Line ("A.all: " & Integer'Image (A.all));
end Show_Anonymous_Access_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_Types.Simple_Anonymous_Access_Types
MD5: f0c92c76d970089c1d503c599d6869dd
```

Runtime output

```
A.all:  22
```

Here, A is an access object whose value is initialized with the access to I_Var. Because the declaration of A includes the declaration of an anonymous access type, we don't declare an extra Integer_Access type, as we did in previous code examples.

In the Ada Reference Manual

- 3.10 Access Types[208]

Relation to named types

Anonymous access types were not part of the first version of the Ada standard, which only had support for named access types. They were introduced later to cover some use-cases that were difficult — or even impossible — with access types.

In this sense, anonymous access types aren't just access types without names. Certain accessibility rules for anonymous access types are a bit less strict. In those cases, it might be interesting to consider using them instead of named access types.

In general, however, we should only use anonymous access types in those specific cases where using named access types becomes too cumbersome. As a general recommendation, we should give preference to named access types whenever possible. (Anonymous access-to-object types have *drawbacks that we discuss later* (page 860).)

[208] http://www.ada-auth.org/standards/22rm/html/RM-3-10.html

Benefits of anonymous access types

One of the main benefits of anonymous access types is their flexibility: since there isn't an explicit access type declaration associated with them, we only have to worry about the subtype S we intend to access.

Also, as long as the subtype S in a declaration `access S` is always the same, no conversion is needed between two access objects of that anonymous type, and the `S'Access` attribute always works.

Let's see an example:

Listing 189: show.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show (Name : String;
                V    : access Integer) is
begin
   Put_Line (Name & ".all: "
             & Integer'Image (V.all));
end Show;
```

Listing 190: show_anonymous_access_types.adb

```
with Show;

procedure Show_Anonymous_Access_Types is
   I_Var : aliased Integer;
   A     : access Integer;
   B     : access Integer;
begin
   A := I_Var'Access;
   B := A;

   A.all := 22;

   Show ("A", A);
   Show ("B", B);
end Show_Anonymous_Access_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_Types.Anonymous_Access_Object_Assignment
MD5: 2822ca0bd6ac251dccc1ced60747fbe1
```

Runtime output

```
A.all:  22
B.all:  22
```

In this example, we have two access objects A and B. Since they're objects of anonymous access types that refer to the same subtype **Integer**, we can assign A to B without a type conversion, and pass those access objects as an argument to the Show procedure.

(Note that the use of an access parameter in the Show procedure is for demonstration purpose only: a simply **Integer** as the type of this input parameter would have been more than sufficient to implement the procedure. Actually, in this case, avoiding the access parameter would be the recommended approach in terms of clean Ada software design.)

In contrast, if we had used named type declarations, the code would be more complicated and more limited:

Listing 191: aux.ads

```
package Aux is

   type Integer_Access is access all Integer;

   procedure Show (Name : String;
                   V    : Integer_Access);

end Aux;
```

Listing 192: aux.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Aux is

   procedure Show (Name : String;
                   V    : Integer_Access) is
   begin
      Put_Line (Name & ".all: "
                & Integer'Image (V.all));
   end Show;

end Aux;
```

Listing 193: show_anonymous_access_types.adb

```
with Aux; use Aux;

procedure Show_Anonymous_Access_Types is
   --  I_Var : aliased Integer;

   A : Integer_Access;
   B : Integer_Access;
begin
   --  A := I_Var'Access;
   --       ^ ERROR: non-local pointer cannot
   --                point to local object.

   A := new Integer;
   B := A;

   A.all := 22;

   Show ("A", A);
   Show ("B", B);
end Show_Anonymous_Access_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_Types.Anonymous_Access_Object_Assignment
MD5: 681c2cf7f5e8d520490cc5594484ce69
```

Runtime output

```
A.all:  22
B.all:  22
```

Here, apart from the access type declaration (`Integer_Access`), we had to make two adap-

tations to convert the previous code example:

1. We had to move the Show procedure to a package (which we simply called Aux) because of the access type declaration.
2. Also, we had to allocate an object for A instead of retrieving the access attribute of I_Var because we cannot use a pointer to a local object in the assignment to a non-local pointer, as indicate in the comments.

This restriction regarding non-local pointer assignments is an example of the stricter accessibility rules that apply to named access types. As mentioned earlier, the S'Access attribute always works when we use anonymous access types — this is not always the case for named access types.

Important

As mentioned earlier, if we want to use two access objects in an operation, the rule says that the subtype S of the anonymous type used in their corresponding declaration must match. In the following example, we can see how this rule works:

Listing 194: show_anonymous_access_subtype_error.adb

```
1  procedure Show_Anonymous_Access_Subtype_Error is
2     subtype Integer_1_10 is Integer range 1 .. 10;
3
4     I_Var : aliased Integer;
5     A     : access Integer := I_Var'Access;
6     B     : access Integer_1_10;
7  begin
8     A := I_Var'Access;
9
10    B := A;
11    --  ^ ERROR: subtype doesn't match!
12
13    B := I_Var'Access;
14    --  ^ ERROR: subtype doesn't match!
15 end Show_Anonymous_Access_Subtype_Error;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.
 ↪Anonymous_Access_Types.Anonymous_Access_Subtype_Error
MD5: cecfe703ea8b42bad61c45f33cbcb67b
```

Build output

```
show_anonymous_access_subtype_error.adb:10:09: error: target designated␣
 ↪subtype not compatible with type "Standard.Integer"
show_anonymous_access_subtype_error.adb:13:09: error: object subtype must␣
 ↪statically match designated subtype
gprbuild: *** compilation phase failed
```

Even though Integer_1_10 is a subtype of **Integer**, we cannot assign A to B because the subtype that their access type declarations refer to — **Integer** and Integer_1_10, respectively — doesn't match. The same issue occurs when retrieving the access attribute of I_Var in the assignment to B.

The later sections on *anonymous access-to-object type* (page 858) and *anonymous access-to-subprograms* (page 901) cover more specific details on anonymous access types.

28.2.2 Anonymous Access-To-Object Types

In the *previous chapter* (page 735), we introduced named access-to-object types and used those types throughout the chapter. Also, in the *previous section* (page 853), we've seen some simple examples of anonymous access-to-object types:

```
procedure Add_One (A : access Integer);
--                     ^ Anonymous access type

A : access Integer;
--  ^ Anonymous access type
```

In addition to parameters and objects, we can use anonymous access types in discriminants, components of array and record types, renamings and function return types. (We discuss *anonymous access discriminants* (page 868) and *anonymous access parameters* (page 877) later on.) Let's see a code example that includes all these cases:

Listing 195: all_anonymous_access_to_object_types.ads

```
1  package All_Anonymous_Access_To_Object_Types is
2
3     procedure Add_One (A : access Integer) is null;
4     --                     ^ Anonymous access type
5
6     AI : access Integer;
7     --  ^ Anonymous access type
8
9     type Rec (AI : access Integer) is private;
10    --              ^ Anonymous access type
11
12    type Access_Array is
13       array (Positive range <>) of
14         access Integer;

MD5: 6533b22a4e4526702320cb327bf6f69a
```

In this example, we see multiple examples of anonymous access-to-object types:

- as the A parameter of the Add_One procedure;
- in the declaration of the AI access object;
- as the AI discriminant of the Rec type;
- as the component type of the Access_Array type;
- as the component type of the Arr array;
- in the AI_Renaming renaming;
- as the return type of the Init_Access_Integer;
- as the Internal_AI of component of the Rec type.

In the Ada Reference Manual

- 3.10 Access Types[209]

Not Null Anonymous Access-To-Object Types

As expected, **null** is a valid value for an anonymous access type. However, we can forbid **null** as a valid value by using **not null** in the anonymous access type declaration. For example:

Listing 196: all_anonymous_access_to_object_types.ads

```
package All_Anonymous_Access_To_Object_Types is

   procedure Add_One (A : not null access Integer)
     is null;
   --                      ^ Anonymous access type

   I : aliased Integer;

   AI : not null access Integer := I'Access;
   --   ^ Anonymous access type
   --                                ^^^^^^^^
   --              Initialization required!

   type Rec (AI : not null access Integer) is
      private;
   --             ^ Anonymous access type

   type Access_Array is
      array (Positive range <>) of
        not null access Integer;
   --   ^ Anonymous access type

   Arr : array (1 .. 5) of
     not null access Integer :=
   --  ^ Anonymous access type
       (others => I'Access);
   --   ^^^^^^^^^^^^^^^^^^
   --         Initialization required!

   AI_Renaming : not null access Integer
```

(continues on next page)

[209] http://www.ada-auth.org/standards/22rm/html/RM-3-10.html

(continued from previous page)

```
31       renames AI;
32    --             ^ Anonymous access type
33
34    function Init_Access_Integer
35      return not null access Integer is (I'Access);
36    --        ^ Anonymous access type
37    --                                  ^^^^^^^^
38    --                    Initialization required!
39
40 private
41
42    type Rec (AI : not null access Integer) is
43    record
44    --              ^ Anonymous access type
45       Internal_AI : not null access Integer;
46    --                 ^ Anonymous access type
47
48    end record;
49

```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_To_Object_Types.All_Not_Null_Anonymous_Access_To_Object_Types
MD5: 027430aa9d5e19979206110f5e260d13
```

As you might have noticed, we took the previous code example and used `not null` for each usage instance of the anonymous access type. In this sense, this version of the code example is very similar to the previous one. Note, however, that we now have to explicitly initialize some elements to avoid the `Constraint_Error` exception being raised at runtime. This is the case for example for the `AI` access object:

```
AI : not null access Integer := I'Access;
```

If we hadn't initialized `AI` explicitly with `I'Access`, it would have been set to `null`, which would fail the `not null` constraint of the anonymous access type. Similarly, we also have to initialize the `Arr` array and return a valid access object for the `Init_Access_Integer` function.

Drawbacks of Anonymous Access-To-Object Types

Anonymous access-to-object types have important drawbacks. For example, some features that are available for named access types aren't available for the anonymous access types. Also, most of the drawbacks are related to how anonymous access-to-object types can potentially make the allocation and deallocation quite complicated or even error-prone.

For starters, some pool-related features aren't available for anonymous access-to-object types. For example, we cannot specify which pool is going to be used in the allocation of an anonymous access-to-object. In fact, the memory pool selection is compiler-dependent, so we cannot rely on an object being allocated from a specific pool when using `new` with an anonymous access-to-object type. (In contrast, as we know, each named access type has an associated pool, so objects allocated via `new` will be allocated from that pool.) Also, we cannot identify which pool was selected for the allocation of a specific object, so we don't have any information to use for the deallocation of that object.

Because the pool selection is hidden from us, this makes the memory deallocation more complicated. For example, we cannot instantiate the `Ada.Unchecked_Deallocation` pro-

cedure for anonymous access types. Also, some of the methods we could use to circumvent this limitation are error-prone, as we discuss in this section.

Also, storage-related features aren't available: specifying the storage size — especially, specifying that the access type has a storage size of zero — isn't possible.

Missing features

Let's see a code example that shows some of the features that aren't available for anonymous access-to-object types:

Listing 197: missing_features.ads

```
with Ada.Unchecked_Deallocation;

package Missing_Features is

   --  We cannot specify which pool will be used
   --  in the anonymous access-to-object
   --  allocation; the pool is selected by the
   --  compiler:
   IA : access Integer := new Integer;

   --
   --  All the features below aren't available
   --  for an anonymous access-to-object:
   --

   --  Having a specific storage pool associated
   --  with the access type:
   type String_Access is
     access String;
   --  Automatically creates
   --  String_Access'Storage_Pool

   type Integer_Access is
     access Integer
       with Storage_Pool =>
              String_Access'Storage_Pool;
   --       ^^^^^^^^^^^^^^^^^^^^^^^^^^
   --         Using the pool from another
   --         access type.

   --  Specifying a deallocation function for the
   --  access type:
   procedure Free is
     new Ada.Unchecked_Deallocation
       (Object => Integer,
        Name   => Integer_Access);

   --  Specifying a limited storage size for
   --  the access type:
   type Integer_Access_Store_128 is
      access Integer
        with Storage_Size => 128;

   --  Limiting the storage size for the
   --  access type to zero:
   type Integer_Access_Store_0 is
      access Integer
        with Storage_Size => 0;
```

(continues on next page)

(continued from previous page)

```
49
50 end Missing_Features;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
↪Access_To_Object_Types.Missing_Anonymous_Access_To_Object_Features
MD5: 87a5c1413a720da84fab414cf63236ec
```

In the `Missing_Features` package, we see some of the features that we cannot use for the anonymous **`access Integer`** type, but that are available for equivalent named access types:

- There's no specific memory pool associated with the access object `IA`. In contrast, named types — such as `String_Access` and `Integer_Access` — have an associated pool, and we can use the `Storage_Pool` aspect and the `Storage_Pool` attribute to customize them.
- We cannot instantiate the `Ada.Unchecked_Deallocation` procedure for the **`access Integer`** type. However, we can instantiate it for named access types such as the `Integer_Access` type.
- We cannot use the `Storage_Size` attribute for the **`access Integer`** type, but we're allowed to use it with named access types, which we do in the declaration of the `Integer_Access_Store_128` and `Integer_Access_Store_0` types.

Dangerous memory deallocation

We might think that we could make up for the absence of the `Ada.Unchecked_Deallocation` procedure for anonymous access-to-object types by converting those access objects (of anonymous access types) to a named type that has the same designated subtype. For example, if we have an access object `IA` of an anonymous **`access Integer`** type, we can convert it to the named `Integer_Access` type, provided this named access type is compatible with the anonymous access type, e.g.:

```
type Integer_Access is access all Integer
```

Let's see a complete code example:

Listing 198: show_dangerous_deallocation.adb

```
1  with Ada.Unchecked_Deallocation;
2
3  procedure Show_Dangerous_Deallocation is
4     type Integer_Access is
5        access all Integer;
6
7     procedure Free is
8       new Ada.Unchecked_Deallocation
9         (Object => Integer,
10         Name   => Integer_Access);
11
12    IA : access Integer;
13 begin
14    IA := new Integer;
15    IA.all := 30;
16
17    --  Potentially erroneous deallocation via type
18    --  conversion:
```

(continues on next page)

(continued from previous page)

```
19    Free (Integer_Access (IA));
20
21 end Show_Dangerous_Deallocation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_To_Object_Types.Deallocation_Anonymous_Access_To_Object_Erronoeus
MD5: 91e024a4338e2e4f8d5b308d95499c1c
```

This example declares the `IA` access object of the anonymous **`access Integer`** type. After allocating an object for `IA` via **`new`**, we try to deallocate it by first converting it to the `Integer_Access` type, so that we can call the `Free` procedure to actually deallocate the object. Although this code compiles, it'll only work if both **`access Integer`** and `Integer_Access` types are using the same memory pool. Since we cannot really determine this, the result is potentially erroneous: it'll work if the compiler selected the same pool, but it'll fail otherwise.

Important

Because allocating memory for anonymous access types is potentially dangerous, we can use the `No_Anonymous_Allocators` restriction — which is available since Ada 2012 — to prevent this kind of memory allocation being used in the code. For example:

Listing 199: show_dangerous_allocation.adb

```
1  pragma Restrictions (No_Anonymous_Allocators);
2
3  procedure Show_Dangerous_Allocation is
4     IA : access Integer;
5  begin
6     IA := new Integer;
7     IA.all := 30;
8  end Show_Dangerous_Allocation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_To_Object_Types.No_Anonymous_Allocators
MD5: 0976821ce632f9635e33fd4f79c81ecd
```

Build output

```
show_dangerous_allocation.adb:6:10: error: violation of restriction "No_Anonymous_
 ↪Allocators" at line 1
gprbuild: *** compilation phase failed
```

Possible solution using named access types

A better solution to avoid issues when allocating and deallocating memory for anonymous access-to-object types is to allocate the object using a known pool. As mentioned before, the memory pool associated with a named access type is well-defined, so we can use this kind of types for memory allocation. In fact, we can use a named memory type to allocate an object via **new**, and then associate this allocated object with the access object of anonymous access type.

Let's see a code example:

Listing 200: show_successful_deallocation.adb

```
with Ada.Unchecked_Deallocation;

procedure Show_Successful_Deallocation is

   type Integer_Access is
      access Integer;

   procedure Free is
     new Ada.Unchecked_Deallocation
       (Object => Integer,
        Name   => Integer_Access);

   IA       : access Integer;
   Typed_IA : Integer_Access;

begin
   Typed_IA := new Integer;
   IA := Typed_IA;
   IA.all := 30;

   --  Deallocation of the access object that has
   --  an associated type:
   Free (Typed_IA);

end Show_Successful_Deallocation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_To_Object_Types.Deallocation_Anonymous_Access_To_Object_1
MD5: eff8b54adfcc8cce10920dc3620ff1b9
```

In this example, all operations related to memory allocation are exclusively making use of the `Integer_Access` type, which is a named access type. In fact, **new Integer** allocates the object from the pool associated with the `Integer_Access` type, and the call to `Free` deallocates this object back into that pool. Therefore, associating this object with the `IA` access object — in the `IA := Typed_IA` assignment — doesn't creates problems afterwards in the object's deallocation. (When calling `Free`, we only refer to the object of named access type, so the object is deallocated from a known pool.)

Of course, a potential issue here is that `IA` becomes a *dangling reference* (page 795) after the call to `Free`. Therefore, we can improve this solution by completely hiding the memory allocation and deallocation for the anonymous access types in subprograms — e.g. as part of a package. By doing so, we don't expose the named access type, thereby reducing the possibility of dangling references.

In fact, we can generalize this approach with the following (generic) package:

Listing 201: hidden_anonymous_allocation.ads

```
generic
   type T is private;
package Hidden_Anonymous_Allocation is

   function New_T
     return not null access T;

   procedure Free (Obj : access T);

end Hidden_Anonymous_Allocation;
```

Listing 202: hidden_anonymous_allocation.adb

```
with Ada.Unchecked_Deallocation;

package body Hidden_Anonymous_Allocation is

   type T_Access is access all T;

   procedure T_Access_Free is
     new Ada.Unchecked_Deallocation
       (Object => T,
        Name   => T_Access);

   function New_T
     return not null access T is
   begin
      return T_Access'(new T);
      --  Using allocation of the T_Access type:
      --  object is allocated from T_Access's pool
   end New_T;

   procedure Free (Obj : access T) is
      Tmp : T_Access := T_Access (Obj);
   begin
      T_Access_Free (Tmp);
      --  Using deallocation procedure of the
      --  T_Access type
   end Free;

end Hidden_Anonymous_Allocation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_To_Object_Types.Hidden_Alloc_Dealloc_Anonymous_Access_To_Object
MD5: bd3831829f34f06a1d3c25a975c850a3
```

In the generic `Hidden_Anonymous_Allocation` package, `New_T` allocates a new object internally and returns an anonymous access to this object. The `Free` procedure deallocates this object.

In the body of the `Hidden_Anonymous_Allocation` package, we use the named access type `T_Access` to handle the actual memory allocation and deallocation. As expected, because those operations happen on the pool associated with the `T_Access` type, we don't have to worry about potential deallocation issues.

Finally, we can instantiate this package for the type we want to have anonymous access types for, say a type named `Rec`. Then, when using the `Rec` type in the main subprogram, we can simply call the corresponding subprograms for memory allocation and deallocation.

For example:

Listing 203: info.ads

```
with Hidden_Anonymous_Allocation;

package Info is

   type Rec is private;

   function New_Rec return not null access Rec;

   procedure Free (Obj : access Rec);

private

   type Rec is record
      I : Integer;
   end record;

   package Rec_Allocation is new
     Hidden_Anonymous_Allocation (T => Rec);

   function New_Rec return not null access Rec
     renames Rec_Allocation.New_T;

   procedure Free (Obj : access Rec)
     renames Rec_Allocation.Free;

end Info;
```

Listing 204: show_info_allocation_deallocation.adb

```
with Info; use Info;

procedure Show_Info_Allocation_Deallocation is
   RA : constant not null access Rec := New_Rec;
begin
   Free (RA);
end Show_Info_Allocation_Deallocation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_To_Object_Types.Hidden_Alloc_Dealloc_Anonymous_Access_To_Object
MD5: d71e8ed70e280c6d5d9fc2d49c1eb6c3
```

In this example, we instantiate the Hidden_Anonymous_Allocation package in the Info package, which also defines the Rec type. We associate the New_T and Free subprograms with the Rec type by using subprogram renaming. Finally, in the Show_Info_Allocation_Deallocation procedure, we use these subprograms to allocate and deallocate the type.

Possible solution using the stack

Another approach that we could consider to avoid memory deallocation issues for anonymous access-to-object types is by simply using the stack for the object creation. For example:

Listing 205: show_automatic_deallocation.adb

```
procedure Show_Automatic_Deallocation is
   I  : aliased Integer;
   --   ^ Allocating object on the stack

   IA : access Integer;
begin
   IA := I'Access;
   --  Indirect allocation:
   --  object creation on the stack.

   IA.all := 30;

   --  Automatic deallocation at the end of the
   --  procedure because the integer variable is
   --  on the stack.
end Show_Automatic_Deallocation;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_To_Object_Types.Deallocation_Anonymous_Access_To_Object_2
MD5: 4381db8ba87717978a9629b1e6a5f1fc
```

In this case, we create the `I` object on the stack by simply declaring it. Then, we get access to it and assign it to the `IA` access object.

With this approach, we're indirectly allocating an object for an anonymous access type by creating it on the stack. Also, because we know that the `I` is automatically deallocated when it gets out of scope, we don't have to worry about explicitly deallocating the object referred by `IA`.

When to use anonymous access-to-objects types

In summary, anonymous access-to-object types have many drawbacks that often outweigh *their benefits* (page 855). In fact, allocation for those types can quickly become very complicated. Therefore, in general, they're not a good alternative to named access types. Indeed, the difficulties that we've just seen might make them a much worse option than just using named access types instead.

We might consider using anonymous access-to-objects types only in cases when we reach a point in our implementation work where using named access types becomes impossible — or when using them becomes even more complicated than equivalent solutions using anonymous access types. This scenario, however, is usually the exception rather than the rule. Thus, as a general guideline, we should always aim to use named access types.

That being said, an important exception to this advice is when we're *interfacing to other languages* (page 880). In this case, as we'll discuss later, using anonymous access-to-objects types can be significantly simpler (compared to named access types) without the drawbacks that we've just discussed.

28.2.3 Access discriminants

Previously, we've discussed *discriminants as access values* (page 745). In that section, we only used named access types. Now, in this section, we see how to use anonymous access types as discriminants. This feature is also known as *access discriminants* and it provides some flexibility that can be interesting in terms of software design, as we'll discuss later.

Let's start with an example:

Listing 206: custom_recs.ads

```
package Custom_Recs is

   --  Declaring a discriminant with an anonymous
   --  access type:
   type Rec (IA : access Integer) is record
      I : Integer := IA.all;
   end record;

   procedure Show (R : Rec);

end Custom_Recs;
```

Listing 207: custom_recs.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Custom_Recs is

   procedure Show (R : Rec) is
   begin
      Put_Line ("R.IA = "
                & Integer'Image (R.IA.all));
      Put_Line ("R.I  = "
                & Integer'Image (R.I));
   end Show;

end Custom_Recs;
```

Listing 208: show_access_discriminants.adb

```
with Custom_Recs; use Custom_Recs;

procedure Show_Access_Discriminants is
   I  : aliased Integer := 10;
   R  : Rec (I'Access);
begin
   Show (R);

   I   := 20;
   R.I := 30;
   Show (R);
end Show_Access_Discriminants;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Access_
 ↪Discriminants.Custom_Recs
MD5: f8e127fda4f7ea0f1593165d6a966df6
```

Runtime output

```
R.IA =  10
R.I  =  10
R.IA =  20
R.I  =  30
```

In this example, we use an anonymous access type for the discriminant in the declaration of the Rec type of the `Custom_Recs` package. In the `Show_Access_Discriminants` procedure, we declare R and provide access to the local `I` integer.

Similarly, we can use unconstrained designated subtypes:

Listing 209: persons.ads

```
package Persons is

   --  Declaring a discriminant with an anonymous
   --  access type whose designated subtype is
   --  unconstrained:
   type Person (Name : access String) is record
      Age : Integer;
   end record;

   procedure Show (P : Person);

end Persons;
```

Listing 210: persons.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Persons is

   procedure Show (P : Person) is
   begin
      Put_Line ("Name = "
                & P.Name.all);
      Put_Line ("Age  = "
                & Integer'Image (P.Age));
   end Show;

end Persons;
```

Listing 211: show_person.adb

```
with Persons; use Persons;

procedure Show_Person is
   S : aliased String := "John";
   P : Person (S'Access);
begin
   P.Age := 30;
   Show (P);
end Show_Person;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Access_
 ↪Discriminants.Persons
MD5: f0149d572e0ec192476836bfdf00dd9e
```

Runtime output

```
Name = John
Age  =  30
```

In this example, for the discriminant of the Person type, we use an anonymous access type whose designated subtype is unconstrained. In the Show_Person procedure, we declare the P object and provide access to the S string.

In the Ada Reference Manual

- 3.7 Discriminants[210]
- 3.10.2 Operations of Access Types[211]

Default Value of Access Discriminants

In contrast to named access types, we cannot use a default value for the access discriminant of a non-limited type:

Listing 212: custom_recs.ads

```
1  package Custom_Recs is
2
3     --  Declaring a discriminant with an anonymous
4     --  access type and a default value:
5     type Rec (IA : access Integer :=
6                    new Integer'(0)) is
7     record
8        I : Integer := IA.all;
9     end record;
10
11    procedure Show (R : Rec);
12
13 end Custom_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Access_
 ↪Discriminants.Custom_Recs
MD5: 9269cea113f29443a6d7bb719d0616f1
```

Build output

```
custom_recs.ads:6:21: warning: coextension will not be deallocated when its␣
 ↪associated owner is deallocated [enabled by default]
custom_recs.ads:6:21: error: (Ada 2005) access discriminants of nonlimited types␣
 ↪cannot have defaults
gprbuild: *** compilation phase failed
```

However, if we change the type declaration to be a limited type, having a default value for the access discriminant is OK:

Listing 213: custom_recs.ads

```
1  package Custom_Recs is
2
3     --  Declaring a discriminant with an anonymous
```

(continues on next page)

[211] http://www.ada-auth.org/standards/22rm/html/RM-3-10-2.html

(continued from previous page)

```
   --  access type and a default value:
   type Rec (IA : access Integer :=
                     new Integer'(0)) is limited
   record
      I : Integer := IA.all;
   end record;

   procedure Show (R : Rec);

end Custom_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Access_
 ↪Discriminants.Custom_Recs
MD5: 9e8683c7a27e9097fd2003ad91bac269
```

Build output

```
custom_recs.ads:6:21: warning: coextension will not be deallocated when its␣
 ↪associated owner is deallocated [enabled by default]
```

Note that, if we don't provide a value for the access discriminant when declaring an object R, the default value is allocated (via **new**) during R's creation.

Listing 214: show_access_discriminants.adb

```
with Custom_Recs; use Custom_Recs;

procedure Show_Access_Discriminants is
   R : Rec;
   --  ^^^
   --  This triggers "new Integer'(0)", so an
   --  integer object is allocated and stored in
   --  the R.IA discriminant.
begin
   Show (R);

   --  R gets out of scope here, and the object
   --  allocated via new hasn't been deallocated.
end Show_Access_Discriminants;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Access_
 ↪Discriminants.Custom_Recs
MD5: f5d9dee26044ccab2193ab419638de79
```

Build output

```
show_access_discriminants.adb:4:04: warning: coextension will not be deallocated␣
 ↪when its associated owner is deallocated [enabled by default]
custom_recs.ads:6:21: warning: coextension will not be deallocated when its␣
 ↪associated owner is deallocated [enabled by default]
```

Runtime output

```
R.IA =  0
R.I  =  0
```

In this case, the allocated object won't be deallocated when R gets out of scope!

Benefits of Access Discriminants

Access discriminants have the same benefits that we've already seen earlier while discussing *discriminants as access values* (page 745). An additional benefit is its extended flexibility: access discriminants are compatible with any access T'Access, as long as T is of the designated subtype.

Consider the following example using the named access type Access_String:

Listing 215: persons.ads

```
package Persons is

   type Access_String is access all String;

   --  Declaring a discriminant with a named
   --  access type:
   type Person (Name : Access_String) is record
      Age : Integer;
   end record;

   procedure Show (P : Person);

end Persons;
```

Listing 216: persons.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Persons is

   procedure Show (P : Person) is
   begin
      Put_Line ("Name = "
                & P.Name.all);
      Put_Line ("Age  = "
                & Integer'Image (P.Age));
   end Show;

end Persons;
```

Listing 217: show_person.adb

```
with Persons; use Persons;

procedure Show_Person is
   S : aliased String := "John";
   P : Person (S'Access);
   --          ^^^^^^^^ ERROR: cannot use local
   --                           object
   --
   --  We can, however, allocate the string via
   --  new:
   --
   --  S : Access_String := new String'("John");
   --  P : Person (S);
begin
   P.Age := 30;
   Show (P);
end Show_Person;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Access_
 ↪Discriminants.Persons
MD5: e918db3790c7ffeeb7c0f54ced9f48b9
```

Build output

```
show_person.adb:5:16: error: non-local pointer cannot point to local object
gprbuild: *** compilation phase failed
```

This code doesn't compile because we cannot have a non-local pointer (`Access_String`) pointing to the local object S. The only way to make this work is by allocating the string via **new** (i.e.: `S : Access_String := new String`).

However, if we use an access discriminant in the declaration of `Person`, the code compiles fine:

Listing 218: persons.ads

```
package Persons is

   --  Declaring a discriminant with an anonymous
   --  access type:
   type Person (Name : access String) is record
      Age : Integer;
   end record;

   procedure Show (P : Person);

end Persons;
```

Listing 219: show_person.adb

```
with Persons; use Persons;

procedure Show_Person is
   S : aliased String := "John";
   P : Person (S'Access);
   --          ^^^^^^^^ OK

   --  Allocating the string via new and using it
   --  in P's declaration is OK as well, but we
   --  should manually deallocate it before S
   --  gets out of scope:
   --
   --  S : access String := new String'("John");
   --  P : Person (S);
begin
   P.Age := 30;
   Show (P);
end Show_Person;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Access_
 ↪Discriminants.Persons
MD5: 6516fb4e0cbbac9cfe07a56e48ea9ff3
```

Runtime output

```
Name = John
Age  =  30
```

In this case, getting access to the local object S and using it for P's discriminant is perfectly fine.

Preventing dangling pointers

Note that the usual rules that prevent dangling pointers still apply here. This ensures that we can safely use access discriminants. For example:

Listing 220: show_person.adb

```
with Persons; use Persons;

procedure Show_Person is

   function Local_Init return Person is
      S : aliased String := "John";
   begin
      return (Name => S'Access, Age => 30);
      --      ^^^^^^^^^^^^^^^^
      --      ERROR: dangling reference!
   end Local_Init;

   P : Person := Local_Init;
begin
   Show (P);
end Show_Person;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Access_
 ↪Discriminants.Persons
MD5: 9c8d2aebf60b8bb19e455cb6bc5730eb
```

Build output

```
show_person.adb:8:07: error: access discriminant in return object would be a␣
 ↪dangling reference
gprbuild: *** compilation phase failed
```

In this example, compilation fails in the `Local_Init` function when trying to return an object of `Person` type because `S'Access` would be a dangling reference.

28.2.4 Self-reference

Previously, we've seen that we can declare *self-references* (page 762) using named access types. We can do the same with anonymous access types. Let's revisit the code example that implements linked lists:

Listing 221: linked_lists.ads

```
generic
   type T is private;
package Linked_Lists is

   type List is limited private;

   procedure Append_Front
      (L : in out List;
       E :        T);
```

(continues on next page)

(continued from previous page)

```
10
11    procedure Append_Rear
12       (L : in out List;
13        E :        T);
14
15    procedure Show (L : List);
16
17 private
18
19    type Component is record
20       Next  : access Component;
21       --      ^^^^^^^^^^^^^^^^
22       --       Self-reference
23       --
24       --       (Note that we haven't finished the
25       --       declaration of the "Component" type
26       --       yet, but we're already referring to
27       --       it.)
28
29       Value : T;
30    end record;
31
32    type List is access all Component;
33
34 end Linked_Lists;
```

Listing 222: linked_lists.adb

```
1  pragma Ada_2022;
2
3  with Ada.Text_IO; use Ada.Text_IO;
4
5  package body Linked_Lists is
6
7     procedure Append_Front
8        (L : in out List;
9         E :        T)
10    is
11       New_First : constant List := new
12         Component'(Value => E,
13                    Next  => L);
14    begin
15       L := New_First;
16    end Append_Front;
17
18    procedure Append_Rear
19       (L : in out List;
20        E :        T)
21    is
22       New_Last : constant List := new
23         Component'(Value => E,
24                    Next  => null);
25    begin
26       if L = null then
27          L := New_Last;
28       else
29          declare
30             Last : List := L;
31          begin
32             while Last.Next /= null loop
33                Last := List (Last.Next);
```

(continues on next page)

(continued from previous page)

```
                --      ^^^^
                --   type conversion:
                --      "access Component" to
                --      "List"
             end loop;
             Last.Next := New_Last;
          end;
       end if;
    end Append_Rear;

    procedure Show (L : List) is
       Curr : List := L;
    begin
       if L = null then
          Put_Line ("[ ]");
       else
          Put ("[");
          loop
             Put (Curr.Value'Image);
             Put (" ");
             exit when Curr.Next = null;
             Curr := Curr.Next;
          end loop;
          Put_Line ("]");
       end if;
    end Show;

end Linked_Lists;
```

Listing 223: test_linked_list.adb

```
with Linked_Lists;

procedure Test_Linked_List is
    package Integer_Lists is new
      Linked_Lists (T => Integer);
    use Integer_Lists;

    L : List;
begin
    Append_Front (L, 3);
    Append_Rear (L, 4);
    Append_Rear (L, 5);
    Append_Front (L, 2);
    Append_Front (L, 1);
    Append_Rear (L, 6);
    Append_Rear (L, 7);

    Show (L);
end Test_Linked_List;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Self_
↪Reference.Linked_List_Example
MD5: 9e42bf9fa630a0af8dcf7c85a1565edb
```

Runtime output

```
[ 1  2  3  4  5  6  7 ]
```

Here, in the declaration of the Component type (in the private part of the generic Linked_Lists package), we declare Next as an anonymous access type that refers to the Component type. (Note that at this point, we haven't finished the declaration of the Component type yet, but we're already using it as the designated subtype of an anonymous access type.) Then, we declare List as a general access type (with Component as the designated subtype).

It's worth mentioning that the List type and the anonymous **access** Component type aren't the same type, although they share the same designated subtype. Therefore, in the implementation of the Append_Rear procedure, we have to use type conversion to convert from the anonymous **access** Component type to the (named) List type.

28.2.5 Mutually dependent types using anonymous access types

In the section on *mutually dependent types using access types* (page 765), we've seen a code example that was using named access types. We could now rewrite it using anonymous access types:

Listing 224: mutually_dependent.ads

```
1  package Mutually_Dependent is
2
3     type T2;
4
5     type T1 is record
6        B : access T2;
7     end record;
8
9     type T2 is record
10       A : access T1;
11    end record;
12
13 end Mutually_Dependent;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Mutually_
 ↪Dependent_Anonymous_Access_Types.Example
MD5: 09f869d99b9c16882554588bb806a113
```

In this example, T1 and T2 are mutually dependent types. We're using anonymous access types in the declaration of the B and A components.

28.2.6 Access parameters

In the previous chapter, we talked about *parameters as access values* (page 752). As you might have expected, we can also use anonymous access types as parameters of a subprogram. However, they're limited to be **in** parameters of a subprogram or return type of a function (also called the access result type):

Listing 225: names.ads

```
1  package Names is
2
3     function Init (S1, S2 : String)
4                    return access String;
5     --             ^^^^^^^^^^^^^^^^^^^^
6     --  Anonymous access type as the access
```

(continues on next page)

(continued from previous page)

```
   --  result type.

   procedure Show (N : access constant String);
   --                  ^^^^^^^^^^^^^^^^^^^^^^
   --  Anonymous access type as a parameter type.

end Names;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_Parameters.Names
MD5: 622a76c4b133ed2715f18c175694cbe2
```

In this example, we have a string as the access result type of the `Init` function, and another string as the access parameter of the Show procedure.

This is the complete code example:

Listing 226: names.ads

```
package Names is

   function Init (S1, S2 : String)
                  return access String;

   procedure Show (N : access constant String);

private

   function Init (S1, S2 : String)
                  return access String is
     (new String'(S1 & "-" & S2));

end Names;
```

Listing 227: names.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Names is

   procedure Show (N : access constant String) is
   begin
      Put_Line ("Name: " & N.all);
   end Show;

end Names;
```

Listing 228: show_names.adb

```
with Names; use Names;

procedure Show_Names is
   N : access String := Init ("Lily", "Ann");
begin
   Show (N);
end Show_Names;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_Parameters.Names
MD5: 9fe629f29de2898f2b82d9146b22fd1a
```

Runtime output

```
Name: Lily-Ann
```

Note that we're not using the **in** parameter mode in the Show procedure above. Usually, this parameter mode can be omitted, as it is the default parameter mode — `procedure P (I : Integer)` is the same as `procedure P (I : in Integer)`. However, in the case of the Show procedure, the **in** parameter mode isn't just optionally absent. In fact, for access parameters, the parameter mode is always implied as **in**, so writing it explicitly is actually forbidden. In other words, we can only write `N : access String` or `N : access constant String`, but we cannot write `N : in access String` or `N : in access constant String`.

For further reading...

When we discussed *parameters as access values* (page 752) in the previous chapter, we saw how we can simply use different parameter modes to write a program instead of using access types. Basically, to implement the same functionality, we just replaced the access types by selecting the correct parameter modes instead and used *simpler* data types.

Let's do the same exercise again, this time by adapting the previous code example with anonymous access types:

Listing 229: names.ads

```
1  package Names is
2
3     function Init (S1, S2 : String)
4                    return String;
5
6     procedure Show (N : String);
7
8  private
9
10    function Init (S1, S2 : String)
11                   return String is
12       (S1 & "-" & S2);
13
14 end Names;
```

Listing 230: names.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Names is
4
5     procedure Show (N : String) is
6     begin
7        Put_Line ("Name: " & N);
8     end Show;
9
10 end Names;
```

Listing 231: show_names.adb

```
1  with Names; use Names;
2
```

(continues on next page)

(continued from previous page)

```
procedure Show_Names is
   N : String := Init ("Lily", "Ann");
begin
   Show (N);
end Show_Names;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_Parameters.Names_String
MD5: 643f193999ef8de9bcefb11d9bdd21d7
```

Runtime output

```
Name: Lily-Ann
```

Although we're using simple strings instead of access types in this version of the code example, we're still getting a similar behavior. However, there is a small, yet important difference in the way the string returned by `Init` is being allocated: while the previous implementation (which was using an access result type) was allocating the string on the heap, we're now allocating the string on the stack.

Later on, we talk about the *accessibility rules in the case of access parameters* (page 900).

In general, we should avoid access parameters whenever possible and simply use objects and parameter modes directly, as it makes the design simpler and less error-prone. One exception is when we're interfacing to other languages, especially C: this is our *next topic* (page 880). Another time when access parameters are vital is for inherited primitive operations for tagged types. We discuss this *later on* (page 884).

In the Ada Reference Manual

- 3.10 Access Types[212]

Interfacing To Other Languages

We can use access parameters to interface to other languages. This can be particularly useful when interfacing to C code that makes use of pointers. For example, let's assume we want to call the add_one function below in our Ada implementation:

Listing 232: operations_c.h

```
void add_one(int *p_i);
```

Listing 233: operations_c.c

```
void add_one(int *p_i)
{
    *p_i = *p_i + 1;
}
```

Code block metadata

[212] http://www.ada-auth.org/standards/22rm/html/RM-3-10.html

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_Parameters.C_Interfacing
MD5: 3270f3b2415266a203a6f4c605c3831b
```

We could map the **int** * parameter of add_one to **access Integer** in the Ada specification:

```
procedure Add_One (IA : access Integer)
  with Import, Convention => C;
```

This is a complete code example:

Listing 234: operations.ads

```
1  package Operations is
2
3     procedure Add_One (IA : access Integer)
4       with Import, Convention => C;
5
6  end Operations;
```

Listing 235: show_operations.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  with Operations;  use Operations;
4
5  procedure Show_Operations is
6     I : aliased Integer := 42;
7  begin
8     Put_Line (I'Image);
9     Add_One (I'Access);
10    Put_Line (I'Image);
11 end Show_Operations;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_Parameters.C_Interfacing
MD5: 0219acdbd2dad69962875199ffdd930e
```

Once again, we can replace access parameters with simpler types by using the appropriate parameter mode. In this case, we could replace **access Integer** by **aliased in out Integer**. This is the modified version of the code:

Listing 236: operations.ads

```
1  package Operations is
2
3     procedure Add_One
4      (IA : aliased in out Integer)
5        with Import, Convention => C;
6
7  end Operations;
```

Listing 237: show_operations.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  with Operations;  use Operations;
4
5  procedure Show_Operations is
```

(continues on next page)

(continued from previous page)

```
   I : aliased Integer := 42;
begin
   Put_Line (I'Image);
   Add_One (I);
   Put_Line (I'Image);
end Show_Operations;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_Parameters.C_Interfacing
MD5: 2c5a81b8d77f0fff8a73f7912be6b6fe
```

However, there are situations where aliased objects cannot be used. For example, suppose we want to allocate memory inside a C function. In this case, the pointer to that memory block must be mapped to an access type in Ada.

Let's extend the previous C code example and introduce the `alloc_integer` and `dealloc_integer` functions, which allocate and deallocate an integer value:

Listing 238: operations_c.h

```
int * alloc_integer();

void dealloc_integer(int *p_i);

void add_one(int *p_i);
```

Listing 239: operations_c.c

```
#include <stdlib.h>

int * alloc_integer()
{
    return malloc(sizeof(int));
}

void dealloc_integer(int *p_i)
{
    free (p_i);
}

void add_one(int *p_i)
{
    *p_i = *p_i + 1;
}
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_Parameters.C_Interfacing
MD5: ec6dea12d0a948489cce21b0cc0a1ad2
```

In this case, we really have to use access types to interface to these C functions. In fact, we need an access result type to interface to the `alloc_integer()` function, and an access parameter in the case of the `dealloc_integer()` function. This is the corresponding specification in Ada:

Listing 240: operations.ads

```
package Operations is

   function Alloc_Integer return access Integer
     with Import, Convention => C;

   procedure Dealloc_Integer (IA : access Integer)
     with Import, Convention => C;

   procedure Add_One
    (IA : aliased in out Integer)
       with Import, Convention => C;

end Operations;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_Parameters.C_Interfacing
MD5: bcbc8a87037b64fc6469e67b928e6172
```

Note that we're still using an aliased integer type for the Add_One procedure, while we're using access types for the other two subprograms.

Finally, as expected, we can use this specification in a test application:

Listing 241: show_operations.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Operations;  use Operations;

procedure Show_Operations is
   I : access Integer := Alloc_Integer;
begin
   I.all := 42;
   Put_Line (I.all'Image);

   Add_One (I.all);
   Put_Line (I.all'Image);

   Dealloc_Integer (I);
end Show_Operations;
```

Code block metadata

```

 ↪Access_Parameters.C_Interfacing
MD5: b2b96a166926528bc44059b56e31fb55
```

In this application, we get a C pointer from the `alloc_integer` function and encapsulate it in an Ada access type, which we then assign to `I`. In the last line of the procedure, we call `Dealloc_Integer` and pass `I` to it, which deallocates the memory block indicated by the C pointer.

In the Ada Reference Manual

- 3.10 Access Types[213]

[213] http://www.ada-auth.org/standards/22rm/html/RM-3-10.html

Inherited Primitive Operations For Tagged Types

In order to declare inherited primitive operations for tagged types that use access types, we need to use access parameters. The reason is that, to be a primitive operation for some tagged type — and hence inheritable — the subprogram must reference the tagged type name directly in the parameter profile. This means that a named access type won't suffice, because only the access type name would appear in the profile. For example:

Listing 242: inherited_primitives.ads

```
package Inherited_Primitives is

   type T is tagged private;

   type T_Access is access all T;

   procedure Proc (N : T_Access);
   --  Proc is not a primitive of type T.

   type T_Child is new T with private;

   type T_Child_Access is access all T_Child;

private

   type T is tagged null record;

   type T_Child is new T with null record;

end Inherited_Primitives;
```

Listing 243: inherited_primitives.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Inherited_Primitives is

   procedure Proc (N : T_Access) is null;

end Inherited_Primitives;
```

Listing 244: show_inherited_primitives.adb

```
with Inherited_Primitives;
use  Inherited_Primitives;

procedure Show_Inherited_Primitives is
   Obj       : T_Access       := new T;
   Obj_Child : T_Child_Access := new T_Child;
begin
   Proc (Obj);
   Proc (Obj_Child);
   --    ^^^^^^^^^
   --    ERROR: Proc is not inherited!
end Show_Inherited_Primitives;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_Parameters.Inherited_Primitives
MD5: 8235b21caa9f1f105f533d74d891adfe
```

Build output

```
show_inherited_primitives.adb:9:10: error: expected type "T_Access" defined at␣
 ↪inherited_primitives.ads:5
show_inherited_primitives.adb:9:10: error: found type "T_Child_Access" defined at␣
 ↪inherited_primitives.ads:12
gprbuild: *** compilation phase failed
```

In this example, `Proc` is not a primitive of type T because it's referring to type `T_Access`, not type T. This means that `Proc` isn't inherited when we derive the `T_Child` type. Therefore, when we call `Proc (Obj_Child)`, a compilation error occurs because the compiler expects type `T_Access` — there's no `Proc (N : T_Child_Access)` that could be used here.

If we replace `T_Access` in the `Proc` procedure with an an access parameter (`access T`), the subprogram becomes a primitive of T:

Listing 245: inherited_primitives.ads

```
1  package Inherited_Primitives is
2
3     type T is tagged private;
4
5     procedure Proc (N : access T);
6     --  Proc is a primitive of type T.
7
8     type T_Child is new T with private;
9
10 private
11
12    type T is tagged null record;
13
14    type T_Child is new T with null record;
15
16 end Inherited_Primitives;
```

Listing 246: inherited_primitives.adb

```
1  package body Inherited_Primitives is
2
3     procedure Proc (N : access T) is null;
4
5  end Inherited_Primitives;
```

Listing 247: show_inherited_primitives.adb

```
1  with Inherited_Primitives;
2  use  Inherited_Primitives;
3
4  procedure Show_Inherited_Primitives is
5     Obj       : access T       := new T;
6     Obj_Child : access T_Child := new T_Child;
7  begin
8     Proc (Obj);
9     Proc (Obj_Child);
10    --    ^^^^^^^^^
11    --    OK: Proc is inherited!
12 end Show_Inherited_Primitives;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_Parameters.Inherited_Primitives
```

(continues on next page)

(continued from previous page)

```
MD5: a7e9b8bc92e346758cc4ade43bb4b02d
```

Now, the child type T_Child (derived from the T) inherits the primitive operation Proc. This inherited operation has an access parameter designating the child type:

```
type T_Child is new T with private;

procedure Proc (N : access T_Child);
--  Implicitly inherited primitive operation
```

In the Ada Reference Manual

- 3.9.2 Dispatching Operations of Tagged Types[214]

28.2.7 User-Defined References

Implicit dereferencing (page 767) isn't limited to the contexts that Ada supports by default: we can also add implicit dereferencing to our own types by using the Implicit_Dereference aspect.

To do this, we have to declare:

- a reference type, where we use the Implicit_Dereference aspect to specify the reference discriminant, which is the record discriminant that will be dereferenced; and
- a reference object, which contains an access value that will be dereferenced.

Also, for the reference type, we have to:

- specify the reference discriminant as an *access discriminant* (page 868); and
- indicate the name of the reference discriminant when specifying the Implicit_Dereference aspect.

Let's see a simple example:

Listing 248: show_user_defined_reference.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Show_User_Defined_Reference is
4
5     type Id_Number is record
6        Id : Positive;
7     end record;
8
9     --
10    --  Reference type:
11    --
12    type Id_Ref (Ref : access Id_Number) is
13    --           ^ reference discriminant
14      null record
15        with Implicit_Dereference => Ref;
16      --                             ^^^
17      --               name of the reference
18      --               discriminant
19
20    --
```

(continues on next page)

[214] http://www.ada-auth.org/standards/22rm/html/RM-3-9-2.html

(continued from previous page)

```
21    --  Access value:
22    --
23    I : constant access Id_Number :=
24          new Id_Number'(Id => 42);
25
26    --
27    --  Reference object:
28    --
29    R : Id_Ref (I);
30 begin
31    Put_Line ("ID: "
32              & Positive'Image (R.Id));
33    --                             ^ Equivalent to:
34    --                                R.Ref.Id
35    --                               or:
36    --                                R.Ref.all.Id
37 end Show_User_Defined_Reference;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.User_
 ↪Defined_References.Simple_User_Defined_References
MD5: 33eaa7e8e75b4eb56d64dcc17e2932aa
```

Runtime output

```
ID:  42
```

Here, we declare a simple record type (`Id_Number`) and a corresponding reference type (`Id_Ref`). Note that:

- the reference discriminant `Ref` has an access to the `Id_Number` type; and
- we indicate this reference discriminant in the `Implicit_Dereference` aspect.

Then, we declare an access value (the `I` constant) and use it for the `Ref` discriminant in the declaration of the reference object `R`.

Finally, we implicitly dereference `R` and access the `Id` component by simply writing `R.Id` — instead of the extended forms `R.Ref.Id` or `R.Ref.all.Id`.

Important

The extended form mentioned in the example that we just saw (`R.Ref.all.Id`) makes it clear that two steps happen when evaluating `R.Id`:

- First, `R.Ref` is implied from `R` because of the `Implicit_Dereference` aspect.
- Then, `R.Ref` is implicitly dereferenced to `R.Ref.all`.

After these two steps, we can access the actual object. (In our case, we can access the `Id` component.)

Note that we cannot use access types directly for the reference discriminant. For example, if we made the following change in the previous code example, it wouldn't compile:

```
type Id_Number_Access is access Id_Number;

--  Reference type:
type Id_Ref (Ref : Id_Number_Access) is
--                 ^ ERROR: it must be
--                          an access
```

(continues on next page)

(continued from previous page)

```
--                              discriminant!
  null record
    with Implicit_Dereference => Ref;
```

However, we could use other forms — such as `not null access` — in the reference discriminant:

```
--  Reference type:
type Id_Ref (Ref : not null access Id_Number) is
  null record
    with Implicit_Dereference => Ref;
```

In the Ada Reference Manual

- 4.1.5 User-Defined References[215]

Dereferencing of tagged types

Naturally, implicit dereferencing is also possible when calling primitives of a tagged type. For example, let's change the declaration of the `Id_Number` type from the previous code example and add a Show primitive.

Listing 249: info.ads

```
package Info is
   type Id_Number (Id : Positive) is
     tagged private;

   procedure Show (R : Id_Number);
private
   type Id_Number (Id : Positive) is
     tagged null record;
end Info;
```

Listing 250: info.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Info is

   procedure Show (R : Id_Number) is
   begin
      Put_Line ("ID: " & Positive'Image (R.Id));
   end Show;

end Info;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.User_
 ↪Defined_References.Dereferencing_Tagged_Types
MD5: 4de65094963450dc3a7505dbf93c2551
```

Then, let's declare a reference type and a reference object in the test application:

[215] http://www.ada-auth.org/standards/22rm/html/RM-4-1-5.html

Listing 251: show_user_defined_reference.adb

```
with Info; use Info;

procedure Show_User_Defined_Reference is

   --  Reference type:
   type Id_Ref (Ref : access Id_Number) is
     null record
       with Implicit_Dereference => Ref;

   --  Access value:
   I : constant access Id_Number :=
         new Id_Number (42);

   --  Reference object:
   R : Id_Ref (I);
begin

   R.Show;
   --  Equivalent to:
   --  R.Ref.all.Show;

end Show_User_Defined_Reference;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.User_
 ↪Defined_References.Dereferencing_Tagged_Types
MD5: 9c5dfc4f2b8e085efde9e61689243f70
```

Runtime output

```
ID:  42
```

Here, we can call the Show procedure by simply writing `R.Show` instead of `R.Ref.all.Show`.

Simple container

A typical application of user-defined references is to create cursors when iterating over a container. As an example, let's implement the `National_Date_Info` package to store the national day of a country:

Listing 252: national_date_info.ads

```
package National_Date_Info is

   subtype Country_Code is String (1 .. 3);

   type Time is record
      Year  : Integer;
      Month : Positive range 1 .. 12;
      Day   : Positive range 1 .. 31;
   end record;

   type National_Date is tagged record
      Country : Country_Code;
      Date    : Time;
   end record;

```

(continues on next page)

(continued from previous page)

```
   type National_Date_Access is
     access National_Date;

   procedure Show (Nat_Date : National_Date);

end National_Date_Info;
```

Listing 253: national_date_info.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body National_Date_Info is

   procedure Show (Nat_Date : National_Date) is
   begin
      Put_Line ("Country: "
                & Nat_Date.Country);
      Put_Line ("Year:    "
                & Integer'Image
                    (Nat_Date.Date.Year));
   end Show;

end National_Date_Info;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.User_
 ↪Defined_References.National_Dates
MD5: 90fd6740d701025e1d5f30c9751a528d
```

Here, `National_Date` is a record type that we use to store the national day information. We can call the `Show` procedure to display this information.

Now, let's implement the `National_Date_Containers` with a container for national days:

Listing 254: national_date_containers.ads

```
with National_Date_Info; use National_Date_Info;

package National_Date_Containers is

   --  Reference type:
   type National_Date_Reference
     (Ref : access National_Date) is
       tagged limited null record
         with Implicit_Dereference => Ref;

   --  Container (as an array):
   type National_Dates is
     array (Positive range <>) of
       National_Date_Access;

   --  The Find function scans the container to
   --  find a specific country, which is returned
   --  as a reference object.
   function Find (Nat_Dates : National_Dates;
                  Country   : Country_Code)
                  return National_Date_Reference;

end National_Date_Containers;
```

Listing 255: national_date_containers.adb

```
package body National_Date_Containers is

   function Find (Nat_Dates : National_Dates;
                  Country   : Country_Code)
                  return National_Date_Reference
   is
   begin
      for I in Nat_Dates'Range loop
         if Nat_Dates (I).Country = Country then
            return National_Date_Reference'(
                     Ref => Nat_Dates (I));
            --      ^^^^^^^^^^^^^^^^^^^^^^^^
            --   Returning reference object with a
            --   reference to the national day we
            --   found.
         end if;
      end loop;

      return
        National_Date_Reference'(Ref => null);
      --  ^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^
      --   Returning reference object with a null
      --   reference in case the country wasn't
      --   found. This will trigger an exception
      --   if we try to dereference it.
   end Find;

end National_Date_Containers;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.User_
 ↪Defined_References.National_Dates
MD5: ec37ae93a7052c4bc731b2a7be0763ab
```

Package `National_Date_Containers` contains the `National_Dates` type, which is an array type for declaring containers that we use to store the national day information. We can also see the declaration of the `National_Date_Reference` type, which is the reference type returned by the `Find` function when looking for a specific country in the container.

Important

We're declaring the container type (`National_Dates`) as an array type just to simplify the code. In many cases, however, this approach isn't recommended! Instead, we should use a private type in order to encapsulate — and better protect — the information stored in the actual container.

Finally, let's see a test application that stores information for some countries into the `Nat_Dates` container and displays the information for a specific country:

Listing 256: show_national_dates.adb

```
with National_Date_Info;
use  National_Date_Info;

with National_Date_Containers;
use  National_Date_Containers;

```

(continues on next page)

(continued from previous page)

```
procedure Show_National_Dates is

   Nat_Dates : constant National_Dates (1 .. 5) :=
     (new National_Date'("USA",
                         Time'(1776,  7,  4)),
      new National_Date'("FRA",
                         Time'(1789,  7, 14)),
      new National_Date'("DEU",
                         Time'(1990, 10,  3)),
      new National_Date'("SPA",
                         Time'(1492, 10, 12)),
      new National_Date'("BRA",
                         Time'(1822,  9,  7)));

begin
   Find (Nat_Dates, "FRA").Show;
   --                      ^ implicit dereference
end Show_National_Dates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.User_
 ↪Defined_References.National_Dates
MD5: 771ecb91e8f890d4bb9b08115ae833f4
```

Runtime output

```
Country: FRA
Year:     1789
```

Here, we call the `Find` function to retrieve a reference object, whose reference (access value) has the national day information of France. We then implicitly dereference it to get the tagged object (of `National_Date` type) and display its information by calling the `Show` procedure.

Relevant topics

The `National_Date_Containers` package was implemented specifically as an accompanying package for the `National_Date_Info` package. It is possible, however, to generalize it, so that we can reuse the container for other record types. In fact, this is actually very straightforward:

Listing 257: generic_containers.ads

```
generic
   type T is private;
   type T_Access is access T;
   type T_Cmp is private;
   with function Matches (E    : T_Access;
                          Elem : T_Cmp)
                          return Boolean;
package Generic_Containers is

   type Ref_Type (Ref : access T) is
     tagged limited null record
       with Implicit_Dereference => Ref;

   type Container is
     array (Positive range <>) of
       T_Access;
```

(continues on next page)

(continued from previous page)

```
17
18    function Find (Cont : Container;
19                   Elem : T_Cmp)
20                   return Ref_Type;
21
22 end Generic_Containers;
```

Listing 258: generic_containers.adb

```
1  package body Generic_Containers is
2
3     function Find (Cont : Container;
4                    Elem : T_Cmp)
5                    return Ref_Type is
6     begin
7        for I in Cont'Range loop
8           if Matches (Cont (I), Elem) then
9              return Ref_Type'(Ref => Cont (I));
10          end if;
11       end loop;
12
13       return Ref_Type'(Ref => null);
14    end Find;
15
16 end Generic_Containers;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.User_
 ↪Defined_References.National_Dates
MD5: 94c23a48131a47439b5b41e985c3d6c1
```

When comparing the `Generic_Containers` package to the `National_Date_Containers` package, we see that the main difference is the addition of the `Matches` function, which indicates whether the current element we're evaluating in the for-loop of the `Find` function is the one we're looking for.

In the main application, we can implement the `Matches` function and declare the `National_Date_Containers` package as an instance of the `Generic_Containers` package:

Listing 259: show_national_dates.adb

```
1  with Generic_Containers;
2  with National_Date_Info; use National_Date_Info;
3
4  procedure Show_National_Dates is
5
6     function Matches_Country
7       (E    : National_Date_Access;
8        Elem : Country_Code)
9        return Boolean is
10         (E.Country = Elem);
11
12    package National_Date_Containers is new
13      Generic_Containers
14        (T        => National_Date,
15         T_Access => National_Date_Access,
16         T_Cmp    => Country_Code,
17         Matches  => Matches_Country);
18
19    use National_Date_Containers;
```

(continues on next page)

(continued from previous page)

```
20
21    subtype National_Dates is Container;
22
23    Nat_Dates : constant
24                  National_Dates (1 .. 5) :=
25      (new National_Date'("USA",
26                          Time'(1776,  7,  4)),
27       new National_Date'("FRA",
28                          Time'(1789,  7, 14)),
29       new National_Date'("DEU",
30                          Time'(1990, 10,  3)),
31       new National_Date'("SPA",
32                          Time'(1492, 10, 12)),
33       new National_Date'("BRA",
34                          Time'(1822,  9,  7)));
35
36 begin
37    Find (Nat_Dates, "FRA").Show;
38 end Show_National_Dates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.User_
 ↪Defined_References.National_Dates
MD5: f4dac1fed69b9bccce5dccbf17844adc
```

Runtime output

```
Country: FRA
Year:     1789
```

Here, we instantiate the `Generic_Containers` package with the `Matches_Country` function, which is an expression function that compares the country component of the current `National_Date` reference with the name of the country we desire to learn about.

This generalized approach is actually used for the standard containers from the `Ada.Containers` packages. For example, the `Ada.Containers.Vectors` is specified as follows:

```
with Ada.Iterator_Interfaces;

generic
   type Index_Type is range <>;
   type Element_Type is private;
   with function "=" (Left, Right : Element_Type)
                     return Boolean is <>;
package Ada.Containers.Vectors
  with Preelaborate, Remote_Types,
       Nonblocking,
       Global => in out synchronized is

   -- OMITTED

   type Reference_Type
     (Element : not null access Element_Type) is
       private
         with Implicit_Dereference => Element,
              Nonblocking,
              Global => in out synchronized,
              Default_Initial_Condition =>
                (raise Program_Error);
```

(continues on next page)

(continued from previous page)

```
   -- OMITTED

   function Reference
     (Container : aliased in out Vector;
      Index     : in Index_Type)
      return Reference_Type
        with Pre  => Index in
                       First_Index (Container) ..
                       Last_Index (Container)
                     or else raise
                             Constraint_Error,
           Post =>
             Tampering_With_Cursors_Prohibited
               (Container),
           Nonblocking,
           Global => null,
           Use_Formal => null;

   -- OMITTED

   function Reference
     (Container : aliased in out Vector;
      Position  : in Cursor)
      return Reference_Type
        with Pre  => (Position /= No_Element
                      or else raise
                              Constraint_Error)
                      and then
                        (Has_Element
                          (Container, Position)
                         or else raise
                                 Program_Error),
           Post   =>
             Tampering_With_Cursors_Prohibited
               (Container),
           Nonblocking,
           Global => null,
           Use_Formal => null;

   -- OMITTED

end Ada.Containers.Vectors;
```

(Note that most parts of the `Vectors` package were omitted for clarity. Please refer to the Ada Reference Manual for the complete package specification.)

Here, we see that the `Implicit_Dereference` aspect is used in the declaration of **`Reference_Type`**, which is the reference type returned by the `Reference` functions for an index or a cursor.

Also, note that the `Vectors` package has a formal equality function (`=`) instead of the `Matches` function we were using in our **`Generic_`**`Containers` package. The purpose of the formal function, however, is basically the same.

28.2.8 Anonymous Access Types and Accessibility Rules

In general, the *accessibility rules* (page 790) we've seen earlier also apply to anonymous access types. However, there are some subtle differences, which we discuss in this section.

Let's adapt the *code example from that section* (page 790) to make use of anonymous access types:

Listing 260: library_level.ads

```
package Library_Level is

   L0_AO  : access Integer;

   L0_Var : aliased Integer;

end Library_Level;
```

Listing 261: show_library_level.adb

```
with Library_Level; use Library_Level;

procedure Show_Library_Level is
   L1_Var : aliased Integer;

   L1_AO  : access Integer;

   procedure Test is
      L2_AO  : access Integer;

      L2_Var : aliased Integer;
   begin
      L1_AO := L2_Var'Access;
      --       ^^^^^^
      --       ILLEGAL: L2 object to
      --                L1 access object

      L2_AO := L2_Var'Access;
      --       ^^^^^^
      --       LEGAL: L2 object to
      --              L2 access object
   end Test;

begin
   L0_AO := new Integer'(22);
   --       ^^^^^^^^^^^
   --       LEGAL: L0 object to
   --              L0 access object

   L0_AO := L1_Var'Access;
   --       ^^^^^^
   --       ILLEGAL: L1 object to
   --                L0 access object

   L1_AO := L0_Var'Access;
   --       ^^^^^^
   --       LEGAL: L0 object to
   --              L1 access object

   L1_AO := L1_Var'Access;
   --       ^^^^^^
   --       LEGAL: L1 object to
```

(continues on next page)

(continued from previous page)

```
43    --              L1 access object
44
45    L0_A0 := L1_A0;  -- legal!!
46    --       ^^^^^
47    --       LEGAL:   L1 access object to
48    --                L0 access object
49    --
50    --       ILLEGAL: L1 object
51    --                (L1_A0 = L1_Var'Access)
52    --                to
53    --                L0 access object
54    --
55    --       This is actually OK at compile time,
56    --       but the accessibility check fails at
57    --       runtime.
58
59    Test;
60 end Show_Library_Level;
```

```

Build output

```
show_library_level.adb:13:16: error: non-local pointer cannot point to local object
show_library_level.adb:30:13: error: non-local pointer cannot point to local object
gprbuild: *** compilation phase failed
```

As we see in the code, in general, most accessibility rules are the same as the ones we've discussed when using named access types. For example, an assignment such as `L0_A0 := L1_Var'Access` is illegal because we're trying to assign to an access object of less deep level.

However, assignment such as `L0_A0 := L1_A0` are possible now: we don't get a type mismatch — as we did with named access types — because both objects are of anonymous access types. Note that the accessibility level cannot be determined at compile time: `L1_A0` can hold an access value at library level (which would make the assignment legal) or at a deeper level. Therefore, the compiler introduces an accessibility check here.

However, the accessibility check used in `L0_A0 := L1_A0` fails at runtime because the corresponding access value (`L1_Var'Access`) is of a deeper level than `L0_A0`, which is illegal. (If you comment out the `L1_A0 := L1_Var'Access` assignment prior to the `L0_A0 := L1_A0` assignment, this accessibility check doesn't fail anymore.)

Conversions between Anonymous and Named Access Types

In the previous sections, we've discussed accessibility rules for named and anonymous access types separately. In this section, we see that the same accessibility rules apply when mixing both flavors together and converting objects of anonymous to named access types.

Let's adapt parts of the previous *code example* (page 790) and add anonymous access types to it:

Listing 262: library_level.ads

```
package Library_Level is

   type L0_Integer_Access is
     access all Integer;

   L0_Var : aliased Integer;

   L0_IA  : L0_Integer_Access;
   L0_AO  : access Integer;

end Library_Level;
```

Listing 263: show_library_level.adb

```
with Library_Level; use Library_Level;

procedure Show_Library_Level is
   type L1_Integer_Access is
     access all Integer;

   L1_IA  : L1_Integer_Access;
   L1_AO  : access Integer;

   L1_Var : aliased Integer;

begin
   ---------------------------------------
   --  From named type to anonymous type
   ---------------------------------------

   L0_IA := new Integer'(22);
   L1_IA := new Integer'(42);

   L0_AO := L0_IA;
   --       ^^^^^
   --       LEGAL: assignment from
   --              L0 access object (named type)
   --              to
   --              L0 access object
   --                (anonymous type)

   L0_AO := L1_IA;
   --       ^^^^^
   --       ILLEGAL: assignment from
   --                L1 access object (named type)
   --                to
   --                L0 access object
   --                  (anonymous type)

   L1_AO := L0_IA;
   --       ^^^^^
   --       LEGAL: assignment from
   --              L0 access object (named type)
   --              to
   --              L1 access object
   --                (anonymous type)

   L1_AO := L1_IA;
   --       ^^^^^
```

(continues on next page)

(continued from previous page)

```
   --       LEGAL: assignment from

```

Build output

```
show_library_level.adb:28:13: error: cannot convert local pointer to non-local␣
 ↪access type
gprbuild: *** compilation phase failed
```

As we can see in this code example, mixing access objects of named and anonymous access types doesn't change the accessibility rules. Again, the rules are only violated when the

target object in the assignment is *less* deep. This is the case in the `L0_A0 := L1_IA` and the `L0_IA := L0_Integer_Access (L1_A0)` assignments. Otherwise, mixing those access objects doesn't impose additional hurdles.

Accessibility rules on access parameters

In the previous chapter, we saw that the accessibility rules also apply to *access values as subprogram parameters* (page 794). In the case of access parameters, the rules are a bit less strict (as you may generally expect for anonymous access types), and the accessibility rules are checked at runtime. This allows use to use access values that would be illegal in the case of named access types because of their accessibility levels.

Let's adapt a previous code example to make use of access parameters:

Listing 264: names.ads

```
package Names is

   procedure Show (N : access constant String);

end Names;
```

Listing 265: names.adb

```
with Ada.Text_IO; use Ada.Text_IO;

--  with Ada.Characters.Handling;
--  use  Ada.Characters.Handling;

package body Names is

   procedure Show (N : access constant String) is
   begin
      --  for I in N'Range loop
      --     N (I) := To_Lower (N (I));
      --  end loop;
      Put_Line ("Name: " & N.all);
   end Show;

end Names;
```

Listing 266: show_names.adb

```
with Names; use Names;

procedure Show_Names is
   S : aliased String := "John";
begin
   Show (S'Access);
end Show_Names;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Access_Types.Accessibility_
 ↪Levels_Rules_Introduction.Accessibility_Checks_Parameters
MD5: aa930ba9be3264d01eb9115d27b884eb
```

Runtime output

```
Name: John
```

As we've seen in the previous chapter, compilation fails when we use named access types in this code example. In the case of access parameters, using S'Access doesn't make the compilation fail, nor does the accessibility check fail at runtime because S is still in scope when we call the Show procedure.

28.2.9 Anonymous Access-To-Subprograms

In the previous chapter, we talked about *named access-to-subprogram types* (page 820). Now, we'll see that the anonymous version of those types isn't much different from the named version.

Let's start our discussion by declaring a subprogram parameter using an anonymous access-to-procedure type:

Listing 267: anonymous_access_to_subprogram.ads

```
package Anonymous_Access_To_Subprogram is

   procedure Proc
     (P : access procedure (I : in out Integer));

end Anonymous_Access_To_Subprogram;
```

Listing 268: anonymous_access_to_subprogram.adb

```
package body Anonymous_Access_To_Subprogram is

   procedure Proc
     (P : access procedure (I : in out Integer))
   is
      I : Integer := 0;
   begin
      P (I);
   end Proc;

end Anonymous_Access_To_Subprogram;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_To_Subprograms.Anonymous_Access_To_Subprogram_Example
MD5: 2cbe76d7e23905d575bd27e29d5e3175
```

In this example, we use the anonymous `access procedure (I : in out Integer)` type as a parameter of the Proc procedure. Note that we need an identifier in the declaration: we cannot leave I out and write `access procedure (in out Integer)`.

Before we look at a test application that makes use of the Anonymous_Access_To_Subprogram package, let's implement two simple procedures that we'll use later on:

Listing 269: add_ten.ads

```
procedure Add_Ten (I : in out Integer);
```

Listing 270: add_ten.adb

```
procedure Add_Ten (I : in out Integer) is
begin
```

(continues on next page)

(continued from previous page)

```
   I := I + 10;
end Add_Ten;
```

Listing 271: add_twenty.ads

```
procedure Add_Twenty (I : in out Integer);
```

Listing 272: add_twenty.adb

```
procedure Add_Twenty (I : in out Integer) is
begin
   I := I + 20;
end Add_Twenty;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_To_Subprograms.Anonymous_Access_To_Subprogram_Example
MD5: 50eaeaf27caaa9618b35ecdf8acc11fe
```

Finally, this is our test application:

Listing 273: show_anonymous_access_to_subprograms.adb

```
with Anonymous_Access_To_Subprogram;
use  Anonymous_Access_To_Subprogram;

with Add_Ten;

procedure Show_Anonymous_Access_To_Subprograms is
begin
   Proc (Add_Ten'Access);
   --            ^ Getting access to Add_Ten
   --              procedure and passing it
   --              to Proc
end Show_Anonymous_Access_To_Subprograms;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_To_Subprograms.Anonymous_Access_To_Subprogram_Example
MD5: 13143ccf9620d26031484ba160a58fe1
```

Here, we get access to the Add_Ten procedure and pass it to the Proc procedure. Note that this implementation is not different from the *example for named access-to-subprogram types* (page 822). In fact, in terms of usage, anonymous access-to-subprogram types are very similar to named access-to-subprogram types. The major differences can be found in the corresponding *accessibility rules* (page 910).

In the Ada Reference Manual

- 3.10 Access Types[217]

[217] http://www.ada-auth.org/standards/22rm/html/RM-3-10.html

Examples of anonymous access-to-subprogram usage

In the section about *named access-to-subprogram types* (page 820), we've seen a couple of different usages for those types. In all those examples we discussed, we could instead have used anonymous access-to-subprogram types. Let's see a code example that illustrates that:

Listing 274: all_anonymous_access_to_subprogram.ads

```
package All_Anonymous_Access_To_Subprogram is

   --
   --  Anonymous access-to-subprogram as
   --  subprogram parameter:
   --
   procedure Proc
     (P : access procedure (I : in out Integer));

   --
   --  Anonymous access-to-subprogram in
   --  array type declaration:
   --
   type Access_To_Procedure_Array is
     array (Positive range <>) of
       access procedure (I : in out Integer);

   protected type Protected_Integer is

     procedure Mult_Ten;

     procedure Mult_Twenty;

   private
     I : Integer := 1;
   end Protected_Integer;

   --
   --  Anonymous access-to-subprogram as
   --  component of a record type.
   --
   type Rec_Access_To_Procedure is record
      AP  : access procedure (I : in out Integer);
   end record;

   --
   --  Anonymous access-to-subprogram as
   --  discriminant:
   --
   type Rec_Access_To_Procedure_Discriminant
          (AP : access procedure
                  (I : in out Integer)) is
   record
      I : Integer := 0;
   end record;

   procedure Process
     (R : in out
            Rec_Access_To_Procedure_Discriminant);

   generic
      type T is private;

```

(continues on next page)

(continued from previous page)

```
      --
      --  Anonymous access-to-subprogram as
      --  formal parameter:
      --
      Proc_T : access procedure
                  (Element : in out T);
   procedure Gen_Process (Element : in out T);

end All_Anonymous_Access_To_Subprogram;
```

Listing 275: all_anonymous_access_to_subprogram.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body All_Anonymous_Access_To_Subprogram is

   procedure Proc
     (P : access procedure (I : in out Integer))
   is
      I : Integer := 0;
   begin
      Put_Line
        ("Calling procedure for Proc...");
      P (I);
      Put_Line ("Finished.");
   end Proc;

   procedure Process
     (R : in out
            Rec_Access_To_Procedure_Discriminant)
   is
   begin
      Put_Line
        ("Calling procedure for"
         & " Rec_Access_To_Procedure_Discriminant"
         & " type...");
      R.AP (R.I);
      Put_Line ("Finished.");
   end Process;

   procedure Gen_Process (Element : in out T) is
   begin
      Put_Line
        ("Calling procedure for Gen_Process...");
      Proc_T (Element);
      Put_Line ("Finished.");
   end Gen_Process;

   protected body Protected_Integer is

      procedure Mult_Ten is
      begin
         I := I * 10;
      end Mult_Ten;

      procedure Mult_Twenty is
      begin
         I := I * 20;
      end Mult_Twenty;

   end Protected_Integer;
```

(continues on next page)

(continued from previous page)

```
50
51 end All_Anonymous_Access_To_Subprogram;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
↪Access_To_Subprograms.Anonymous_Access_To_Subprogram_Example
MD5: 628dcfdc5fe9b712f33fa044057093c2
```

In the `All_Anonymous_Access_To_Subprogram` package, we see examples of anonymous access-to-subprogram types:

- as a subprogram parameter;
- in an array type declaration;
- as a component of a record type;
- as a record type discriminant;
- as a formal parameter of a generic procedure.

Let's implement a test application that makes use of this package:

Listing 276: show_anonymous_access_to_subprograms.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  with Add_Ten;
4  with Add_Twenty;
5
6  with All_Anonymous_Access_To_Subprogram;
7  use  All_Anonymous_Access_To_Subprogram;
8
9  procedure Show_Anonymous_Access_To_Subprograms is
10    --
11    --  Anonymous access-to-subprogram as
12    --  an object:
13    --
14    P   : access procedure (I : in out Integer);
15
16    --
17    --  Array of anonymous access-to-subprogram
18    --  components
19    --
20    PA  : constant
21          Access_To_Procedure_Array (1 .. 2) :=
22            (Add_Ten'Access,
23             Add_Twenty'Access);
24
25    --
26    --  Anonymous array of anonymous
27    --  access-to-subprogram components:
28    --
29    PAA : constant
30          array (1 .. 2) of access
31            procedure (I : in out Integer) :=
32              (Add_Ten'Access,
33               Add_Twenty'Access);
34
35    --
36    --  Record with anonymous
37    --  access-to-subprogram components:
```

(continues on next page)

(continued from previous page)

```
   --
   RA : constant Rec_Access_To_Procedure :=
          (AP => Add_Ten'Access);

   --
   --  Record with anonymous
   --  access-to-subprogram discriminant:
   --
   RD : Rec_Access_To_Procedure_Discriminant
          (AP => Add_Twenty'Access) :=
            (AP => Add_Twenty'Access, I => 0);

   --
   --  Generic procedure with formal anonymous
   --  access-to-subprogram:
   --
   procedure Process_Integer is new
     Gen_Process (T      => Integer,
                  Proc_T => Add_Twenty'Access);

   --
   --  Object (APP) of anonymous
   --  access-to-protected-subprogram:
   --

In the Show_Anonymous_Access_To_Subprograms procedure, we see examples of anonymous access-to-subprogram types in:

- in objects (P) and (APP);
- in arrays (PA and PAA);
- in records (RA and RD);
- in the binding to a formal parameter (Proc_T) of an instantiated procedure (Process_Integer);
- as a parameter of a procedure (Proc).

Because we already discussed all these usages in the section about *named access-to-subprogram types* (page 820), we won't repeat this discussion here. If anything in this code example is still unclear to you, make sure to revisit that section from the previous chapter.

Application of anonymous access-to-subprogram types

In general, there isn't much that speaks against using anonymous access-to-subprogram types. We can say, for example, that they're much more useful than *anonymous access-to-objects types* (page 858), which have *many drawbacks* (page 860) — as we discussed earlier.

There isn't much to be concerned when using anonymous access-to-subprogram types. For example, we cannot allocate or deallocate a subprogram. As a consequence, we won't have storage management issues affecting these types because the access to those subprograms will always be available and no memory leak can occur.

Also, anonymous access-to-subprogram types can be easier to use than named access-to-subprogram types because of their less strict *accessibility rules* (page 910). Some of the accessibility issues we might encounter when using named access-to-subprogram types can be solved by declaring them as anonymous types. (We discuss the accessibility rules of anonymous access-to-subprogram types in the next section.)

Readability

Note that readability suffers if you use a *cascade* of anonymous access-to-subprograms. For example:

Listing 277: readability_issue.ads

```
1 package Readability_Issue is
2
3    function F
4      return access
5        function (A : Integer)
6                  return access
```

(continues on next page)

(continued from previous page)

```
                    function (B : Float)
                             return Integer;

end Readability_Issue;
```

Listing 278: readability_issue-functions.ads

```
package Readability_Issue.Functions is

   function To_Integer (V : Float)
                        return Integer is
     (Integer (V));

   function Select_Conversion
     (A : Integer)
      return access
        function (B : Float)
                  return Integer is
     (To_Integer'Access);

end Readability_Issue.Functions;
```

Listing 279: readability_issue.adb

```
with Readability_Issue.Functions;
use  Readability_Issue.Functions;

package body Readability_Issue is

   function F
     return access
       function (A : Integer)
                 return access
                   function (B : Float)
                       return Integer is
     (Select_Conversion'Access);

end Readability_Issue;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
↪Access_To_Subprograms.Readability_Issue
MD5: 9e2ac58942c97b44c0d847c28e39bd11
```

In this example, the definition of F might compile fine, but it's simply too long to be readable. Not only that: we need to carry this *chain* to other functions as well — such as the `Select_Conversion` function above. Also, using these functions in an application is not straightforward:

Listing 280: show_readability_issue.adb

```
with Readability_Issue;
use  Readability_Issue;

procedure Show_Readability_Issue is
   F1 : access
          function (A : Integer)
                    return access
                      function (B : Float)
```

(continues on next page)

(continued from previous page)

```
                                  return Integer
         := F;
   F2 : access function (B : Float)
                         return Integer
         := F1 (2);
   I  : Integer := F2 (0.1);
begin
   I := F1 (2) (0.1);
end Show_Readability_Issue;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.Anonymous_
 ↪Access_To_Subprograms.Readability_Issue
MD5: 80267b1d673663e3cacba0c4978e6abf
```

Therefore, our recommendation is to avoid this kind of *access cascading* by carefully designing your application. In general, you won't need that.

28.2.10 Accessibility Rules and Anonymous Access-To-Subprograms

In principle, the *accessibility rules for anonymous access types* (page 896) that we've seen before apply to anonymous access-to-subprograms as well. Also, we had a discussion about *accessibility rules and access-to-subprograms* (page 845) in the previous chapter. In this section, we review some of the rules that we already know and discuss how they relate to anonymous access-to-subprograms.

In the Ada Reference Manual

- 3.10 Access Types[218]

Named vs. anonymous access-to-subprograms

Let's see an example of a named access-to-subprogram type:

Listing 281: show_access_to_subprogram_error.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Access_To_Subprogram_Error is

   type PI is access
     procedure (I : in out Integer);

   P : PI;

   I : Integer := 0;
begin
   declare
      procedure Add_One (I : in out Integer) is
      begin
         I := I + 1;
      end Add_One;
```

(continues on next page)

[218] http://www.ada-auth.org/standards/22rm/html/RM-3-10.html

(continued from previous page)

```
   begin
      P := Add_One'Access;
   end;
end Show_Access_To_Subprogram_Error;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.
 ↪Accessibility_Rules_Anonymous_Access_To_Subprograms.Simple_Example_Named
MD5: 41c36426112e799210b7704dd43b6217
```

Build output

```
show_access_to_subprogram_error.adb:18:12: error: subprogram must not be deeper␣
 ↪than access type
gprbuild: *** compilation phase failed
```

In this example, we get a compilation error because the lifetime of the Add_One procedure is shorter than the access type PI.

In contrast, using an anonymous access-to-subprogram type eliminates the compilation error, i.e. the assignment P := Add_One'Access becomes legal:

Listing 282: show_access_to_subprogram_error.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Access_To_Subprogram_Error is
   P : access procedure (I : in out Integer);

   I : Integer := 0;
begin
   declare
      procedure Add_One (I : in out Integer) is
      begin
         I := I + 1;
      end Add_One;
   begin
      P := Add_One'Access;
      --  RUNTIME ERROR: Add_One is out-of-scope
      --                 after this line.
   end;
end Show_Access_To_Subprogram_Error;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.
 ↪Accessibility_Rules_Anonymous_Access_To_Subprograms.Simple_Example_Anonymous
MD5: a5eeb4a716b4f6a932dd74c580a07b66
```

Runtime output

```

raised PROGRAM_ERROR : show_access_to_subprogram_error.adb:14 accessibility check␣
 ↪failed
```

In this case, the compiler introduces an accessibility check, which fails at runtime because the lifetime of Add_One is shorter than the lifetime of the access object P.

Named vs. anonymous access-to-subprograms as parameters

Using anonymous access-to-subprograms as parameters allows us to pass subprograms at any level. For certain applications, the restrictions that are applied to named access types might be too strict, so using anonymous access-to-subprograms might be a good way to circumvent those restrictions. They also allow the component developer to be independent of the clients' specific access types.

Note that the increased flexibility for anonymous access-to-subprograms means that some of the checks that are performed at compile time for named access-to-subprograms are done at runtime for anonymous access-to-subprograms.

Named access-to-subprograms as a parameter

Let's see an example using a named access-to-procedure type:

Listing 283: access_to_subprogram_types.ads

```
package Access_To_Subprogram_Types is

   type Integer_Array is
     array (Positive range <>) of Integer;

   type Process_Procedure is
     access
       procedure (Arr : in out Integer_Array);

   procedure Process
     (Arr : in out Integer_Array;
      P   :        Process_Procedure);

end Access_To_Subprogram_Types;
```

Listing 284: access_to_subprogram_types.adb

```
package body Access_To_Subprogram_Types is

   procedure Process
     (Arr : in out Integer_Array;
      P   :        Process_Procedure) is
   begin
      P (Arr);
   end Process;

end Access_To_Subprogram_Types;
```

Listing 285: show_access_to_subprogram_error.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Access_To_Subprogram_Types;
use  Access_To_Subprogram_Types;

procedure Show_Access_To_Subprogram_Error is

   procedure Add_One
     (Arr : in out Integer_Array) is
   begin
      for E of Arr loop
```

(continues on next page)

(continued from previous page)

```
12          E := E + 1;
13       end loop;
14    end Add_One;
15
16    procedure Display
17      (Arr : in out Integer_Array) is
18    begin
19       for I in Arr'Range loop
20          Put_Line ("Arr (" &
21                    Integer'Image (I)
22                    & "): "
23                   & Integer'Image (Arr (I)));
24       end loop;
25    end Display;
26
27    Arr : Integer_Array (1 .. 3) := (1, 2, 3);
28 begin
29    Process (Arr, Display'Access);
30
31    Put_Line ("Add_One...");
32    Process (Arr, Add_One'Access);
33
34    Process (Arr, Display'Access);
35 end Show_Access_To_Subprogram_Error;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.
 ↪Accessibility_Rules_Anonymous_Access_To_Subprograms.Access_To_Subprogram_
 ↪Parameter_Named
MD5: 76b70b52a0374fe0fd398024fe869876
```

Build output

```
show_access_to_subprogram_error.adb:29:18: error: subprogram must not be deeper␣
 ↪than access type
show_access_to_subprogram_error.adb:32:18: error: subprogram must not be deeper␣
 ↪than access type
show_access_to_subprogram_error.adb:34:18: error: subprogram must not be deeper␣
 ↪than access type
gprbuild: *** compilation phase failed
```

In this example, we declare the `Process_Procedure` type in the `Access_To_Subprogram_Types` package and use it in the `Process` procedure, which we call in the `Show_Access_To_Subprogram_Error` procedure. The accessibility rules trigger a compilation error because the accesses (`Add_One'Access` and `Display'Access`) are at a deeper level than the access-to-procedure type (`Process_Procedure`).

As we know already, there's no `Unchecked_Access` attribute that we could use here. An easy way to make this code compile could be to move `Add_One` and `Display` to the library level.

Anonymous access-to-subprograms as a parameter

To circumvent the compilation error, we could also use anonymous access-to-subprograms instead:

Listing 286: access_to_subprogram_types.ads

```
package Access_To_Subprogram_Types is

   type Integer_Array is
     array (Positive range <>) of Integer;

   procedure Process
     (Arr : in out Integer_Array;
      P   : access procedure
               (Arr : in out Integer_Array));

end Access_To_Subprogram_Types;
```

Listing 287: access_to_subprogram_types.adb

```
package body Access_To_Subprogram_Types is

   procedure Process
     (Arr : in out Integer_Array;
      P   : access procedure
               (Arr : in out Integer_Array)) is
   begin
      P (Arr);
   end Process;

end Access_To_Subprogram_Types;
```

Listing 288: show_access_to_subprogram_error.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Access_To_Subprogram_Types;
use  Access_To_Subprogram_Types;

procedure Show_Access_To_Subprogram_Error is

   procedure Add_One
     (Arr : in out Integer_Array) is
   begin
      for E of Arr loop
         E := E + 1;
      end loop;
   end Add_One;

   procedure Display
     (Arr : in out Integer_Array) is
   begin
      for I in Arr'Range loop
         Put_Line ("Arr (" &
                   Integer'Image (I)
                   & "): "
                  & Integer'Image (Arr (I)));
      end loop;
   end Display;

```

(continues on next page)

(continued from previous page)

```
27    Arr : Integer_Array (1 .. 3) := (1, 2, 3);
28 begin
29    Process (Arr, Display'Access);
30
31    Put_Line ("Add_One...");
32    Process (Arr, Add_One'Access);
33
34    Process (Arr, Display'Access);
35 end Show_Access_To_Subprogram_Error;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.
 ↪Accessibility_Rules_Anonymous_Access_To_Subprograms.Access_To_Subprogram_
 ↪Parameter_Anonymous
MD5: a500e0a864f0adadc1d6823c1f50bd64
```

Runtime output

```
Arr ( 1):  1
Arr ( 2):  2
Arr ( 3):  3
Add_One...
Arr ( 1):  2
Arr ( 2):  3
Arr ( 3):  4
```

Now, the code is accepted by the compiler because anonymous access-to-subprograms used as parameters allow passing of subprograms at any level. Also, we don't see a runtime exception because the subprograms are still *accessible* when we call `Process`.

Iterator

A typical example that illustrates well the necessity of using anonymous access-to-subprograms is that of a container iterator. In fact, many of the standard Ada containers — the child packages of `Ada.Containers` — make use of anonymous access-to-subprograms for their `Iterate` subprograms.

In the Ada Reference Manual

- A.18.2 The Package Containers.Vectors[219]
- A.18.4 Maps[220]
- A.18.7 Sets[221]

---

[219] http://www.ada-auth.org/standards/22rm/html/RM-A-18-2.html
[220] http://www.ada-auth.org/standards/22rm/html/RM-A-18-4.html
[221] http://www.ada-auth.org/standards/22rm/html/RM-A-18-7.html

Using named access-to-subprograms

Let's start with a simplified container type (`Data_Container`) using a named access-to-subprogram type (`Process_Element`) for iteration:

Listing 289: data_processing.ads

```
generic
   type Element is private;
package Data_Processing is

   type Data_Container (Last : Positive) is
     private;

   Data_Container_Full : exception;

   procedure Append (D : in out Data_Container;
                     E :        Element);

   type Process_Element is
     not null access procedure (E : Element);

   procedure Iterate
     (D    : Data_Container;
      Proc : Process_Element);

private

   type Data_Container_Storage is
     array (Positive range <>) of Element;

   type Data_Container (Last : Positive) is
   record
      S    : Data_Container_Storage (1 .. Last);
      Curr : Natural := 0;
   end record;

end Data_Processing;
```

Listing 290: data_processing.adb

```
package body Data_Processing is

   procedure Append (D : in out Data_Container;
                     E :        Element) is
   begin
      if D.Curr < D.S'Last then
         D.Curr := D.Curr + 1;
         D.S (D.Curr) := E;
      else
         raise Data_Container_Full;
         --  NOTE: This is just a dummy
         --        implementation. A better
         --        strategy is to add actual error
         --        handling when the container is
         --        full.
      end if;
   end Append;

   procedure Iterate
     (D    : Data_Container;
      Proc : Process_Element) is
```

(continues on next page)

(continued from previous page)

```
   begin
      for I in D.S'First .. D.Curr loop
         Proc (D.S (I));
      end loop;
   end Iterate;

end Data_Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.
 ↪Accessibility_Rules_Anonymous_Access_To_Subprograms.Iterator_Named
MD5: e48e8200e571b62d027753ee96c47fcb
```

In this example, we declare the `Process_Element` type in the generic `Data_Processing` package, and we use it in the `Iterate` procedure. We then instantiate this package as `Float_Data_Processing`, and we use it in the `Show_Access_To_Subprograms` procedure:

Listing 291: float_data_processing.ads

```
with Data_Processing;

package Float_Data_Processing is
  new Data_Processing (Element => Float);
```

Listing 292: show_access_to_subprograms.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Float_Data_Processing;
use  Float_Data_Processing;

procedure Show_Access_To_Subprograms is

   procedure Display (F : Float) is
   begin
      Put_Line ("F :" & Float'Image (F));
   end Display;

   D : Data_Container (5);
begin
    Append (D, 1.0);
    Append (D, 2.0);
    Append (D, 3.0);

    Iterate (D, Display'Access);
end Show_Access_To_Subprograms;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.
 ↪Accessibility_Rules_Anonymous_Access_To_Subprograms.Iterator_Named
MD5: 64ee435aac5f2817b7d9cecf538a1e4c
```

Build output

```
show_access_to_subprograms.adb:19:17: error: subprogram must not be deeper than␣
 ↪access type
gprbuild: *** compilation phase failed
```

Using `Display'Access` in the call to `Iterate` triggers a compilation error because its life-

time is shorter than the lifetime of the `Process_Element` type.

Using anonymous access-to-subprograms

Now, let's use an anonymous access-to-subprogram type in the `Iterate` procedure:

Listing 293: data_processing.ads

```
generic
   type Element is private;
package Data_Processing is

   type Data_Container (Last : Positive) is
     private;

   Data_Container_Full : exception;

   procedure Append (D : in out Data_Container;
                     E :        Element);

   procedure Iterate
     (D    : Data_Container;
      Proc : not null access
                procedure (E : Element));

private

   type Data_Container_Storage is
     array (Positive range <>) of Element;

   type Data_Container (Last : Positive) is
   record
      S    : Data_Container_Storage (1 .. Last);
      Curr : Natural := 0;
   end record;

end Data_Processing;
```

Listing 294: data_processing.adb

```
package body Data_Processing is

   procedure Append (D : in out Data_Container;
                     E :        Element) is
   begin
      if D.Curr < D.S'Last then
         D.Curr := D.Curr + 1;
         D.S (D.Curr) := E;
      else
         raise Data_Container_Full;
         --  NOTE: This is just a dummy
         --        implementation. A better
         --        strategy is to add actual error
         --        handling when the container is
         --        full.
      end if;
   end Append;

   procedure Iterate
     (D    : Data_Container;
```

(continues on next page)

(continued from previous page)

```
      Proc : not null access
                procedure (E : Element)) is
   begin
      for I in D.S'First .. D.Curr loop
         Proc (D.S (I));
      end loop;
   end Iterate;

end Data_Processing;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.
 ↪Accessibility_Rules_Anonymous_Access_To_Subprograms.Iterator_Anonymous
MD5: fa56595ef1734f2f07ad719c36dfd8b5
```

Note that the only changes we did to the package were to remove the `Process_Element` type and replace the type of the `Proc` parameter of the `Iterate` procedure from a named type (`Process_Element`) to an anonymous type (`not null access procedure (E : Element)`).

Now, the same test application we used before (`Show_Access_To_Subprograms`) compiles as expected:

Listing 295: float_data_processing.ads

```
with Data_Processing;

package Float_Data_Processing is
  new Data_Processing (Element => Float);
```

Listing 296: show_access_to_subprograms.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Float_Data_Processing;
use  Float_Data_Processing;

procedure Show_Access_To_Subprograms is

   procedure Display (F : Float) is
   begin
      Put_Line ("F :" & Float'Image (F));
   end Display;

   D : Data_Container (5);
begin
    Append (D, 1.0);
    Append (D, 2.0);
    Append (D, 3.0);

    Iterate (D, Display'Access);
end Show_Access_To_Subprograms;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Anonymous_Access_Types.
 ↪Accessibility_Rules_Anonymous_Access_To_Subprograms.Iterator_Anonymous
MD5: 64ee435aac5f2817b7d9cecf538a1e4c
```

Runtime output

```
F : 1.00000E+00
F : 2.00000E+00
F : 3.00000E+00
```

Remember that the compiler introduces an accessibility check in the call to `Iterate`, which is successful because the lifetime of `Display'Access` is the same as the lifetime of the `Proc` parameter of `Iterate`.

28.3 Limited Types

So far, we discussed nonlimited types in most cases. In this chapter, we discuss limited types.

We can think of limited types as an easy way to avoid inappropriate semantics. For example, a lock should not be copied — neither directly, via assignment, nor with pass-by-copy. Similarly, a *file*, which is really a file descriptor, should not be copied. In this chapter, we'll see example of unwanted side-effects that arise if we don't use limited types for these cases.

28.3.1 Assignment and equality

Limited types have the following restrictions, which we discussed in the *Introduction to Ada* (page 116) course:

- copying objects of limited types via direct assignments is forbidden; and
- there's no predefined equality operator for limited types.

(Of course, in the case of nonlimited types, assignments are possible and the equality operator is available.)

By having these restrictions for limited types, we avoid inappropriate side-effects for assignment and equality operations. As an example of inappropriate side-effects, consider the case when we apply those operations on record types that have components of access types:

Listing 297: nonlimited_types.ads

```
1  package Nonlimited_Types is
2
3     type Simple_Rec is private;
4
5     type Integer_Access is access Integer;
6
7     function Init (I : Integer) return Simple_Rec;
8
9     procedure Set (E : Simple_Rec;
10                   I : Integer);
11
12    procedure Show (E      : Simple_Rec;
13                    E_Name : String);
14
15 private
16
17    type Simple_Rec is record
18       V : Integer_Access;
19    end record;
```

(continues on next page)

(continued from previous page)

```
20
21 end Nonlimited_Types;
```

Listing 298: nonlimited_types.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Nonlimited_Types is
4
5     function Init (I : Integer) return Simple_Rec
6     is
7     begin
8        return E : Simple_Rec do
9           E.V := new Integer'(I);
10       end return;
11    end Init;
12
13    procedure Set (E : Simple_Rec;
14                   I : Integer) is
15    begin
16       E.V.all := I;
17    end Set;
18
19    procedure Show (E      : Simple_Rec;
20                    E_Name : String) is
21    begin
22       Put_Line (E_Name
23                 & ".V.all = "
24                 & Integer'Image (E.V.all));
25    end Show;
26
27 end Nonlimited_Types;
```

Listing 299: show_wrong_assignment_equality.adb

A.V.all =  7
B.V.all =  7
A = B
--------
```

In this code, we declare the `Simple_Rec` type in the `Nonlimited_Types` package and use it in the `Show_Wrong_Assignment_Equality` procedure. In principle, we're already doing many things right here. For example, we're declaring the `Simple_Rec` type private, so that the component `V` of access type is encapsulated. Programmers that declare objects of this type cannot simply mess up with the `V` component. Instead, they have to call the `Init` function and the `Set` procedure to initialize and change, respectively, objects of the `Simple_Rec` type. That being said, there are two problems with this code, which we discuss next.

The first problem we can identify is that the first call to `Show_Compare` shows that `A` and `B`

are different, although both have the same value in the V component (`A.V.all = 0` and `B.V.all = 0`) — this was set by the call to the `Init` function. What's happening here is that the `A = B` expression is comparing the access values (`A.V = B.V`), while we might have been expecting it to compare the actual integer values after dereferencing (`A.V.all = B.V.all`). Therefore, the predefined equality function of the `Simple_Rec` type is useless and dangerous for us, as it misleads us to expect something that it doesn't do.

After the assignment of A to B (`B := A`), the information that the application displays seems to be correct — both `A.V.all` and `B.V.all` have the same value of two. However, when assigning the value seven to B by calling `Set (B, 7)`, we see that the value of `A.V.all` has also changed. What's happening here is that the previous assignment (`B := A`) has actually assigned access values (`B.V := A.V`), while we might have been expecting it to assign the dereferenced values (`B.V.all := A.V.all`). Therefore, we cannot simply directly assign objects of `Simple_Rec` type, as this operation changes the internal structure of the type due to the presence of components of access type.

For these reasons, forbidding these operations for the `Simple_Rec` type is the most appropriate software design decision. If we still need assignment and equality operators, we can implement custom subprograms for the limited type. We'll discuss this topic in the next sections.

In addition to the case when we have components of access types, limited types are useful for example when we want to avoid the situation in which the same information is copied to multiple objects of the same type.

In the Ada Reference Manual

- 7.5 Limited Types[222]

Assignments

Assignments are forbidden when using objects of limited types. For example:

Listing 300: limited_types.ads

```
package Limited_Types is

   type Simple_Rec is limited private;

   type Integer_Access is access Integer;

   function Init (I : Integer) return Simple_Rec;

private

   type Simple_Rec is limited record
      V : Integer_Access;
   end record;

end Limited_Types;
```

Listing 301: limited_types.adb

```
package body Limited_Types is

   function Init (I : Integer) return Simple_Rec
   is
```

(continues on next page)

[222] http://www.ada-auth.org/standards/22rm/html/RM-7-5.html

(continued from previous page)

```
   begin
      return E : Simple_Rec do
         E.V := new Integer'(I);
      end return;
   end Init;

end Limited_Types;
```

Listing 302: show_limited_assignment.adb

```
with Limited_Types; use Limited_Types;

procedure Show_Limited_Assignment is
   A, B : Simple_Rec := Init (0);
begin
   B := A;
end Show_Limited_Assignment;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Assignment_
 ↪Equality.Assignment
MD5: 019c16f7feac896fd8c37d40d0522dc8
```

Build output

```
show_limited_assignment.adb:6:04: error: left hand of assignment must not be␣
 ↪limited type
gprbuild: *** compilation phase failed
```

In this example, we declare the limited private type `Simple_Rec` and two objects of this type (`A` and `B`) in the `Show_Limited_Assignment` procedure. (We discuss more about limited private types *later* (page 928)).

As expected, we get a compilation error for the `B := A` statement (in the `Show_Limited_Assignment` procedure). If we need to copy two objects of limited type, we have to provide a custom procedure to do that. For example, we can implement a `Copy` procedure for the `Simple_Rec` type:

Listing 303: limited_types.ads

```
package Limited_Types is

   type Integer_Access is access Integer;

   type Simple_Rec is limited private;

   function Init (I : Integer) return Simple_Rec;

   procedure Copy (From :        Simple_Rec;
                   To   : in out Simple_Rec);

private

   type Simple_Rec is limited record
      V : Integer_Access;
   end record;

end Limited_Types;
```

Listing 304: limited_types.adb

```
package body Limited_Types is

   function Init (I : Integer) return Simple_Rec
   is
   begin
      return E : Simple_Rec do
         E.V := new Integer'(I);
      end return;
   end Init;

   procedure Copy (From :        Simple_Rec;
                   To   : in out Simple_Rec)
   is
   begin
      --  Copying record components
      To.V.all := From.V.all;
   end Copy;

end Limited_Types;
```

Listing 305: show_limited_assignment.adb

```
with Limited_Types; use Limited_Types;

procedure Show_Limited_Assignment is
   A, B : Simple_Rec := Init (0);
begin
   Copy (From => A, To => B);
end Show_Limited_Assignment;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Assignment_
 ↪Equality.Assignment
MD5: 2c017c3592c93be8c19fe247e9241fcb
```

The Copy procedure from this example copies the dereferenced values of `From` to `To`, which matches our expectation for the `Simple_Rec`. Note that we could have also implemented a `Shallow_Copy` procedure to copy the actual access values (i.e. `To.V := From.V`). However, having this kind of procedure can be dangerous in many case, so this design decision must be made carefully. In any case, using limited types ensures that only the assignment subprograms that are explicitly declared in the package specification are available.

Equality

Limited types don't have a predefined equality operator. For example:

Listing 306: limited_types.ads

```
package Limited_Types is

   type Integer_Access is access Integer;

   type Simple_Rec is limited private;

   function Init (I : Integer) return Simple_Rec;

```

(continues on next page)

(continued from previous page)

```
private

   type Simple_Rec is limited record
      V : Integer_Access;
   end record;

end Limited_Types;
```

Listing 307: limited_types.adb

```
package body Limited_Types is

   function Init (I : Integer) return Simple_Rec
   is
   begin
      return E : Simple_Rec do
         E.V := new Integer'(I);
      end return;
   end Init;

end Limited_Types;
```

Listing 308: show_limited_equality.adb

```
with Ada.Text_IO;   use Ada.Text_IO;
with Limited_Types; use Limited_Types;

procedure Show_Limited_Equality is
   A : Simple_Rec := Init (5);
   B : Simple_Rec := Init (6);
begin
   if A = B then
      Put_Line ("A = B");
   else
      Put_Line ("A /= B");
   end if;
end Show_Limited_Equality;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Assignment_
 ↪Equality.Equality
MD5: dad31b5e36de0b3b7824f723a60e5aa0
```

Build output

```
show_limited_equality.adb:8:09: error: there is no applicable operator "=" for␣
 ↪private type "Simple_Rec" defined at limited_types.ads:5
gprbuild: *** compilation phase failed
```

As expected, the comparison `A = B` triggers a compilation error because no predefined `=` operator is available for the `Simple_Rec` type. If we want to be able to compare objects of this type, we have to implement the `=` operator ourselves. For example, we can do that for the `Simple_Rec` type:

Listing 309: limited_types.ads

```
package Limited_Types is

   type Integer_Access is access Integer;
```

(continues on next page)

(continued from previous page)

```
4
5     type Simple_Rec is limited private;
6
7     function Init (I : Integer) return Simple_Rec;
8
9     function "=" (Left, Right : Simple_Rec)
10                  return Boolean;
11
12 private
13
14    type Simple_Rec is limited record
15       V : Integer_Access;
16    end record;
17
18 end Limited_Types;
```

Listing 310: limited_types.adb

```
1  package body Limited_Types is
2
3     function Init (I : Integer) return Simple_Rec
4     is
5     begin
6        return E : Simple_Rec do
7           E.V := new Integer'(I);
8        end return;
9     end Init;
10
11    function "=" (Left, Right : Simple_Rec)
12                  return Boolean is
13    begin
14       --  Comparing record components
15       return Left.V.all = Right.V.all;
16    end "=";
17
18 end Limited_Types;
```

Listing 311: show_limited_equality.adb

```
1  with Ada.Text_IO;   use Ada.Text_IO;
2  with Limited_Types; use Limited_Types;
3
4  procedure Show_Limited_Equality is
5     A : Simple_Rec := Init (5);
6     B : Simple_Rec := Init (6);
7  begin
8     if A = B then
9        Put_Line ("A = B");
10    else
11       Put_Line ("A /= B");
12    end if;
13 end Show_Limited_Equality;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Assignment_
 ↪Equality.Equality
MD5: f56b2229443a5e4e33c402b41b02d318
```

Runtime output

```
A /= B
```

Here, the = operator compares the dereferenced values of `Left.V` and `Right.V`, which matches our expectation for the `Simple_Rec` type. Declaring types as limited ensures that we don't have unreasonable equality comparisons, and allows us to create reasonable replacements when required.

In other languages

In C++, you can overload the assignment operator. For example:

```
class Simple_Rec
{
public:
    // Overloaded assignment
    Simple_Rec& operator= (const Simple_Rec& obj);
private:
int *V;
};
```

In Ada, however, we can only define the equality operator (=). Defining the assignment operator (:=) is not possible. The following code triggers a compilation error as expected:

```
package Limited_Types is

   type Integer_Access is access Integer;

   type Simple_Rec is limited private;

   procedure ":=" (To   : in out Simple_Rec
                   From :        Simple_Rec);

   -- ...

end Limited_Types;
```

28.3.2 Limited private types

As we've seen in code examples from the previous section, we can apply *information hiding* (page 307) to limited types. In other words, we can declare a type as **`limited private`** instead of just **`limited`**. For example:

Listing 312: simple_recs.ads

```
1  package Simple_Recs is
2
3     type Rec is limited private;
4
5  private
6
7     type Rec is limited record
8        I : Integer;
9     end record;
10
11 end Simple_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Private_
↪Types.Limited_Private
MD5: ececb364f5365a74db43952e9421dee0
```

In this case, in addition to the fact that assignments are forbidden for objects of this type (because Rec is limited), we cannot access the record components.

Note that in this example, both partial and full views of the Rec record are of limited type. In the next sections, we discuss how the partial and full views can have non-matching declarations.

In the Ada Reference Manual

- 7.5 Limited Types[223]

Non-Record Limited Types

In principle, only record types can be declared limited, so we cannot use scalar or array types. For example, the following declarations won't compile:

Listing 313: non_record_limited_error.ads

```
1  package Non_Record_Limited_Error is
2
3     type Limited_Enumeration is
4       limited (Off, On);
5
6     type Limited_Integer is new
7       limited Integer;
8
9     type Integer_Array is
10      array (Positive range <>) of Integer;
11
12    type Rec is new
13      limited Integer_Array (1 .. 2);
14
15 end Non_Record_Limited_Error;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Private_
↪Types.Non_Record_Limited_Error
MD5: c155e02d809caf28352cbbb579deb861
```

However, we've mentioned *in a previous chapter* (page 309) that private types don't have to be record types necessarily. In this sense, limited private types makes it possible for us to use types other than record types in the full view and still benefit from the restrictions of limited types. For example:

Listing 314: simple_recs.ads

```
1  package Simple_Recs is
2
3     type Limited_Enumeration is
4       limited private;
5
6     type Limited_Integer is
```

(continues on next page)

[223] http://www.ada-auth.org/standards/22rm/html/RM-7-5.html

(continued from previous page)

```
     limited private;

   type Limited_Integer_Array_2 is
     limited private;

private

   type Limited_Enumeration is (Off, On);

   type Limited_Integer is new Integer;

   type Integer_Array is
     array (Positive range <>) of Integer;

   type Limited_Integer_Array_2 is
     new Integer_Array (1 .. 2);

end Simple_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Private_
 ↪Types.Non_Record_Limited
MD5: 9e65b56a5cb3d7a3da11c7f63ee9bb19
```

Here, `Limited_Enumeration`, `Limited_Integer`, and `Limited_Integer_Array_2` are limited private types that encapsulate an enumeration type, an integer type, and a constrained array type, respectively.

Partial and full view of limited types

In the previous example, both partial and full views of the Rec type were limited. We may actually declare a type as **`limited private`** (in the public part of a package), while its full view is nonlimited. For example:

Listing 315: simple_recs.ads

```
package Simple_Recs is

   type Rec is limited private;
   --  Partial view of Rec is limited

private

   type Rec is record
   --  Full view of Rec is nonlimited
      I : Integer;
   end record;

end Simple_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Private_
 ↪Types.Limited_Partial_Full_View
MD5: 5d0dbc3e87531476856f0ac1f9b22c78
```

In this case, only the partial view of Rec is limited, while its full view is nonlimited. When deriving from Rec, the view of the derived type is the same as for the parent type:

Listing 316: simple_recs-child.ads

```
package Simple_Recs.Child
is
   type Rec_Derived is new Rec;
   --  As for its parent, the
   --  partial view of Rec_Derived
   --  is limited, but the full view
   --  is nonlimited.

end Simple_Recs.Child;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Private_
 ↪Types.Limited_Partial_Full_View
MD5: fdf0ffa87ac2b8766830bf8e17ac7b5e
```

Clients must nevertheless comply with their partial view, and treat the type as if it is in fact limited. In other words, if you use the Rec type in a subprogram or package outside of the Simple_Recs package (or its child packages), the type is limited from that perspective:

Listing 317: use_rec_in_subprogram.adb

```
with Simple_Recs; use Simple_Recs;

procedure Use_Rec_In_Subprogram is
   R1, R2 : Rec;
begin
   R1.I := 1;
   R2   := R1;
end Use_Rec_In_Subprogram;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Private_
 ↪Types.Limited_Partial_Full_View
MD5: f0af323a951853b97a2b67ce9b13e732
```

Build output

```
use_rec_in_subprogram.adb:6:04: error: invalid prefix in selected component "R1"
use_rec_in_subprogram.adb:7:04: error: left hand of assignment must not be limited␣
 ↪type
gprbuild: *** compilation phase failed
```

Here, compilation fails because the type Rec is limited from the procedure's perspective.

Limitations

Note that the opposite — declaring a type as **private** and its full full view as **limited private** — is not possible. For example:

Listing 318: simple_recs.ads

```
package Simple_Recs is

   type Rec is private;

```

(continues on next page)

(continued from previous page)

```
private

   type Rec is limited record
      I : Integer;
   end record;

end Simple_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Private_
 ↪Types.Limited_Partial_Full_View
MD5: ec1c8a2dcf3cc2c49b1497cf4c9d3a5a
```

Build output

```
use_rec_in_subprogram.adb:6:04: error: invalid prefix in selected component "R1"
simple_recs.ads:7:09: error: completion of nonlimited type cannot be limited
gprbuild: *** compilation phase failed
```

As expected, we get a compilation error in this case. The issue is that the partial view cannot be allowed to mislead the client about what's possible. In this case, if the partial view allows assignment, then the full view must actually provide assignment. But the partial view can restrict what is actually possible, so a limited partial view need not be completed in the full view as a limited type.

In addition, tagged limited private types cannot have a nonlimited full view. For example:

Listing 319: simple_recs.ads

```
package Simple_Recs is

   type Rec is tagged limited private;

private

   type Rec is tagged record
      I : Integer;
   end record;

end Simple_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Private_
 ↪Types.Limited_Partial_Full_View
MD5: cadb9ca1346a98fb65f9059fdb29f865
```

Build output

```
simple_recs.ads:7:09: error: completion of limited tagged type must be limited
gprbuild: *** compilation phase failed
```

Here, compilation fails because the type Rec is nonlimited in its full view.

Limited and nonlimited in full view

Declaring the full view of a type as limited or nonlimited has implications in the way we can use objects of this type in the package body. For example:

Listing 320: simple_recs.ads

```
package Simple_Recs is

   type Rec_Limited_Full is limited private;
   type Rec_Nonlimited_Full is limited private;

   procedure Copy
     (From :        Rec_Limited_Full;
      To   : in out Rec_Limited_Full);
   procedure Copy
     (From :        Rec_Nonlimited_Full;
      To   : in out Rec_Nonlimited_Full);

private

   type Rec_Limited_Full is limited record
      I : Integer;
   end record;

   type Rec_Nonlimited_Full is record
      I : Integer;
   end record;

end Simple_Recs;
```

Listing 321: simple_recs.adb

```
package body Simple_Recs is

   procedure Copy
     (From :        Rec_Limited_Full;
      To   : in out Rec_Limited_Full)
   is
   begin
      To := From;
      --  ERROR: assignment is forbidden because
      --         Rec_Limited_Full is limited in
      --         its full view.
   end Copy;

   procedure Copy
     (From :        Rec_Nonlimited_Full;
      To   : in out Rec_Nonlimited_Full)
   is
   begin
      To := From;
      --  OK: assignment is allowed because
      --      Rec_Nonlimited_Full is
      --      nonlimited in its full view.
   end Copy;

end Simple_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Private_
↪Types.Limited_Non_Limited_Partial_Full_View
MD5: 24b75bb97ddd485bd6825bb8647607c1
```

Build output

```
simple_recs.adb:8:07: error: left hand of assignment must not be limited type
gprbuild: *** compilation phase failed
```

Here, both Rec_Limited_Full and Rec_Nonlimited_Full are declared as **private limited**. However, Rec_Limited_Full type is limited in its full view, while Rec_Nonlimited_Full is nonlimited. As expected, the compiler complains about the To := From assignment in the Copy procedure for the Rec_Limited_Full type because its full view is limited (so no assignment is possible). Of course, in the case of the objects of Rec_Nonlimited_Full type, this assignment is perfectly fine.

Limited private component

Another example mentioned by the Ada Reference Manual (7.3.1[224], 5/1) is about an array type whose component type is limited private, but nonlimited in its full view. Let's see a complete code example for that:

Listing 322: limited_nonlimited_arrays.ads

```
1  package Limited_Nonlimited_Arrays is
2
3     type Limited_Private is
4       limited private;
5
6     function Init return Limited_Private;
7
8     --  The array type Limited_Private_Array
9     --  is limited because the type of its
10    --  component is limited.
11    type Limited_Private_Array is
12      array (Positive range <>) of
13        Limited_Private;
14
15 private
16
17    type Limited_Private is
18    record
19       A : Integer;
20    end record;
21
22    --  Limited_Private_Array type is
23    --  nonlimited at this point because
24    --  its component is nonlimited.
25    --
26    --  The assignments below are OK:
27    A1 : Limited_Private_Array (1 .. 5);
28
29    A2 : Limited_Private_Array := A1;
30
31 end Limited_Nonlimited_Arrays;
```

[224] http://www.ada-auth.org/standards/22rm/html/RM-7-3-1.html

Listing 323: limited_nonlimited_arrays.adb

```
package body Limited_Nonlimited_Arrays is

   function Init return Limited_Private is
     ((A => 1));

end Limited_Nonlimited_Arrays;
```

Listing 324: show_limited_nonlimited_array.adb

```
with Limited_Nonlimited_Arrays;
use  Limited_Nonlimited_Arrays;

procedure Show_Limited_Nonlimited_Array is
   A3 : Limited_Private_Array (1 .. 2) :=
          (others => Init);
   A4 : Limited_Private_Array (1 .. 2);
begin
   --  ERROR: this assignment is illegal because
   --  Limited_Private_Array is limited, as
   --  its component is limited at this point.
   A4 := A3;
end Show_Limited_Nonlimited_Array;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Private_
 ↪Types.Limited_Nonlimited_Array
MD5: 211670e99e6e3a63a785bb2dde255b58
```

Build output

```
show_limited_nonlimited_array.adb:12:04: error: left hand of assignment must not␣
 ↪be limited type
show_limited_nonlimited_array.adb:12:04: error: component type "Limited_Private"␣
 ↪of subtype of "Limited_Private_Array" is limited
gprbuild: *** compilation phase failed
```

As we can see in this example, the limitedness of the array type `Limited_Private_Array` depends on the limitedness of its component type `Limited_Private`. In the private part of `Limited_Nonlimited_Arrays` package, where `Limited_Private` is nonlimited, the array type `Limited_Private_Array` becomes nonlimited as well. In contrast, in the `Show_Limited_Nonlimited_Array`, the array type is limited because its component is limited in that scope.

In the Ada Reference Manual

- 7.3.1 Private Operations[225]

[225] http://www.ada-auth.org/standards/22rm/html/RM-7-3-1.html

Tagged limited private types

For tagged private types, the partial and full views must match: if a tagged type is limited in the partial view, it must be limited in the full view. For example:

Listing 325: simple_recs.ads

```
package Simple_Recs is

   type Rec is tagged limited private;

private

   type Rec is tagged limited record
      I : Integer;
   end record;

end Simple_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Private_
 ↪Types.Tagged_Limited_Private_Types
MD5: bee48bd7e0d70ddfd288c0de5e21b039
```

Here, the tagged Rec type is limited both in its partial and full views. Any mismatch in one of the views triggers a compilation error. (As an exercise, you may remove any of the **limited** keywords from the code example and try to compile it.)

For further reading...

This rule is for the sake of dynamic dispatching and classwide types. The compiler must not allow any of the types in a derivation class — the set of types related by inheritance — to be different regarding assignment and equality (and thus inequality). That's necessary because we are meant to be able to manipulate objects of any type in the entire set of types via the partial view presented by the root type, without knowing which specific tagged type is involved.

28.3.3 Explicitly limited types

Under certain conditions, limited types can be called explicitly limited — note that using the **limited** keyword in a part of the declaration doesn't necessary ensure this, as we'll see later.

Let's start with an example of an explicitly limited type:

Listing 326: simple_recs.ads

```
package Simple_Recs is

   type Rec is limited record
      I : Integer;
   end record;

end Simple_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Explicitly_Limited_
 ↪Types.Explicitly_Limited_Types
MD5: de73a20140628420830ed9fe0b2dedb5
```

The Rec type is also explicitly limited when it's declared limited in the private type's completion (in the package's private part):

Listing 327: simple_recs.ads

```
1  package Simple_Recs is
2
3     type Rec is limited private;
4
5  private
6
7     type Rec is limited record
8        I : Integer;
9     end record;
10
11 end Simple_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Explicitly_Limited_
 ↪Types.Explicitly_Limited_Types
MD5: ececb364f5365a74db43952e9421dee0
```

In this case, Rec is limited both in the partial and in the full view, so it's considered explicitly limited.

However, *as we've learned before* (page 930), we may actually declare a type as **limited private** in the public part of a package, while its full view is nonlimited. In this case, the limited type is not consider explicitly limited anymore.

For example, if we make the full view of the Rec nonlimited (by removing the **limited** keyword in the private part), then the Rec type isn't explicitly limited anymore:

Listing 328: simple_recs.ads

```
1  package Simple_Recs is
2
3     type Rec is limited private;
4
5  private
6
7     type Rec is record
8        I : Integer;
9     end record;
10
11 end Simple_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Explicitly_Limited_
 ↪Types.Explicitly_Limited_Types
MD5: bd54dec4f9b67d3d14d80511b3ac311f
```

Now, even though the Rec type was declared as limited private, the full view indicates that it's actually a nonlimited type, so it isn't explicitly limited.

Note that *tagged limited private types* (page 936) are always explicitly limited types — because, as we've learned before, they cannot have a nonlimited type declaration in its full view.

In the Ada Reference Manual

- 6.2 Formal Parameter Modes[226]
- 6.4.1 Parameter Associations[227]
- 7.5 Limited Types[228]

28.3.4 Subtypes of Limited Types

We can declare subtypes of limited types. For example:

Listing 329: simple_recs.ads

```
package Simple_Recs is

   type Limited_Integer_Array (L : Positive) is
     limited private;

   subtype Limited_Integer_Array_2 is
     Limited_Integer_Array (2);

private

   type Integer_Array is
     array (Positive range <>) of Integer;

   type Limited_Integer_Array (L : Positive) is
     limited record
      Arr : Integer_Array (1 .. L);
   end record;

end Simple_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Deriving_From_
 ↪Limited_Types.Limited_Subtype
MD5: 2a82c3c96fad2a01b9a8c15912d4b974
```

Here, `Limited_Integer_Array_2` is a subtype of the `Limited_Integer_Array` type. Since `Limited_Integer_Array` is a limited type, the `Limited_Integer_Array_2` subtype is limited as well. A subtype just introduces a name for some constraints on an existing type. As such, a subtype doesn't change the limitedness of the constrained type.

We can test this in a small application:

Listing 330: test_limitedness.adb

```
with Simple_Recs; use Simple_Recs;

procedure Test_Limitedness is
   Dummy_1, Dummy_2 : Limited_Integer_Array_2;
begin
   Dummy_2 := Dummy_1;
end Test_Limitedness;
```

[226] http://www.ada-auth.org/standards/22rm/html/RM-6-2.html
[227] http://www.ada-auth.org/standards/22rm/html/RM-6-4-1.html
[228] http://www.ada-auth.org/standards/22rm/html/RM-7-5.html

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Deriving_From_
 ↪Limited_Types.Limited_Subtype
MD5: c24d07be96f27298a97e18d955cc6161
```

Build output

```
test_limitedness.adb:6:04: error: left hand of assignment must not be limited type
gprbuild: *** compilation phase failed
```

As expected, compilations fails because `Limited_Integer_Array_2` is a limited (sub)type.

28.3.5 Deriving from limited types

In this section, we discuss the implications of deriving from limited types. As usual, let's start with a simple example:

Listing 331: simple_recs.ads

```
1  package Simple_Recs is
2
3     type Rec is limited null record;
4
5     type Rec_Derived is new Rec;
6
7  end Simple_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Deriving_From_
 ↪Limited_Types.Derived_Limited_Type
MD5: cd23dfb69645ba5f1ebfdd65ee761ebe
```

In this example, the `Rec_Derived` type is derived from the `Rec` type. Note that the `Rec_Derived` type is limited because its ancestor is limited, even though the **`limited`** keyword doesn't show up in the declaration of the `Rec_Derived` type. Note that we could have actually used the **`limited`** keyword here:

```
type Rec_Derived is limited new Rec;
```

Therefore, we cannot use the assignment operator for objects of `Rec_Derived` type:

Listing 332: test_limitedness.adb

```
1  with Simple_Recs; use Simple_Recs;
2
3  procedure Test_Limitedness is
4     Dummy_1, Dummy_2 : Rec_Derived;
5  begin
6     Dummy_2 := Dummy_1;
7  end Test_Limitedness;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Deriving_From_
 ↪Limited_Types.Derived_Limited_Type
MD5: ce1b5fc8c96c4ede0cc6768b84296b51
```

Build output

```
test_limitedness.adb:6:04: error: left hand of assignment must not be limited type
gprbuild: *** compilation phase failed
```

Note that we cannot derive a limited type from a nonlimited ancestor:

Listing 333: simple_recs.ads

```
package Simple_Recs is

   type Rec is null record;

   type Rec_Derived is limited new Rec;

end Simple_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Deriving_From_
 ↪Limited_Types.Derived_Limited_Type_Nonlimited_Ancestor
MD5: 78a7574cc6233ddc826359acb6e644ee
```

Build output

```
simple_recs.ads:5:04: error: parent type "Rec" of limited type must be limited
gprbuild: *** compilation phase failed
```

As expected, the compiler indicates that the ancestor Rec should be of limited type.

In fact, all types in a derivation class are the same — either limited or not. (That is especially important with dynamic dispatching via tagged types. We discuss this topic in another chapter.)

In the Ada Reference Manual

- 7.3 Private Types and Private Extensions[229]
- 7.5 Limited Types[230]

Deriving from limited private types

Of course, we can also derive from limited private types. However, there are more rules in this case than the ones we've seen so far. Let's start with an example:

Listing 334: simple_recs.ads

```
package Simple_Recs is

   type Rec is limited private;

private

   type Rec is limited null record;

end Simple_Recs;
```

[229] http://www.ada-auth.org/standards/22rm/html/RM-7-3.html
[230] http://www.ada-auth.org/standards/22rm/html/RM-7-5.html

Listing 335: simple_recs-ext.ads

```
package Simple_Recs.Ext is

   type Rec_Derived is new Rec;

   --  OR:
   --
   --  type Rec_Derived is
   --    limited new Rec;

end Simple_Recs.Ext;
```

Listing 336: test_limitedness.adb

```
with Simple_Recs.Ext; use Simple_Recs.Ext;

procedure Test_Limitedness is
   Dummy_1, Dummy_2 : Rec_Derived;
begin
   Dummy_2 := Dummy_1;
end Test_Limitedness;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Deriving_From_
 ↪Limited_Types.Derived_Limited_Private_Type
MD5: c6eed14520589b9c1e11c17bd6179c19
```

Build output

```
test_limitedness.adb:6:04: error: left hand of assignment must not be limited type
gprbuild: *** compilation phase failed
```

Here, Rec_Derived is a limited type derived from the (limited private) Rec type. We can verify that Rec_Derived type is limited because the compilation of the Test_Limitedness procedure fails.

Deriving from non-explicitly limited private types

Up to this point, we have discussed *explicitly limited types* (page 936). Now, let's see how derivation works with *non-explicitly* limited types.

Any type derived from a limited type is always limited, even if the full view of its ancestor is nonlimited. For example, let's modify the full view of Rec and make it nonlimited (i.e. make it *not explicitly* limited):

Listing 337: simple_recs.ads

```
package Simple_Recs is

   type Rec is limited private;

private

   type Rec is null record;

end Simple_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Deriving_From_
 ↪Limited_Types.Derived_Limited_Private_Type
MD5: 30a2a88ff46b7e528bb8d75d3d6ad6ce
```

Build output

```
simple_recs.ads:1: Simple_Recs cannot be used as a main program
gprbind: invocation of gnatbind failed
gprbuild: unable to bind simple_recs.ads
```

Here, `Rec_Derived` is a limited type because the partial view of `Rec` is limited. The fact that the full view of `Rec` is nonlimited doesn't affect the `Rec_Derived` type — as we can verify with the compilation error in the `Test_Limitedness` procedure.

Note, however, that a derived type becomes nonlimited in the **private part or the body** of a child package if it isn't explicitly limited. In this sense, the derived type inherits the *nonlimitedness* of the parent's full view. For example, because we're declaring `Rec_Derived` as `is new` `Rec` in the child package (`Simple_Recs.Ext`), we're saying that `Rec_Derived` is limited *outside* this package, but nonlimited in the private part and body of the `Simple_Recs.Ext` package. We can verify this by copying the code from the `Test_Limitedness` procedure to a new procedure in the body of the `Simple_Recs.Ext` package:

Listing 338: simple_recs-ext.ads

```
1  package Simple_Recs.Ext
2    with Elaborate_Body is
3
4    --  Rec_Derived is derived from Rec, which is a
5    --  limited private type that is nonlimited in
6    --  its full view.
7    --
8    --  Rec_Derived isn't explicitly limited.
9    --  Therefore, it's nonlimited in the private
10   --  part of Simple_Recs.Ext and its package
11   --  body.
12   --
13   type Rec_Derived is new Rec;
14
15 end Simple_Recs.Ext;
```

Listing 339: simple_recs-ext.adb

```
1  package body Simple_Recs.Ext is
2
3     procedure Test_Child_Limitedness is
4        Dummy_1, Dummy_2 : Rec_Derived;
5     begin
6        --  Here, Rec_Derived is a nonlimited
7        --  type because Rec is nonlimited in
8        --  its full view.
9
10       Dummy_2 := Dummy_1;
11    end Test_Child_Limitedness;
12
13 end Simple_Recs.Ext;
```

Listing 340: test_limitedness.adb

```
1  --  We copied the code to the
2  --  Test_Child_Limitedness procedure (in the
3  --  body of the Simple_Recs.Ext package) and
```

(continues on next page)

(continued from previous page)

```
--  commented it out here.
--
--  You may uncomment the code to verify
--  that Rec_Derived is limited in this
--  procedure.
--

--  with Simple_Recs.Ext; use Simple_Recs.Ext;

procedure Test_Limitedness is
   --  Dummy_1, Dummy_2 : Rec_Derived;
begin
   --  Dummy_2 := Dummy_1;
   null;
end Test_Limitedness;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Deriving_From_
 ↪Limited_Types.Derived_Limited_Private_Type
MD5: f480cd05afff622e451684a0293cb982
```

In the `Test_Child_Limitedness` procedure of the `Simple_Recs.Ext` package, we can use the `Rec_Derived` as a nonlimited type because its ancestor `Rec` is nonlimited in its full view. (*As we've learned before* (page 933), if a limited type is nonlimited in its full view, we can copy objects of this type in the private part of the package specification or in the package body.)

Outside of the package, both `Rec` and `Rec_Derived` types are limited types. Therefore, if we uncomment the code in the `Test_Limitedness` procedure, compilation fails there (because `Rec_Derived` is viewed as descending from a limited type).

Deriving from tagged limited private types

The rules for deriving from tagged limited private types are slightly different than the rules we've seen so far. This is because tagged limited types are always *explicitly limited types* (page 936).

Let's look at an example:

Listing 341: simple_recs.ads

```
package Simple_Recs is

   type Tagged_Rec is tagged limited private;

private

   type Tagged_Rec is tagged limited null record;

end Simple_Recs;
```

Listing 342: simple_recs-ext.ads

```
package Simple_Recs.Ext is

   type Rec_Derived is new
     Tagged_Rec with private;

```

(continues on next page)

(continued from previous page)

```
private

   type Rec_Derived is new
     Tagged_Rec with null record;

end Simple_Recs.Ext;
```

Listing 343: test_limitedness.adb

```
with Simple_Recs.Ext; use Simple_Recs.Ext;

procedure Test_Limitedness is
   Dummy_1, Dummy_2 : Rec_Derived;
begin
   Dummy_2 := Dummy_1;
end Test_Limitedness;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Deriving_From_
 ↪Limited_Types.Derived_Tagged_Limited_Private_Type
MD5: 81c8a010f093d8823b84bb6e69c4114e
```

Build output

```
test_limitedness.adb:6:04: error: left hand of assignment must not be limited type
gprbuild: *** compilation phase failed
```

In this example, Rec_Derived is a tagged limited type derived from the Tagged_Rec type. (Again, we can verify the limitedness of the Rec_Derived type with the Test_Limitedness procedure.)

As explained previously, the derived type (Rec_Derived) is a limited type, even though the **limited** keyword doesn't appear in its declaration. We could, of course, include the **limited** keyword in the declaration of Rec_Derived:

Listing 344: simple_recs-ext.ads

```
package Simple_Recs.Ext is

   type Rec_Derived is limited new
     Tagged_Rec with private;

private

   type Rec_Derived is limited new
     Tagged_Rec with null record;

end Simple_Recs.Ext;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Deriving_From_
 ↪Limited_Types.Derived_Tagged_Limited_Private_Type
MD5: b82a58a4bf9701b321000c52bf121977
```

Build output

```
simple_recs-ext.ads:1: Simple_Recs.ext cannot be used as a main program
gprbind: invocation of gnatbind failed
gprbuild: unable to bind simple_recs-ext.ads
```

(Obviously, if we include the **limited** keyword in the partial view of the derived type, we must include it in its full view as well.)

Deriving from limited interfaces

The rules for limited interfaces are different from the ones for limited tagged types. In contrast to the rule we've seen in the previous section, a type that is derived from a limited type isn't automatically limited. In other words, it does **not** inherit the *limitedness* from the interface. For example:

Listing 345: simple_recs.ads

```
package Simple_Recs is

   type Limited_IF is limited interface;

end Simple_Recs;
```

Listing 346: simple_recs-ext.ads

```
package Simple_Recs.Ext is

   type Rec_Derived is new
     Limited_IF with private;

private

   type Rec_Derived is new
     Limited_IF with null record;

end Simple_Recs.Ext;
```

Listing 347: test_limitedness.adb

```
with Simple_Recs.Ext; use Simple_Recs.Ext;

procedure Test_Limitedness is
   Dummy_1, Dummy_2 : Rec_Derived;
begin
   Dummy_2 := Dummy_1;
end Test_Limitedness;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Deriving_From_
 ↪Limited_Types.Derived_Interface_Limited_Private
MD5: d9cf0bd26b86d0caec82eff2a2ec6ead
```

Here, `Rec_Derived` is derived from the limited `Limited_IF` interface. As we can see, the `Test_Limitedness` compiles fine because `Rec_Derived` is nonlimited.

Of course, if we want `Rec_Derived` to be limited, we can make this explicit in the type declaration:

Listing 348: simple_recs-ext.ads

```
package Simple_Recs.Ext is

   type Rec_Derived is limited new
     Limited_IF with private;
```

(continues on next page)

(continued from previous page)

```
5
6  private
7
8     type Rec_Derived is limited new
9       Limited_IF with null record;
10
11 end Simple_Recs.Ext;
```

Listing 349: test_limitedness.adb

```
1 with Simple_Recs.Ext; use Simple_Recs.Ext;
2
3 procedure Test_Limitedness is
4    Dummy_1, Dummy_2 : Rec_Derived;
5 begin
6    Dummy_2 := Dummy_1;
7 end Test_Limitedness;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Deriving_From_
 ↪Limited_Types.Derived_Interface_Limited_Private
MD5: abb295cbfd5ade5f351991c2fbaf519c
```

Build output

```
test_limitedness.adb:6:04: error: left hand of assignment must not be limited type
gprbuild: *** compilation phase failed
```

Now, compilation of `Test_Limitedness` fails because `Rec_Derived` is explicitly limited.

28.3.6 Immutably Limited Types

According to the Annotated Ada Reference Manual, "an immutably limited type is a type that cannot become nonlimited subsequently in a private part or in a child unit." In fact, while we were talking about *partial and full view of limited types* (page 930), we've seen that limited private types can become nonlimited in their full view. Such limited types are *not* immutably limited.

The Annotated Ada Reference Manual also says that "if a view of the type makes it immutably limited, then no copying (assignment) operations are ever available for objects of the type. This allows other properties; for instance, it is safe for such objects to have access discriminants that have defaults or designate other limited objects." We'll see examples of this later on.

Immutably limited types include:

- explicitly limited types
- tagged limited types (i.e. with the keyword **`limited`**);
- tagged limited private type;
- limited private type that have at least one *access discriminant* (page 868) with a default expression;
- task types, protected types, and synchronized interfaces;
- any types derived from immutably limited types.

Let's look at a code example that shows instances of immutably limited types:

Listing 350: show_immutably_limited_types.ads

```
package Show_Immutably_Limited_Types is

   --
   --  Explicitly limited type
   --
   type Explicitly_Limited_Rec is limited
   record
      A : Integer;
   end record;

   --
   --  Tagged limited type
   --
   type Limited_Tagged_Rec is tagged limited
   record
      A : Integer;
   end record;

   --
   --  Tagged limited private type
   --
   type Limited_Tagged_Private is
     tagged limited private;

   --
   --  Limited private type with an access
   --  discriminant that has a default
   --  expression
   --
   type Limited_Rec_Access_D
     (AI : access Integer := new Integer) is
       limited private;

   --
   --  Task type
   --
   task type TT is
     entry Start;
     entry Stop;
   end TT;

   --
   --  Protected type
   --
   protected type PT is
     function Value return Integer;
   private
     A : Integer;
   end PT;

  --
  --  Synchronized interface
  --
  type SI is synchronized interface;

  --
  --  A type derived from an immutably
  --  limited type
  --
  type Derived_Immutable is new
```

(continues on next page)

(continued from previous page)

```
    Explicitly_Limited_Rec;

private

   type Limited_Tagged_Private is tagged limited
   record
      A : Integer;
   end record;

   type Limited_Rec_Access_D
     (AI : access Integer := new Integer)
   is limited
     record
       A : Integer;
     end record;

end Show_Immutably_Limited_Types;
```

Listing 351: show_immutably_limited_types.adb

```
package body Show_Immutably_Limited_Types is

   task body TT is
   begin
     accept Start;
     accept Stop;
   end TT;

   protected body PT is
     function Value return Integer is
       (PT.A);
   end PT;

end Show_Immutably_Limited_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Immutably_Limited_
 ↪Types.Example
MD5: 6bcb9582a10eedc96040ab11cd320153
```

Build output

```
show_immutably_limited_types.ads:31:30: warning: coextension will not be␣
 ↪deallocated when its associated owner is deallocated [enabled by default]
```

In the Show_Immutably_Limited_Types package above, we see multiple instances of immutably limited types. (The comments in the source code indicate each type.)

In the Ada Reference Manual

- 7.5 Limited Types[231]

[231] http://www.ada-auth.org/standards/22rm/html/RM-7-5.html

Non immutably limited types

Not every limited type is immutably limited. We already mentioned untagged private limited types, which can become nonlimited in their full view. In addition, we have nonsynchronized limited interface types. As mentioned earlier in this chapter, a *type derived from a nonsynchronized limited interface* (page 945), can be nonlimited, so it's not immutably limited.

In the Ada Reference Manual

- 7.3.1 Private Operations[232]
- 7.5 Limited Types[233]

28.3.7 Record components of limited type

In this section, we discuss the implications of using components of limited type. Let's start by declaring a record component of limited type:

Listing 352: simple_recs.ads

```
package Simple_Recs is

   type Int_Rec is limited record
      V : Integer;
   end record;

   type Rec is limited record
      IR : Int_Rec;
   end record;

end Simple_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Record_Components_
 ↪Limited_Type.Record_Components_Limited_Type
MD5: 71badd1e38cc4ff37f16d99dd203614b
```

As soon as we declare a record component of some limited type, the whole record is limited. In this example, the Rec record is limited due to the presence of the IR component of limited type.

Also, if we change the declaration of the Rec record from the previous example and remove the **limited** keyword, the type itself remains implicitly limited. We can see that when trying to assign to objects of Rec type in the Show_Implicitly_Limited procedure:

Listing 353: simple_recs.ads

```
package Simple_Recs is

   type Int_Rec is limited record
      V : Integer;
   end record;

   type Rec is record
```

(continues on next page)

[232] http://www.ada-auth.org/standards/22rm/html/RM-7-3-1.html
[233] http://www.ada-auth.org/standards/22rm/html/RM-7-5.html

(continued from previous page)

```
8        IR : Int_Rec;
9     end record;
10
11 end Simple_Recs;
```

Listing 354: show_implicitly_limited.adb

```
1  with Simple_Recs; use Simple_Recs;
2
3  procedure Show_Implicitly_Limited is
4     A, B : Rec;
5  begin
6     B := A;
7  end Show_Implicitly_Limited;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Record_Components_
 ↪Limited_Type.Record_Components_Limited_Type
MD5: 39770daecfc4579407a799e14f9feff9
```

Build output

```
show_implicitly_limited.adb:6:04: error: left hand of assignment must not be␣
 ↪limited type
show_implicitly_limited.adb:6:04: error: component "IR" of type "Rec" has limited␣
 ↪type
gprbuild: *** compilation phase failed
```

Here, the compiler indicates that the assignment is forbidden because the Rec type has a component of limited type. The rationale for this rule is that an object of a limited type doesn't allow assignment or equality, including the case in which that object is a component of some enclosing composite object. If we allowed the enclosing object to be copied or tested for equality, we'd be doing it for all the components, too.

In the Ada Reference Manual

- 3.8 Record Types[234]

28.3.8 Limited types and aggregates

Note: This section was originally written by Robert A. Duff and published as Gem #1: Limited Types in Ada 2005[235] and Gem #2[236].

In this section, we focus on using aggregates to initialize limited types.

Historically

Prior to Ada 2005, aggregates were illegal for limited types. Therefore, we would be faced with a difficult choice: Make the type limited, and initialize it like this:

[234] http://www.ada-auth.org/standards/22rm/html/RM-3-8.html
[235] https://www.adacore.com/gems/gem-1
[236] https://www.adacore.com/gems/gem-2

Listing 355: persons.ads

```
with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

package Persons is

   type Limited_Person;
   type Limited_Person_Access is
     access all Limited_Person;

   type Limited_Person is limited record
      Name      : Unbounded_String;
      Age       : Natural;
   end record;

end Persons;
```

Listing 356: show_non_aggregate_init.adb

```
with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

with Persons; use Persons;

procedure Show_Non_Aggregate_Init is
   X : Limited_Person;
begin
   X.Name := To_Unbounded_String ("John Doe");
   X.Age := 25;
end Show_Non_Aggregate_Init;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Types_
 ↪Aggregates.Full_Coverage_Rules_Limited_Ada95
MD5: fd3dcb6251f7b6912dafcca052932be2
```

which has the maintenance problem the full coverage rules are supposed to prevent. Or, make the type nonlimited, and gain the benefits of aggregates, but lose the ability to prevent copies.

Full coverage rules for limited types

Previously, we discussed *full coverage rules for aggregates* (page 448). They also apply to limited types.

Historically

The full coverage rules have been aiding maintenance since Ada 83. However, prior to Ada 2005, we couldn't use them for limited types.

Suppose we have the following limited type:

Listing 357: persons.ads

```
with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

package Persons is

   type Limited_Person;
   type Limited_Person_Access is
     access all Limited_Person;

   type Limited_Person is limited record
      Self : Limited_Person_Access :=
               Limited_Person'Unchecked_Access;
      Name : Unbounded_String;
      Age  : Natural;
      Shoe_Size : Positive;
   end record;

end Persons;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Types_
 ↪Aggregates.Full_Coverage_Rules_Limited
MD5: b8ece44a10d512061cb138be21e42034
```

This type has a self-reference; it doesn't make sense to copy objects, because `Self` would end up pointing to the wrong place. Therefore, we would like to make the type limited, to prevent developers from accidentally making copies. After all, the type is probably private, so developers using this package might not be aware of the problem. We could also solve that problem with controlled types, but controlled types are expensive, and add unnecessary complexity if not needed.

We can initialize objects of limited type with an aggregate. Here, we can say:

Listing 358: show_aggregate_box_init.adb

```
with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

with Persons; use Persons;

procedure Show_Aggregate_Box_Init is
   X : aliased Limited_Person :=
         (Self      => <>,
          Name      =>
            To_Unbounded_String ("John Doe"),
          Age       => 25,
          Shoe_Size => 10);
begin
   null;
end Show_Aggregate_Box_Init;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Types_
 ↪Aggregates.Full_Coverage_Rules_Limited
MD5: ded40ff29b53ea5528efba94efaadbec
```

The `Self => <>` means use the default value of `Limited_Person'Unchecked_Access`. Since `Limited_Person` appears inside the type declaration, it refers to the "current instance" of

the type, which in this case is X. Thus, we are setting `X.Self` to be `X'Unchecked_Access`.

One very important requirement should be noted: the implementation is required to build the value of X *in place*; it cannot construct the aggregate in a temporary variable and then copy it into X, because that would violate the whole point of limited objects — you can't copy them.

Historically

Since Ada 2005, an aggregate is allowed to be limited; we can say:

Listing 359: show_aggregate_init.adb

```
with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;
with Persons; use Persons;

procedure Show_Aggregate_Init is

   X : aliased Limited_Person :=
         (Self      => null, -- Wrong!
          Name      =>
            To_Unbounded_String ("John Doe"),
          Age       => 25,
          Shoe_Size => 10);
begin
   X.Self := X'Unchecked_Access;
end Show_Aggregate_Init;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Types_
 ↪Aggregates.Full_Coverage_Rules_Limited
MD5: 793ee000fd777d0aa5c15e16132ec411
```

It seems uncomfortable to set the value of `Self` to the wrong value (**`null`**) and then correct it. It also seems annoying that we have a (correct) default value for `Self`, but prior to Ada 2005, we couldn't use defaults with aggregates. Since Ada 2005, a new syntax in aggregates is available: <> means "use the default value, if any". Therefore, we can replace `Self => null` by `Self => <>`.

Important

Note that using <> in an aggregate can be dangerous, because it can leave some components uninitialized. <> means "use the default value". If the type of a component is scalar, and there is no record-component default, then there is no default value.

For example, if we have an aggregate of type **`String`**, like this:

Listing 360: show_string_box_init.adb

```
procedure Show_String_Box_Init is
    Uninitialized_Const_Str : constant String :=
                                (1 .. 10 => <>);
begin
   null;
end Show_String_Box_Init;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Types_
 ↪Aggregates.String_Box_Init
MD5: 28931ced4e1113d55bdc9dc64b42f70a
```

we end up with a 10-character string all of whose characters are invalid values. Note that this is no more nor less dangerous than this:

Listing 361: show_dangerous_string.adb

```
procedure Show_Dangerous_String is
    Uninitialized_String_Var : String (1 .. 10);
    --  ^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^
    --  no initialization

    Uninitialized_Const_Str : constant String :=
        Uninitialized_String_Var;
begin
   null;
end Show_Dangerous_String;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Types_
 ↪Aggregates.Dangerous_String
MD5: 6c26e9c8d5d031d4e6eac1ac8458f17e
```

Build output

```
show_dangerous_string.adb:2:05: warning: variable "Uninitialized_String_Var" is␣
 ↪read but never assigned [-gnatwv]
```

As always, one must be careful about uninitialized scalar objects.

28.3.9 Constructor functions for limited types

Note: This section was originally written by Robert A. Duff and published as Gem #3[237].

Given that we can use build-in-place aggregates for limited types, the obvious next step is to allow such aggregates to be wrapped in an abstraction — namely, to return them from functions. After all, interesting types are usually private, and we need some way for clients to create and initialize objects.

Historically

Prior to Ada 2005, constructor functions (that is, functions that create new objects and return them) were not allowed for limited types. Since Ada 2005, fully-general constructor functions are allowed.

Let's see an example:

[237] https://www.adacore.com/gems/gem-3

Listing 362: p.ads

```
with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

package P is
   task type Some_Task_Type;

   protected type Some_Protected_Type is
      --  dummy type
   end Some_Protected_Type;

   type T (<>) is limited private;
   function Make_T (Name : String) return T;
   --       ^^^^^^
   --  constructor function
private
   type T is limited
      record
         Name    : Unbounded_String;
         My_Task : Some_Task_Type;
         My_Prot : Some_Protected_Type;
      end record;
end P;
```

Listing 363: p.adb

```
package body P is

   task body Some_Task_Type is
   begin
      null;
   end Some_Task_Type;

   protected body Some_Protected_Type is
   end Some_Protected_Type;

   function Make_T (Name : String) return T is
   begin
      return (Name   =>
                 To_Unbounded_String (Name),
              others => <>);
   end Make_T;

end P;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Constructor_
 ↪Functions_Limited_Types.Constructor_Functions
MD5: 2e73eea0ba7852d45ba96dc1f6fae14d
```

Given the above, clients can say:

Listing 364: show_constructor_function.adb

```
with P; use P;

procedure Show_Constructor_Function is
   My_T : T := Make_T
                  (Name => "Bartholomew Cubbins");
begin
```

(continues on next page)

(continued from previous page)

```
7     null;
8  end Show_Constructor_Function;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Constructor_
 ↪Functions_Limited_Types.Constructor_Functions
MD5: 52801fafbd58fedbf268a6704008627b
```

As for aggregates, the result of Make_T is built in place (that is, in My_T), rather than being created and then copied into My_T. Adding another level of function call, we can do:

Listing 365: show_rumplestiltskin_constructor.adb

```
1  with P; use P;
2
3  procedure Show_Rumplestiltskin_Constructor is
4
5     function Make_Rumplestiltskin return T is
6     begin
7         return Make_T (Name => "Rumplestiltskin");
8     end Make_Rumplestiltskin;
9
10    Rumplestiltskin_Is_My_Name : constant T :=
11      Make_Rumplestiltskin;
12 begin
13    null;
14 end Show_Rumplestiltskin_Constructor;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Constructor_
 ↪Functions_Limited_Types.Constructor_Functions
MD5: d8d9e9f22a0f2f034057fe97f75eacfe
```

It might help to understand the implementation model: In this case, Rumplestiltskin_Is_My_Name is allocated in the usual way (on the stack, presuming it is declared local to some subprogram). Its address is passed as an extra implicit parameter to Make_Rumplestiltskin, which then passes that same address on to Make_T, which then builds the aggregate in place at that address. Limited objects must never be copied! In this case, Make_T will initialize the Name component, and create the My_Task and My_Prot components, all directly in Rumplestiltskin_Is_My_Name.

Historically

Note that Rumplestiltskin_Is_My_Name is constant. Prior to Ada 2005, it was impossible to create a constant limited object, because there was no way to initialize it.

The (<>) on type T means that it has *unknown discriminants* from the point of view of the client. This is a trick that prevents clients from creating default-initialized objects (that is, X : T; is illegal). Thus clients must call Make_T whenever an object of type T is created, giving package P full control over initialization of objects.

Ideally, limited and nonlimited types should be just the same, except for the essential difference: you can't copy limited objects (and there's no language-defined equality operator). By allowing functions and aggregates for limited types, we're very close to this goal. Some languages have a specific feature called *constructor*. In Ada, a *constructor* is just a function that creates a new object.

Historically

Prior to Ada 2005, *constructors* only worked for nonlimited types. For limited types, the only way to *construct* on declaration was via default values, which limits you to one constructor. And the only way to pass parameters to that construction was via discriminants.

Consider the following package:

Listing 366: aux.ads

```
with Ada.Containers.Ordered_Sets;

package Aux is
   generic
      with package OS is new
        Ada.Containers.Ordered_Sets (<>);
   function Gen_Singleton_Set
     (Element : OS.Element_Type)
      return OS.Set;
end Aux;
```

Listing 367: aux.adb

```
package body Aux is
   function Gen_Singleton_Set
     (Element : OS.Element_Type)
      return OS.Set
   is
   begin
      return S : OS.Set := OS.Empty_Set do
         S.Insert (Element);
      end return;
   end Gen_Singleton_Set;
end Aux;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Constructor_
 ↪Functions_Limited_Types.Constructor_Functions_2
MD5: b715ae504c49ed59b7fd5ead4cc7bbb4
```

Since Ada 2005, we can say:

Listing 368: show_set_decl.adb

```
with Ada.Containers.Ordered_Sets;
with Aux;

procedure Show_Set_Decl is

   package Integer_Sets is new
     Ada.Containers.Ordered_Sets
       (Element_Type => Integer);
   use Integer_Sets;

   function Singleton_Set is new
     Aux.Gen_Singleton_Set
       (OS => Integer_Sets);

   This_Set : Set := Empty_Set;
   That_Set : Set := Singleton_Set
                       (Element => 42);
```

(continues on next page)

(continued from previous page)

```
18 begin
19    null;
20 end Show_Set_Decl;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Constructor_
 ↪Functions_Limited_Types.Constructor_Functions_2
MD5: 443fc3390b0f3e5516d91c80f16bed3f
```

whether or not Set is limited. `This_Set : Set := Empty_Set;` seems clearer than:

Listing 369: show_set_decl.adb

```
1  with Ada.Containers.Ordered_Sets;
2
3  procedure Show_Set_Decl is
4
5     package Integer_Sets is new
6       Ada.Containers.Ordered_Sets
7         (Element_Type => Integer);
8     use Integer_Sets;
9
10    This_Set : Set;
11 begin
12    null;
13 end Show_Set_Decl;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Constructor_
 ↪Functions_Limited_Types.Constructor_Functions_2
MD5: e5b6c0e148cfdb1987ab3002ec1f53bd
```

which might mean "default-initialize to the empty set" or might mean "leave it uninitialized, and we'll initialize it in later".

28.3.10 Return objects

Extended return statements for limited types

Note: This section was originally written by Robert A. Duff and published as Gem #10: Limited Types in Ada 2005[238].

Previously, we discussed *extended return statements* (page 615). For most types, extended return statements are no big deal — it's just syntactic sugar. But for limited types, this syntax is almost essential:

Listing 370: task_construct_error.ads

```
1  package Task_Construct_Error is
2
3     task type Task_Type (Discriminant : Integer);
4
```

(continues on next page)

[238] https://www.adacore.com/gems/ada-gem-10

(continued from previous page)

```
   function Make_Task (Val : Integer)
                       return Task_Type;

end Task_Construct_Error;
```

Listing 371: task_construct_error.adb

```
package body Task_Construct_Error is

   task body Task_Type is
   begin
      null;
   end Task_Type;

   function Make_Task (Val : Integer)
                       return Task_Type
   is
      Result : Task_Type
                 (Discriminant => Val * 3);
   begin
      --  some statements...
      return Result; -- Illegal!
   end Make_Task;

end Task_Construct_Error;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Extended_Return_
↪Statements_Limited_Types.Extended_Return_Limited_Error
MD5: f55b1c367d2931ece4d352d209fe6b3b
```

The return statement here is illegal, because `Result` is local to `Make_Task`, and returning it would involve a copy, which makes no sense (which is why task types are limited). Since Ada 2005, we can write constructor functions for task types:

Listing 372: task_construct.ads

```
package Task_Construct is

   task type Task_Type (Discriminant : Integer);

   function Make_Task (Val : Integer)
                       return Task_Type;

end Task_Construct;
```

Listing 373: task_construct.adb

```
package body Task_Construct is

   task body Task_Type is
   begin
      null;
   end Task_Type;

   function Make_Task (Val : Integer)
                       return Task_Type is
   begin
      return Result : Task_Type
```

(continues on next page)

(continued from previous page)

```
                        (Discriminant => Val * 3)
      do
         --  some statements...
         null;
      end return;
   end Make_Task;

end Task_Construct;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Extended_Return_
 ↪Statements_Limited_Types.Extended_Return_Limited
MD5: c91a24f09a76aef1c25d1a55bcbee910
```

If we call it like this:

Listing 374: show_task_construct.adb

```
with Task_Construct; use Task_Construct;

procedure Show_Task_Construct is
   My_Task : Task_Type := Make_Task (Val => 42);
begin
   null;
end Show_Task_Construct;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Extended_Return_
 ↪Statements_Limited_Types.Extended_Return_Limited
MD5: 01809b031a844c829f2ead253864ca75
```

`Result` is created *in place* in `My_Task`. `Result` is temporarily considered local to `Make_Task` during the `-- some statements` part, but as soon as `Make_Task` returns, the task becomes more global. `Result` and `My_Task` really are one and the same object.

When returning a task from a function, it is activated after the function returns. The `-- some statements` part had better not try to call one of the task's entries, because that would deadlock. That is, the entry call would wait until the task reaches an accept statement, which will never happen, because the task will never be activated.

Initialization and function return

As mentioned in the previous section, the object of limited type returned by the initialization function is built *in place*. In other words, the return object is built in the object that is the target of the assignment statement.

For example, we can see this when looking at the address of the object *returned* by the `Init` function, which we call to initialize the limited type `Simple_Rec`:

Listing 375: limited_types.ads

```
package Limited_Types is

   type Integer_Access is access Integer;

   type Simple_Rec is limited private;

```

(continues on next page)

(continued from previous page)

```
   function Init (I : Integer) return Simple_Rec;

private

   type Simple_Rec is limited record
      V : Integer_Access;
   end record;

end Limited_Types;
```

Listing 376: limited_types.adb

```
with Ada.Text_IO;           use Ada.Text_IO;
with System;
with System.Address_Image;

package body Limited_Types is

   function Init (I : Integer) return Simple_Rec
   is
   begin
      return E : Simple_Rec do
         E.V := new Integer'(I);

         Put_Line ("E'Address (Init):  "
                   & System.Address_Image
                       (E'Address));
      end return;
   end Init;

end Limited_Types;
```

Listing 377: show_limited_init.adb

```
with Ada.Text_IO;           use Ada.Text_IO;
with System;
with System.Address_Image;

with Limited_Types;         use Limited_Types;

procedure Show_Limited_Init is
begin
   declare
      A : Simple_Rec := Init (0);
   begin
      Put_Line ("A'Address (local): "
                & System.Address_Image
                    (A'Address));
   end;
   Put_Line ("----");

   declare
      B : Simple_Rec := Init (0);
   begin
      Put_Line ("B'Address (local): "
                & System.Address_Image
                    (B'Address));
   end;
end Show_Limited_Init;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Extended_Return_
 ↪Statements_Limited_Types.Initialization_Return_Do
MD5: 67235f804206e07fa4eba3a45cc1096f
```

Runtime output

```
E'Address (Init):  00007FFC52732DC8
A'Address (local): 00007FFC52732DC8
----
E'Address (Init):  00007FFC52732DC0
B'Address (local): 00007FFC52732DC0
```

When running this code example and comparing the address of the object E in the `Init` function and the object that is being initialized in the `Show_Limited_Init` procedure, we see that the return object E (of the `Init` function) and the local object in the `Show_Limited_Init` procedure are the same object.

Important

When we use nonlimited types, we're actually copying the returned object — which was locally created in the function — to the object that we're assigning the function to.

For example, let's modify the previous code and make `Simple_Rec` nonlimited:

Listing 378: non_limited_types.ads

```
1  package Non_Limited_Types is
2
3     type Integer_Access is access Integer;
4
5     type Simple_Rec is private;
6
7     function Init (I : Integer)
8                    return Simple_Rec;
9
10 private
11
12    type Simple_Rec is record
13       V : Integer_Access;
14    end record;
15
16 end Non_Limited_Types;
```

Listing 379: non_limited_types.adb

```
1  with Ada.Text_IO;           use Ada.Text_IO;
2  with System;
3  with System.Address_Image;
4
5  package body Non_Limited_Types is
6
7     function Init (I : Integer)
8                    return Simple_Rec is
9     begin
10       return E : Simple_Rec do
11          E.V := new Integer'(I);
12
13          Put_Line ("E'Address (Init):  "
14                    & System.Address_Image
15                        (E'Address));
16       end return;
```

(continues on next page)

(continued from previous page)

```
   end Init;

end Non_Limited_Types;
```

Listing 380: show_non_limited_init_by_copy.adb

```
with Ada.Text_IO;           use Ada.Text_IO;
with System;
with System.Address_Image;

with Non_Limited_Types;
use  Non_Limited_Types;

procedure Show_Non_Limited_Init_By_Copy is
   A, B : Simple_Rec;
begin
   declare
      A : Simple_Rec := Init (0);
   begin
      Put_Line ("A'Address (local): "
                & System.Address_Image
                    (A'Address));
   end;
   Put_Line ("----");

   declare
      B : Simple_Rec := Init (0);
   begin
      Put_Line ("B'Address (local): "
                & System.Address_Image
                    (B'Address));
   end;
end Show_Non_Limited_Init_By_Copy;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.
 ↪Extended_Return_Statements_Limited_Types.Initialization_Return_
 ↪Copy
MD5: 6e224b64b90dabdf5064c70364fa80cb
```

Runtime output

```
E'Address (Init):  00007FFFF0D96010
A'Address (local): 00007FFFF0D96138
----
E'Address (Init):  00007FFFF0D96010
B'Address (local): 00007FFFF0D96130
```

In this case, we see that the local object E in the `Init` function is not the same as the object it's being assigned to in the `Show_Non_Limited_Init_By_Copy` procedure. In fact, E is being copied to A and B.

28.3.11 Building objects from constructors

Note: This section was originally written by Robert A. Duff and published as Gem #11: Limited Types in Ada 2005[239].

We've earlier seen examples of constructor functions for limited types similar to this:

Listing 381: p.ads

```
with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

package P is
   task type Some_Task_Type;

   protected type Some_Protected_Type is
      --  dummy type
   end Some_Protected_Type;

   type T is limited private;
   function Make_T (Name : String) return T;
   --       ^^^^^^
   --  constructor function
private
   type T is limited
      record
         Name    : Unbounded_String;
         My_Task : Some_Task_Type;
         My_Prot : Some_Protected_Type;
      end record;
end P;
```

Listing 382: p.adb

```
package body P is

   task body Some_Task_Type is
   begin
      null;
   end Some_Task_Type;

   protected body Some_Protected_Type is
   end Some_Protected_Type;

   function Make_T (Name : String) return T is
   begin
      return (Name   =>
                 To_Unbounded_String (Name),
              others => <>);
   end Make_T;

end P;
```

Listing 383: p-aux.ads

```
package P.Aux is
   function Make_Rumplestiltskin return T;
end P.Aux;
```

[239] https://www.adacore.com/gems/ada-gem-11

Listing 384: p-aux.adb

```
package body P.Aux is

   function Make_Rumplestiltskin return T is
   begin
      return Make_T (Name => "Rumplestiltskin");
   end Make_Rumplestiltskin;

end P.Aux;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Building_Objects_
 ↪From_Constructors.Building_Objs_From_Constructors
MD5: 1956721292a82899d244afcd10ff63ed
```

It is useful to consider the various contexts in which these functions may be called. We've already seen things like:

Listing 385: show_rumplestiltskin_constructor.adb

```
with P;     use P;
with P.Aux; use P.Aux;

procedure Show_Rumplestiltskin_Constructor is
   Rumplestiltskin_Is_My_Name : constant T :=
     Make_Rumplestiltskin;
begin
   null;
end Show_Rumplestiltskin_Constructor;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Building_Objects_
 ↪From_Constructors.Building_Objs_From_Constructors
MD5: 2fe193516df6452eccece8132660f8e5
```

in which case the limited object is built directly in a standalone object. This object will be finalized whenever the surrounding scope is left.

We can also do:

Listing 386: show_parameter_constructor.adb

```
with P;     use P;
with P.Aux; use P.Aux;

procedure Show_Parameter_Constructor is
   procedure Do_Something (X : T) is null;
begin
   Do_Something (X => Make_Rumplestiltskin);
end Show_Parameter_Constructor;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Building_Objects_
 ↪From_Constructors.Building_Objs_From_Constructors
MD5: 61ccaefb4b7cfc42c065aa15543fc13b
```

Here, the result of the function is built directly in the formal parameter X of `Do_Something`. X will be finalized as soon as we return from `Do_Something`.

We can allocate initialized objects on the heap:

Listing 387: show_heap_constructor.adb

```
with P;     use P;
with P.Aux; use P.Aux;

procedure Show_Heap_Constructor is

   type T_Ref is access all T;

   Global : T_Ref;

   procedure Heap_Alloc is
      Local : T_Ref;
      To_Global : Boolean := True;
   begin
      Local := new T'(Make_Rumplestiltskin);
      if To_Global then
         Global := Local;
      end if;
   end Heap_Alloc;

begin
   null;
end Show_Heap_Constructor;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Building_Objects_
 ↪From_Constructors.Building_Objs_From_Constructors
MD5: 8eb794884f1dfbdbedf1bc4369f45cf8
```

The result of the function is built directly in the heap-allocated object, which will be finalized when the scope of `T_Ref` is left (long after `Heap_Alloc` returns).

We can create another limited type with a component of type T, and use an aggregate:

Listing 388: show_outer_type.adb

```
with P;     use P;
with P.Aux; use P.Aux;

procedure Show_Outer_Type is

   type Outer_Type is limited record
      This : T;
      That : T;
   end record;

   Outer_Obj : Outer_Type :=
                (This => Make_Rumplestiltskin,
                 That => Make_T (Name => ""));

begin
   null;
end Show_Outer_Type;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Building_Objects_
 ↪From_Constructors.Building_Objs_From_Constructors
MD5: 00817649406492b79977d67eb0fd3955
```

As usual, the function results are built in place, directly in `Outer_Obj.This` and `Outer_Obj.That`, with no copying involved.

The one case where we *cannot* call such constructor functions is in an assignment statement:

Listing 389: show_illegal_constructor.adb

```
with P;     use P;
with P.Aux; use P.Aux;

procedure Show_Illegal_Constructor is
   Rumplestiltskin_Is_My_Name : T;
begin
   Rumplestiltskin_Is_My_Name :=
     Make_T (Name => "");  --  Illegal!
end Show_Illegal_Constructor;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Building_Objects_
 ↪From_Constructors.Building_Objs_From_Constructors
MD5: f7b0c78e9fbe2e104b82dfff25ac3e3a
```

Build output

```
show_illegal_constructor.adb:7:04: error: left hand of assignment must not be␣
 ↪limited type
gprbuild: *** compilation phase failed
```

which is illegal because assignment statements involve copying. Likewise, we can't copy a limited object into some other object:

Listing 390: show_illegal_constructor.adb

```
with P;     use P;
with P.Aux; use P.Aux;

procedure Show_Illegal_Constructor is
   Rumplestiltskin_Is_My_Name : constant T :=
     Make_T (Name => "");
   Other : T :=
     Rumplestiltskin_Is_My_Name; -- Illegal!
begin
   null;
end Show_Illegal_Constructor;
```

28.3.12 Limited types as parameter

Previously, we saw that *parameters can be passed by copy or by reference* (page 618). Also, we discussed the concept of by-copy and by-reference types. *Explicitly limited types* (page 936) are by-reference types. Consequently, parameters of these types are always passed by reference.

For further reading...

As an example of the importance of this rule, consider the case of a lock (as an abstract data type). If such a lock object were passed by copy, the `Acquire` and `Release` operations

would be working on copies of this object, not on the original one. This would lead to timing-dependent bugs.

Let's reuse an example of an explicitly limited type:

Listing 391: simple_recs.ads

```
package Simple_Recs is

   type Rec is limited record
      I : Integer;
   end record;

end Simple_Recs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Types_
 ↪Parameters.Explicitly_Limited_Types
MD5: de73a20140628420830ed9fe0b2dedb5
```

In this example, Rec is a by-reference type because the type declaration is an explicit limited record. Therefore, the parameter R of the Proc procedure is passed by reference.

We can run the Test application below and compare the address of the R object from Test to the address of the R parameter of Proc to determine whether both R s refer to the same object or not:

Listing 392: simple_recs.ads

```
with System;

package Simple_Recs is

   type Rec is limited record
      I : Integer;
   end record;

   procedure Proc (R : in out Rec;
                   A :    out System.Address);

end Simple_Recs;
```

Listing 393: simple_recs.adb

```
package body Simple_Recs is

   procedure Proc (R : in out Rec;
                   A :    out System.Address) is
   begin
      R.I := 0;
      A   := R'Address;
   end Proc;

end Simple_Recs;
```

Listing 394: test.adb

```
with Ada.Text_IO;           use Ada.Text_IO;
with System;                use System;
with System.Address_Image;
```

(continues on next page)

(continued from previous page)

```
4  with Simple_Recs;           use Simple_Recs;
5
6  procedure Test is
7     R : Rec;
8
9     AR_Proc, AR_Test : System.Address;
10 begin
11    AR_Proc := R'Address;
12
13    Proc (R, AR_Test);
14
15    Put_Line ("R'Address (Proc): "
16              & System.Address_Image (AR_Proc));
17    Put_Line ("R'Address (Test): "
18              & System.Address_Image (AR_Test));
19
20    if AR_Proc = AR_Test then
21       Put_Line ("R was passed by reference.");
22    else
23       Put_Line ("R was passed by copy.");
24    end if;
25
26 end Test;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Limited_Types.Limited_Types_
 ↪Parameters.Explicitly_Limited_Types
MD5: d4fe2bb47d2223ef013d22aa305403e5
```

Runtime output

```
R'Address (Proc): 00007FFFC414438C
R'Address (Test): 00007FFFC414438C
R was passed by reference.
```

When running the Test application, we confirm that R was passed by reference. Note, however, that the fact that R was passed by reference doesn't automatically imply that Rec is a by-reference type: the type could have been ambiguous, and the compiler could have just decided to pass the parameter by reference in this case.

Therefore, we have to rely on the rules specified in the Ada Reference Manual:

1. If a limited type is explicitly limited, a parameter of this type is a by-reference type.
   - The rule applies to all kinds of explicitly limited types. For example, consider private limited types where the type is declared limited in the private type's completion (in the package's private part): a parameter of this type is a by-reference type.
2. If a limited type is not *explicitly* limited, a parameter of this type is neither a by-copy nor a by-reference type.
   - In this case, the decision whether the parameter is passed by reference or by copy is made by the compiler.

In the Ada Reference Manual

- 6.2 Formal Parameter Modes[240]

[240] http://www.ada-auth.org/standards/22rm/html/RM-6-2.html

- 6.4.1 Parameter Associations[241]
- 7.5 Limited Types[242]

[241] http://www.ada-auth.org/standards/22rm/html/RM-6-4-1.html

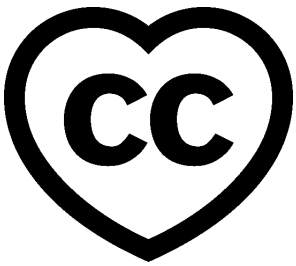
Introduction To SPARK

Warning: This version of the website contains UNPUBLISHED contents. Please do not share it externally!

Copyright © 2018 – 2022, AdaCore

This book is published under a CC BY-SA license, which means that you can copy, redistribute, remix, transform, and build upon the content for any purpose, even commercially, as long as you give appropriate credit, provide a link to the license, and indicate if changes were made. If you remix, transform, or build upon the material, you must distribute your contributions under the same license as the original. You can find license details on this page[243]



This tutorial is an interactive introduction to the SPARK programming language and its formal verification tools. You will learn the difference between Ada and SPARK and how to use the various analysis tools that come with SPARK.

This document was prepared by Claire Dross and Yannick Moy.

Note: The code examples in this course use an 80-column limit, which is a typical limit for Ada code. Note that, on devices with a small screen size, some code examples might be difficult to read.

Note: Each code example from this book has an associated "code block metadata", which contains the name of the "project" and an MD5 hash value. This information is used to identify a single code example.

You can find all code examples in a zip file, which you can download from the learn website[244]. The directory structure in the zip file is based on the code block metadata. For example, if you're searching for a code example with this metadata:

- Project: Courses.Intro_To_Ada.Imperative_Language.Greet
- MD5: cba89a34b87c9dfa71533d982d05e6ab

you will find it in this directory:

```
projects/Courses/Intro_To_Ada/Imperative_Language/Greet/
cba89a34b87c9dfa71533d982d05e6ab/
```

In order to use this code example, just follow these steps:

1. Unpack the zip file;
2. Go to target directory;
3. Start GNAT Studio on this directory;
4. Build (or compile) the project;
5. Run the application (if a main procedure is available in the project).

CHAPTER

TWENTYNINE

SPARK OVERVIEW

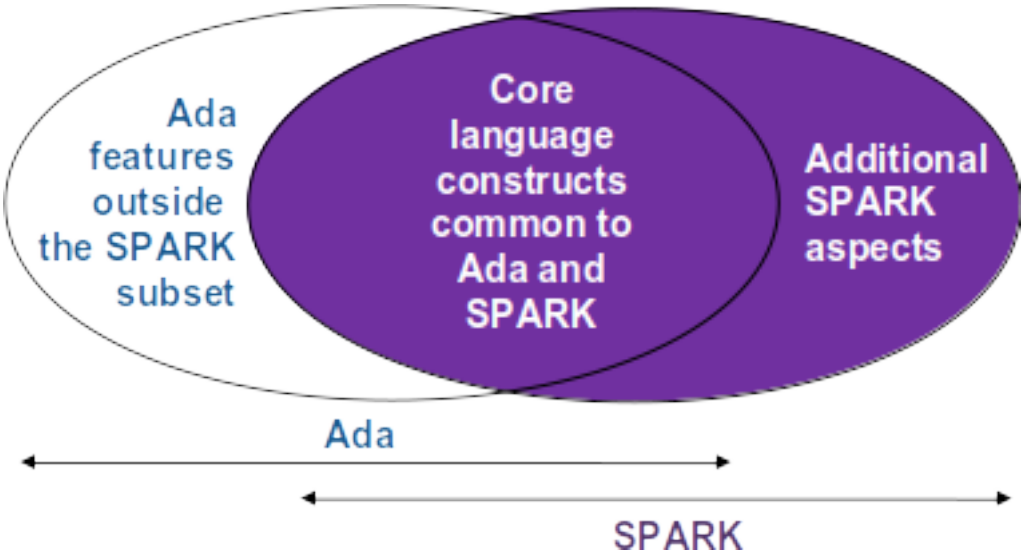
This tutorial is an introduction to the SPARK programming language and its formal verification tools. You need not know any specific programming language (although going over the *Introduction to Ada course* (page 5) first may help) or have experience in formal verification.

29.1 What is it?

SPARK refers to two different things:

- a programming language targeted at functional specification and static verification, and
- a set of development and verification tools for that language.

The SPARK language is based on a subset of the Ada language. Ada is particularly well suited to formal verification since it was designed for critical software development. SPARK builds on that foundation.



Version 2012 of Ada introduced the use of *aspects*, which can be used for subprogram contracts, and version 2014 of SPARK added its own aspects to further aid static analysis.

29.2 What do the tools do?

We start by reviewing static verification of programs, which is verification of the source code performed without compiling or executing it. Verification uses tools that perform static analysis. These can take various forms. They include tools that check types and enforce visibility rules, such as the compiler, in addition to those that perform more complex reasoning, such as abstract interpretation, as done by a tool like CodePeer[245] from AdaCore. The tools that come with SPARK perform two different forms of static analysis:

- *flow analysis* is the fastest form of analysis. It checks initializations of variables and looks at data dependencies between inputs and outputs of subprograms. It can also find unused assignments and unmodified variables.
- *proof* checks for the absence of runtime errors as well as the conformance of the program with its specifications.

29.3 Key Tools

The tool for formal verification of the SPARK language is called *GNATprove*. It checks for conformance with the SPARK subset and performs flow analysis and proof of the source code. Several other tools support the SPARK language, including both the GNAT compiler[246] and the GNAT Studio integrated development environment[247].

29.4 A trivial example

We start with a simple example of a subprogram in Ada that uses SPARK aspects to specify verifiable subprogram contracts. The subprogram, called `Increment`, adds 1 to the value of its parameter X:

Listing 1: increment.ads

```
procedure Increment
  (X : in out Integer)
with
  Global  => null,
  Depends => (X => X),
  Pre     => X < Integer'Last,
  Post    => X = X'Old + 1;
```

Listing 2: increment.adb

```
procedure Increment
  (X : in out Integer)
is
begin
  X := X + 1;
end Increment;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Overview.Trivial_Example
MD5: ce28b1facb44917b6cc208639c187064
```

[245] https://www.adacore.com/codepeer
[246] https://www.adacore.com/gnatpro
[247] https://www.adacore.com/gnatpro/toolsuite/gps

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
increment.adb:5:10: info: overflow check proved
increment.ads:4:03: info: data dependencies proved
increment.ads:5:03: info: flow dependencies proved
increment.ads:7:14: info: postcondition proved
increment.ads:7:24: info: overflow check proved
```

The contracts are written using the Ada *aspect* feature and those shown specify several properties of this subprogram:

- The SPARK Global aspect says that `Increment` does not read or write any global variables.
- The SPARK Depend aspect is especially interesting for security: it says that the value of the parameter X after the call depends only on the (previous) value of X.
- The `Pre` and `Post` aspects of Ada specify functional properties of `Increment`:
  - `Increment` is only allowed to be called if the value of X prior to the call is less than `Integer'Last`. This ensures that the addition operation performed in the subprogram body doesn't overflow.
  - `Increment` does indeed perform an increment of X: the value of X after a call is one greater than its value before the call.

GNATprove can verify all of these contracts. In addition, it verifies that no error can be raised at runtime when executing `Increment`'s body.

29.5 The Programming Language

It's important to understand why there are differences between the SPARK and Ada languages. The aim when designing the SPARK subset of Ada was to create the largest possible subset of Ada that was still amenable to simple specification and sound verification.

The most notable restrictions from Ada are related to exceptions and access types, both of which are known to considerably increase the amount of user-written annotations required for full support. Backwards goto statements and controlled types are also not supported since they introduce non-trivial control flow. The two remaining restrictions relate to side-effects in expressions and aliasing of names, which we now cover in more detail.

29.6 Limitations

29.6.1 No side-effects in expressions

The SPARK language doesn't allow side-effects in expressions. In other words, evaluating a SPARK expression must not update any object. This limitation is necessary to avoid unpredictable behavior that depends on order of evaluation, parameter passing mechanisms, or compiler optimizations. The expression for `Dummy` below is non-deterministic due to the order in which the two calls to F are evaluated. It's therefore not legal SPARK.

Listing 3: show_illegal_ada_code.adb

```
procedure Show_Illegal_Ada_Code is

   function F (X : in out Integer) return Integer is
      Tmp : constant Integer := X;
   begin
      X := X + 1;
      return Tmp;
   end F;

   Dummy : Integer := 0;

begin
   Dummy := F (Dummy) - F (Dummy); -- ??
end Show_Illegal_Ada_Code;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Overview.Illegal_Ada_Code
MD5: a5cbf1824526857da94791ac1790200c
```

Build output

```
show_illegal_ada_code.adb:13:28: error: value may be affected by call to "F"␣
 ↪because order of evaluation is arbitrary
gprbuild: *** compilation phase failed
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
show_illegal_ada_code.adb:13:28: error: value may be affected by call to "F"␣
 ↪because order of evaluation is arbitrary
gnatprove: error during generation of Global contracts
```

In fact, the code above is not even legal Ada, so the same error is generated by the GNAT compiler. But SPARK goes further and GNATprove also produces an error for the following equivalent code that is accepted by the Ada compiler:

Listing 4: show_illegal_spark_code.adb

```
procedure Show_Illegal_SPARK_Code is

   Dummy : Integer := 0;

   function F return Integer is
      Tmp : constant Integer := Dummy;
   begin
      Dummy := Dummy + 1;
      return Tmp;
   end F;

begin
   Dummy := F - F; -- ??
end Show_Illegal_SPARK_Code;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Overview.Illegal_SPARK_Code
MD5: e747edb6ee147adb7fba97c9e7c8d5ef
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
show_illegal_spark_code.adb:5:13: error: function with output global "Dummy" is␣
 ↪not allowed in SPARK
gnatprove: error during analysis of data and information flow
```

The SPARK languages enforces the lack of side-effects in expressions by forbidding side-effects in functions, which include modifications to either parameters or global variables. As a consequence, SPARK forbids functions with **out** or **in out** parameters in addition to functions modifying a global variable. Function F below is illegal in SPARK, while Function Incr might be legal if it doesn't modify any global variables and function Incr_And_Log might be illegal if it modifies global variables to perform logging.

```
function F (X : in out Integer) return Integer;     -- Illegal

function Incr (X : Integer) return Integer;         -- OK?

function Incr_And_Log (X : Integer) return Integer; -- OK?
```

In most cases, you can easily replace these functions by procedures with an **out** parameter that returns the computed value.

When it has access to function bodies, GNATprove verifies that those functions are indeed free from side-effects. Here for example, the two functions Incr and Incr_And_Log have the same signature, but only Incr is legal in SPARK. Incr_And_Log isn't: it attempts to update the global variable Call_Count.

Listing 5: side_effects.ads

```
1  package Side_Effects is
2
3     function Incr (X : Integer) return Integer;         -- OK?
4
5     function Incr_And_Log (X : Integer) return Integer; -- OK?
6
7  end Side_Effects;
```

Listing 6: side_effects.adb

```
1  package body Side_Effects is
2
3     function Incr (X : Integer) return Integer
4     is (X + 1); -- OK
5
6     Call_Count : Natural := 0;
7
8     function Incr_And_Log (X : Integer) return Integer is
9     begin
10       Call_Count := Call_Count + 1; -- Illegal
11       return X + 1;
12    end Incr_And_Log;
13
14 end Side_Effects;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Overview.Side_Effects
MD5: 1b555e4b7bb519eea4df718a9356a2ed
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
side_effects.ads:5:13: error: function with output global "Call_Count" is not␣
 ↪allowed in SPARK
gnatprove: error during analysis of data and information flow
```

29.6.2 No aliasing of names

Another restriction imposed by the SPARK subset concerns aliasing[248]. We say that two names are *aliased* if they refer to the same object. There are two reasons why aliasing is forbidden in SPARK:

- It makes verification more difficult because it requires taking into account the fact that modifications to variables with different names may actually update the same object.
- Results may seem unexpected from a user point of view. The results of a subprogram call may depend on compiler-specific attributes, such as parameter passing mechanisms, when its parameters are aliased.

Aliasing can occur as part of the parameter passing that occurs in a subprogram call. Functions have no side-effects in SPARK, so aliasing of parameters in function calls isn't problematic; we need only consider procedure calls. When a procedure is called, SPARK verifies that no **out** or **in out** parameter is aliased with either another parameter of the procedure or a global variable modified in the procedure's body.

Procedure `Move_To_Total` is an example where the possibility of aliasing wasn't taken into account by the programmer:

Listing 7: no_aliasing.adb

```
procedure No_Aliasing is

   Total : Natural := 0;

   procedure Move_To_Total (Source : in out Natural)
     with Post => Total = Total'Old + Source'Old and Source = 0
   is
   begin
      Total  := Total + Source;
      Source := 0;
   end Move_To_Total;

   X : Natural := 3;

begin
   Move_To_Total (X);          -- OK
   pragma Assert (Total = 3); -- OK
   Move_To_Total (Total);      -- flow analysis error
   pragma Assert (Total = 6); -- runtime error
end No_Aliasing;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Overview.Aliasing
MD5: 91038ef030fe27e3b000ab3db9c134ad
```

Prover output

[248] https://en.wikipedia.org/wiki/Aliasing_(computing)

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
no_aliasing.adb:18:19: high: formal parameter "Source" and global "Total" are␣
 ↪aliased (SPARK RM 6.4.2)
gnatprove: unproved check messages considered as errors
```

Runtime output

```
raised ADA.ASSERTIONS.ASSERTION_ERROR : no_aliasing.adb:19
```

`Move_To_Total` adds the value of its input parameter `Source` to the global variable `Total` and then resets `Source` to 0. The programmer has clearly not taken into account the possibility of an aliasing between `Total` and `Source`. (This sort of error is quite common.)

This procedure itself is valid SPARK. When doing verification, GNATprove assumes, like the programmer did, that there's no aliasing between `Total` and `Source`. To ensure this assumption is valid, GNATprove checks for possible aliasing on every call to `Move_To_Total`. Its final call in procedure `No_Aliasing` violates this assumption, which produces both a message from GNATprove and a runtime error (an assertion violation corresponding to the expected change in `Total` from calling `Move_To_Total`). Note that the postcondition of `Move_To_Total` is not violated on this second call since integer parameters are passed by copy and the postcondition is checked before the copy-back from the formal parameters to the actual arguments.

Aliasing can also occur as a result of using access types (pointers[249] in Ada). These are restricted in SPARK so that only benign aliasing is allowed, when both names are only used to read the data. In particular, assignment between access objects operates a transfer of ownership, where the source object loses its permission to read or write the underlying allocated memory.

Procedure `Ownership_Transfer` is an example of code that is legal in Ada but rejected in SPARK due to aliasing:

Listing 8: ownership_transfer.adb

```
1  procedure Ownership_Transfer is
2     type Int_Ptr is access Integer;
3     X     : Int_Ptr;
4     Y     : Int_Ptr;
5     Dummy : Integer;
6  begin
7     X     := new Integer'(1);
8     X.all := X.all + 1;
9     Y     := X;
10    Y.all := Y.all + 1;
11    X.all := X.all + 1;  --  illegal
12    X.all := 1;          --  illegal
13    Dummy := X.all;      --  illegal
14 end Ownership_Transfer;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Overview.Ownership_Transfer
MD5: 951fe1c930d43a5009e607994ae0dd03
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
```

(continues on next page)

[249] https://en.wikipedia.org/wiki/Pointer_(computer_programming)

(continued from previous page)

```
ownership_transfer.adb:11:06: error: dereference from "X" is not writable
ownership_transfer.adb:11:06: error: object was moved at line 9
ownership_transfer.adb:11:15: error: dereference from "X" is not readable
ownership_transfer.adb:11:15: error: object was moved at line 9
ownership_transfer.adb:12:06: error: dereference from "X" is not writable
ownership_transfer.adb:12:06: error: object was moved at line 9
ownership_transfer.adb:13:15: error: dereference from "X" is not readable
ownership_transfer.adb:13:15: error: object was moved at line 9
gnatprove: error during analysis of data and information flow
```

After the assignment of X to Y, variable X cannot be used anymore to read or write the underlying allocated memory.

Note: For more details on these limitations, see the SPARK User's Guide[250].

29.7 Designating SPARK Code

Since the SPARK language is restricted to only allow easily specifiable and verifiable constructs, there are times when you can't or don't want to abide by these limitations over your entire code base. Therefore, the SPARK tools only check conformance to the SPARK subset on code which you identify as being in SPARK.

You do this by using an aspect named SPARK_Mode. If you don't explicitly specify otherwise, SPARK_Mode is *Off*, meaning you can use the complete set of Ada features in that code and that it should not be analyzed by GNATprove. You can change this default either selectively (on some units or subprograms or packages inside units) or globally (using a configuration pragma, which is what we're doing in this tutorial). To allow simple reuse of existing Ada libraries, entities declared in imported units with no explicit SPARK_Mode can still be used from SPARK code. The tool only checks for SPARK conformance on the declaration of those entities which are actually used within the SPARK code.

Here's a common case of using the SPARK_Mode aspect:

```
package P
  with SPARK_Mode => On
is
   -- package spec is IN SPARK, so can be used by SPARK clients
end P;

package body P
  with SPARK_Mode => Off
is
   -- body is NOT IN SPARK, so is ignored by GNATprove
end P;
```

The package P only defines entities whose specifications are in the SPARK subset. However, it wants to use all Ada features in its body. Therefore the body should not be analyzed and has its SPARK_Mode aspect set to *Off*.

You can specify SPARK_Mode in a fine-grained manner on a per-unit basis. An Ada package has four different components: the visible and private parts of its specification and the declarative and statement parts of its body. You can specify SPARK_Mode as being either *On* or *Off* on any of those parts. Likewise, a subprogram has two parts: its specification and its body.

[250] https://docs.adacore.com/live/wave/spark2014/html/spark2014_ug/en/source/language_restrictions.html#language-restrictions

A general rule in SPARK is that once SPARK_Mode has been set to *Off*, it can never be switched *On* again in the same part of a package or subprogram. This prevents setting SPARK_Mode to *On* for local units of a unit with SPARK_Mode *Off* and switching back to SPARK_Mode *On* for a part of a given unit where it was set fo *Off* in a previous part.

Note: For more details on the use of SPARK_Mode, see the SPARK User's Guide[251].

29.8 Code Examples / Pitfalls

29.8.1 Example #1

Here's a package defining an abstract stack type (defined as a private type in SPARK) of Element objects along with some subprograms providing the usual functionalities of stacks. It's marked as being in the SPARK subset.

Listing 9: stack_package.ads

```
package Stack_Package
  with SPARK_Mode => On
is
   type Element is new Natural;
   type Stack is private;

   function Empty return Stack;
   procedure Push (S : in out Stack; E : Element);
   function Pop (S : in out Stack) return Element;

private
   type Stack is record
      Top : Integer;
      --  ...
   end record;

end Stack_Package;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Overview.Example_01
MD5: 2b15e13e850435fb93406054d70b51c6
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
stack_package.ads:9:13: error: function with "in out" parameter is not allowed in␣
 ↪SPARK
stack_package.ads:9:13: error: violation of aspect SPARK_Mode at line 2
gnatprove: error during analysis of data and information flow
```

Side-effects in expressions are not allowed in SPARK. Therefore, Pop is not allowed to modify its parameter S.

[251] https://docs.adacore.com/live/wave/spark2014/html/spark2014_ug/en/spark_mode.html

29.8.2 Example #2

Let's turn to an abstract state machine version of a stack, where the unit provides a single instance of a stack. The content of the stack (global variables Content and Top) is not directly visible to clients. In this stripped-down version, only the function Pop is available to clients. The package spec and body are marked as being in the SPARK subset.

Listing 10: global_stack.ads

```
package Global_Stack
  with SPARK_Mode => On
is
   type Element is new Integer;

   function Pop return Element;

end Global_Stack;
```

Listing 11: global_stack.adb

```
package body Global_Stack
  with SPARK_Mode => On
is
   Max : constant Natural := 100;
   type Element_Array is array (1 .. Max) of Element;

   Content : Element_Array;
   Top     : Natural;

   function Pop return Element is
      E : constant Element := Content (Top);
   begin
      Top := Top - 1;
      return E;
   end Pop;

end Global_Stack;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Overview.Example_02
MD5: 8c4eb564643eef48264b5e43a6f580b9
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
global_stack.adb:7:04: warning: variable "Content" is read but never assigned [-
 ↪gnatwv]
global_stack.ads:6:13: error: function with output global "Top" is not allowed in␣
 ↪SPARK
gnatprove: error during analysis of data and information flow
```

As above, functions should be free from side-effects. Here, Pop updates the global variable Top, which is not allowed in SPARK.

29.8.3 Example #3

We now consider two procedures: Permute and Swap. Permute applies a circular permutation to the value of its three parameters. Swap then uses Permute to swap the value of X and Y.

Listing 12: p.ads

```
package P
  with SPARK_Mode => On
is
   procedure Permute (X, Y, Z : in out Positive);
   procedure Swap (X, Y : in out Positive);
end P;
```

Listing 13: p.adb

```
package body P
  with SPARK_Mode => On
is
   procedure Permute (X, Y, Z : in out Positive) is
      Tmp : constant Positive := X;
   begin
      X := Y;
      Y := Z;
      Z := Tmp;
   end Permute;

   procedure Swap (X, Y : in out Positive) is
   begin
      Permute (X, Y, Y);
   end Swap;
end P;
```

Listing 14: test_swap.adb

```
with P; use P;

procedure Test_Swap
  with SPARK_Mode => On
is
   A : Integer := 1;
   B : Integer := 2;
begin
   Swap (A, B);
end Test_Swap;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Overview.Example_03
MD5: 0868a806061d86af4d2a03b1e7dc83c2
```

Build output

```
p.adb:14:19: error: writable actual for "Y" overlaps with actual for "Z"
gprbuild: *** compilation phase failed
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
p.adb:14:19: error: writable actual for "Y" overlaps with actual for "Z"
gnatprove: error during generation of Global contracts
```

Here, the values for parameters Y and Z are aliased in the call to Permute, which is not allowed in SPARK. In fact, in this particular case, this is even a violation of Ada rules so the same error is issued by the Ada compiler.

In this example, we see the reason why aliasing is not allowed in SPARK: since Y and Z are **Positive**, they are passed by copy and the result of the call to Permute depends on the order in which they're copied back after the call.

29.8.4 Example #4

Here, the Swap procedure is used to swap the value of the two record components of R.

Listing 15: p.ads

```
package P
  with SPARK_Mode => On
is
   type Rec is record
      F1 : Positive;
      F2 : Positive;
   end record;

   procedure Swap_Fields (R : in out Rec);
   procedure Swap (X, Y : in out Positive);
end P;
```

Listing 16: p.adb

```
package body P
  with SPARK_Mode => On
is
   procedure Swap (X, Y : in out Positive) is
      Tmp : constant Positive := X;
   begin
      X := Y;
      Y := Tmp;
   end Swap;

   procedure Swap_Fields (R : in out Rec) is
   begin
      Swap (R.F1, R.F2);
   end Swap_Fields;

end P;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Overview.Example_04
MD5: ae4d3ebe8dd1a8f67f35cedffdea2ac9
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
```

This code is correct. The call to Swap is safe: two different components of the same record can't refer to the same object.

29.8.5 Example #5

Here's a slight modification of the previous example using an array instead of a record: Swap_Indexes calls Swap on values stored in the array A.

Listing 17: p.ads

```
package P
  with SPARK_Mode => On
is
   type P_Array is array (Natural range <>) of Positive;

   procedure Swap_Indexes (A : in out P_Array; I, J : Natural);
   procedure Swap (X, Y : in out Positive);
end P;
```

Listing 18: p.adb

```
package body P
  with SPARK_Mode => On
is
   procedure Swap (X, Y : in out Positive) is
      Tmp : constant Positive := X;
   begin
      X := Y;
      Y := Tmp;
   end Swap;

   procedure Swap_Indexes (A : in out P_Array; I, J : Natural) is
   begin
      Swap (A (I), A (J));
   end Swap_Indexes;

end P;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Overview.Example_05
MD5: 62a95179572e36443995ff54a2d5ef08
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
p.adb:13:13: medium: formal parameters "X" and "Y" might be aliased (SPARK RM 6.4.
 ↪2)
gnatprove: unproved check messages considered as errors
```

GNATprove detects a possible case of aliasing. Unlike the previous example, it has no way of knowing that the two elements `A (I)` and `A (J)` are actually distinct when we call Swap. GNATprove issues a check message here instead of an error, giving you the possibility of justifying the message after review (meaning that you've verified manually that this can't, in fact, occur).

29.8.6 Example #6

We now consider a package declaring a type `Dictionary`, an array containing a word per letter. The procedure `Store` allows us to insert a word at the correct index in a dictionary.

Listing 19: p.ads

```
with Ada.Finalization;

package P
  with SPARK_Mode => On
is
   subtype Letter is Character range 'a' .. 'z';
   type String_Access is new Ada.Finalization.Controlled with record
      Ptr : access String;
   end record;
   type Dictionary is array (Letter) of String_Access;

   procedure Store (D : in out Dictionary; W : String);
end P;
```

Listing 20: p.adb

```
package body P
  with SPARK_Mode => On
is
   procedure Store (D : in out Dictionary; W : String) is
      First_Letter : constant Letter := W (W'First);
   begin
      D (First_Letter).Ptr := new String'(W);
   end Store;
end P;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Overview.Example_06
MD5: 9175bcd1474e2143462b860c01d8602e
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
p.adb:7:07: error: "String_Access" is not allowed in SPARK (due to controlled␣
 ↪types)

p.ads:7:09: error: "Controlled" is not allowed in SPARK (due to controlled types)
p.ads:7:09: error: violation of aspect SPARK_Mode at line 4
p.ads:10:04: error: "String_Access" is not allowed in SPARK (due to controlled␣
 ↪types)
p.ads:10:04: error: violation of aspect SPARK_Mode at line 4
gnatprove: error during analysis of data and information flow
```

This code is not correct: controlled types are not part of the SPARK subset. The solution here is to use SPARK_Mode to separate the definition of `String_Access` from the rest of the code in a fine grained manner.

29.8.7 Example #7

Here's a new version of the previous example, which we've modified to hide the controlled type inside the private part of package P, using `pragma SPARK_Mode (Off)` at the start of the private part.

Listing 21: p.ads

```
with Ada.Finalization;

package P
  with SPARK_Mode => On
is
   subtype Letter is Character range 'a' .. 'z';
   type String_Access is private;
   type Dictionary is array (Letter) of String_Access;

   function New_String_Access (W : String) return String_Access;

   procedure Store (D : in out Dictionary; W : String);

private
   pragma SPARK_Mode (Off);

   type String_Access is new Ada.Finalization.Controlled with record
      Ptr : access String;
   end record;

   function New_String_Access (W : String) return String_Access is
     (Ada.Finalization.Controlled with Ptr => new String'(W));
end P;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Overview.Example_07
MD5: cb04206c9734eb95f6444757d005dae2
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
```

Since the controlled type is defined and used inside of a part of the code ignored by GNATprove, this code is correct.

29.8.8 Example #8

Let's put together the new spec for package P with the body of P seen previously.

Listing 22: p.ads

```
with Ada.Finalization;

package P
  with SPARK_Mode => On
is
   subtype Letter is Character range 'a' .. 'z';
   type String_Access is private;
   type Dictionary is array (Letter) of String_Access;

```

(continues on next page)

(continued from previous page)

```
   function New_String_Access (W : String) return String_Access;

   procedure Store (D : in out Dictionary; W : String);

private
   pragma SPARK_Mode (Off);

   type String_Access is new Ada.Finalization.Controlled with record
      Ptr : access String;
   end record;

   function New_String_Access (W : String) return String_Access is
     (Ada.Finalization.Controlled with Ptr => new String'(W));
end P;
```

Listing 23: p.adb

```
package body P
  with SPARK_Mode => On
is
   procedure Store (D : in out Dictionary; W : String) is
      First_Letter : constant Letter := W (W'First);
   begin
      D (First_Letter) := New_String_Access (W);
   end Store;
end P;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Overview.Example_08
MD5: dacb2d50d0ddc6c620ee9945cb819369
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
p.adb:1:01: error: incorrect application of SPARK_Mode at /vagrant/frontend/dist/
 ↪test_output/projects/Courses/Intro_To_Spark/Overview/Example_08/
 ↪dacb2d50d0ddc6c620ee9945cb819369/main_spark.adc:12
p.adb:1:01: error: value Off was set for SPARK_Mode on "P" at p.ads:15
p.adb:2:08: error: incorrect use of SPARK_Mode
p.adb:2:08: error: value Off was set for SPARK_Mode on "P" at p.ads:15
gnatprove: error during generation of Global contracts
```

The body of `Store` doesn't actually use any construct that's not in the SPARK subset, but we nevertheless can't set SPARK_Mode to On for P's body because it has visibility to P's private part, which is not in SPARK, even if we don't use it.

29.8.9 Example #9

Next, we moved the declaration and the body of the procedure `Store` to another package named Q.

Listing 24: p.ads

```
with Ada.Finalization;

package P
  with SPARK_Mode => On
is
```

(continues on next page)

(continued from previous page)

```
   subtype Letter is Character range 'a' .. 'z';
   type String_Access is private;
   type Dictionary is array (Letter) of String_Access;

   function New_String_Access (W : String) return String_Access;

private
   pragma SPARK_Mode (Off);

   type String_Access is new Ada.Finalization.Controlled with record
      Ptr : access String;
   end record;

   function New_String_Access (W : String) return String_Access is
     (Ada.Finalization.Controlled with Ptr => new String'(W));
end P;
```

Listing 25: q.ads

```
with P; use P;
package Q
  with SPARK_Mode => On
is
   procedure Store (D : in out Dictionary; W : String);
end Q;
```

Listing 26: q.adb

```
package body Q
  with SPARK_Mode => On
is
   procedure Store (D : in out Dictionary; W : String)  is
      First_Letter : constant Letter := W (W'First);
   begin
      D (First_Letter) := New_String_Access (W);
   end Store;
end Q;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Overview.Example_09
MD5: b397e82987c100de5a53ede16fbef37f
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
```

And now everything is fine: we've managed to retain the use of the controlled type while having most of our code in the SPARK subset so GNATprove is able to analyze it.

29.8.10 Example #10

Our final example is a package with two functions to search for the value 0 inside an array A. The first raises an exception if 0 isn't found in A while the other simply returns 0 in that case.

Listing 27: p.ads

```
package P
  with SPARK_Mode => On
is
   type N_Array is array (Positive range <>) of Natural;
   Not_Found : exception;

   function Search_Zero_P (A : N_Array) return Positive;

   function Search_Zero_N (A : N_Array) return Natural;
end P;
```

Listing 28: p.adb

```
package body P
  with SPARK_Mode => On
is
   function Search_Zero_P (A : N_Array) return Positive is
   begin
      for I in A'Range loop
         if A (I) = 0 then
            return I;
         end if;
      end loop;
      raise Not_Found;
   end Search_Zero_P;

   function Search_Zero_N (A : N_Array) return Natural
     with SPARK_Mode => Off is
   begin
      return Search_Zero_P (A);
   exception
      when Not_Found => return 0;
   end Search_Zero_N;
end P;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Overview.Example_10
MD5: 4b9656698ab1d42cebc72817f8a00637
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
p.adb:11:07: medium: exception might be raised
gnatprove: unproved check messages considered as errors
```

This code is perfectly correct, despite the use of exception handling, because we've carefully isolated this non-SPARK feature in a function body marked with a SPARK_Mode of Off so it's ignored by GNATprove. However, GNATprove tries to show that Not_Found is never raised in Search_Zero_P, producing a message about a possible exception being raised. Looking at Search_Zero_N, it's indeed likely that an exception is meant to be raised in some cases, which means you need to verify that Not_Found is only raised when appropriate using other methods such as peer review or testing.

CHAPTER

THIRTY

FLOW ANALYSIS

In this section we present the flow analysis capability provided by the GNATprove tool, a critical tool for using SPARK.

30.1 What does flow analysis do?

Flow analysis concentrates primarily on variables. It models how information flows through them during a subprogram's execution, connecting the final values of variables to their initial values. It analyzes global variables declared at library level, local variables, and formal parameters of subprograms.

Nesting of subprograms creates what we call *scope variables*: variables declared locally to an enclosing unit. From the perspective of a nested subprogram, scope variables look very much like global variables

Flow analysis is usually fast, roughly as fast as compilation. It detects various types of errors and finds violations of some SPARK legality rules, such as the absence of aliasing and freedom of expressions from side-effects. We discussed these rules in the *SPARK Overview* (page 975).

Flow analysis is *sound*: if it doesn't detect any errors of a type it's supposed to detect, we know for sure there are no such errors.

30.2 Errors Detected

30.2.1 Uninitialized Variables

We now present each class of errors detected by flow analysis. The first is the reading of an uninitialized variable. This is nearly always an error: it introduces non-determinism and breaks the type system because the value of an uninitialized variable may be outside the range of its subtype. For these reasons, SPARK requires every variable to be initialized before being read.

Flow analysis is responsible for ensuring that SPARK code always fulfills this requirement. For example, in the function `Max_Array` shown below, we've neglected to initialize the value of `Max` prior to entering the loop. As a consequence, the value read by the condition of the if statement may be uninitialized. Flow analysis detects and reports this error.

Listing 1: show_uninitialized.ads

```
1 package Show_Uninitialized is
2
3    type Array_Of_Naturals is array (Integer range <>) of Natural;
```

(continues on next page)

(continued from previous page)

```
4
5     function Max_Array (A : Array_Of_Naturals) return Natural;
6
7  end Show_Uninitialized;
```

Listing 2: show_uninitialized.adb

```
1  package body Show_Uninitialized is
2
3     function Max_Array (A : Array_Of_Naturals) return Natural is
4        Max : Natural;
5     begin
6        for I in A'Range loop
7           if A (I) > Max then -- Here Max may not be initialized
8              Max := A (I);
9           end if;
10       end loop;
11       return Max;
12    end Max_Array;
13
14 end Show_Uninitialized;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Flow_Analysis.Uninitialized
MD5: 82fe32cbe33e25bac5466f86ee2e03c4
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
show_uninitialized.adb:7:21: warning: "Max" may be referenced before it has a␣
 ↪value [enabled by default]
show_uninitialized.adb:7:21: medium: "Max" might not be initialized
show_uninitialized.adb:11:14: medium: "Max" might not be initialized
gnatprove: unproved check messages considered as errors
```

Note: For more details on how flow analysis verifies data initialization, see the SPARK User's Guide[252].

30.2.2 Ineffective Statements

Ineffective statements are different than dead code: they're executed, and often even modify the value of variables, but have no effect on any of the subprogram's visible outputs: parameters, global variables or the function result. Ineffective statements should be avoided because they make the code less readable and more difficult to maintain.

More importantly, they're often caused by errors in the program: the statement may have been written for some purpose, but isn't accomplishing that purpose. These kinds of errors can be difficult to detect in other ways.

For example, the subprograms Swap1 and Swap2 shown below don't properly swap their two parameters X and Y. This error caused a statement to be ineffective. That ineffective statement is not an error in itself, but flow analysis produces a warning since it can be indicative of an error, as it is here.

[252] https://docs.adacore.com/live/wave/spark2014/html/spark2014_ug/en/source/language_restrictions.html#data-initialization-policy

Listing 3: show_ineffective_statements.ads

```
package Show_Ineffective_Statements is

   type T is new Integer;

   procedure Swap1 (X, Y : in out T);
   procedure Swap2 (X, Y : in out T);

end Show_Ineffective_Statements;
```

Listing 4: show_ineffective_statements.adb

```
package body Show_Ineffective_Statements is

   procedure Swap1 (X, Y : in out T) is
      Tmp : T;
   begin
      Tmp := X; -- This statement is ineffective
      X   := Y;
      Y   := X;
   end Swap1;

   Tmp : T := 0;

   procedure Swap2 (X, Y : in out T) is
      Temp : T := X; -- This variable is unused
   begin
      X := Y;
      Y := Tmp;
   end Swap2;

end Show_Ineffective_Statements;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Flow_Analysis.Ineffective_Statements
MD5: 473a9215e9e98bd25147998d43847a12
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
show_ineffective_statements.adb:6:11: warning: unused assignment
show_ineffective_statements.adb:14:07: warning: initialization of "Temp" has no␣
 ↪effect
show_ineffective_statements.ads:5:21: warning: unused initial value of "X"
show_ineffective_statements.ads:6:21: warning: unused initial value of "X"
```

So far, we've seen examples where flow analysis warns about ineffective statements and unused variables.

30.2.3 Incorrect Parameter Mode

Parameter modes are an important part of documenting the usage of a subprogram and affect the code generated for that subprogram. Flow analysis checks that each specified parameter mode corresponds to the usage of that parameter in the subprogram's body. It checks that an **in** parameter is never modified, either directly or through a subprogram call, checks that the initial value of an **out** parameter is never read in the subprogram (since it may not be defined on subprogram entry), and warns when an **in out** parameter isn't modified or when its initial value isn't used. All of these may be signs of an error.

We see an example below. The subprogram Swap is incorrect and GNATprove warns about an input which isn't read:

Listing 5: show_incorrect_param_mode.ads

```
package Show_Incorrect_Param_Mode is

   type T is new Integer;

   procedure Swap (X, Y : in out T);

end Show_Incorrect_Param_Mode;
```

Listing 6: show_incorrect_param_mode.adb

```
package body Show_Incorrect_Param_Mode is

   procedure Swap (X, Y : in out T) is
      Tmp : T := X;
   begin
      Y := X;   -- The initial value of Y is not used
      X := Tmp; -- Y is computed to be an out parameter
   end Swap;

end Show_Incorrect_Param_Mode;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Flow_Analysis.Incorrect_Param_Mode
MD5: 1e33dbf461daab0daed01c83025232fc
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
show_incorrect_param_mode.ads:5:23: warning: unused initial value of "Y"
```

In SPARK, unlike Ada, you should declare an **out** parameter to be **in out** if it's not modified on every path, in which case its value may depend on its initial value. SPARK is stricter than Ada to allow more static detection of errors. This table summarizes SPARK's valid parameter modes as a function of whether reads and writes are done to the parameter.

Initial value read	Written on some path	Written on every path	Parameter mode
X			**in**
X	X		**in out**
X		X	**in out**
	X		**in out**
		X	**out**

30.3 Additional Verifications

30.3.1 Global Contracts

So far, none of the verifications we've seen require you to write any additional annotations. However, flow analysis also checks flow annotations that you write. In SPARK, you can specify the set of global and scoped variables accessed or modified by a subprogram. You do this using a contract named `Global`.

When you specify a `Global` contract for a subprogram, flow analysis checks that it's both correct and complete, meaning that no variables other than those stated in the contract are accessed or modified, either directly or through a subprogram call, and that all those listed are accessed or modified. For example, we may want to specify that the function `Get_Value_Of_X` reads the value of the global variable `X` and doesn't access any other global variable. If we do this through a comment, as is usually done in other languages, GNATprove can't verify that the code complies with this specification:

```
package Show_Global_Contracts is

   X : Natural := 0;

   function Get_Value_Of_X return Natural;
   --  Get_Value_Of_X reads the value of the global variable X

end Show_Global_Contracts;
```

You write global contracts as part of the subprogram specification. In addition to their value in flow analysis, they also provide useful information to users of a subprogram. The value you specify for the `Global` aspect is an aggregate-like list of global variable names, grouped together according to their mode.

In the example below, the procedure `Set_X_To_Y_Plus_Z` reads both `Y` and `Z`. We indicate this by specifying them as the value for `Input`. It also writes `X`, which we specify using `Output`. Since `Set_X_To_X_Plus_Y` both writes `X` and reads its initial value, `X`'s mode is `In_Out`. Like parameters, if no mode is specified in a `Global` aspect, the default is `Input`. We see this in the case of the declaration of `Get_Value_Of_X`. Finally, if a subprogram, such as `Incr_Parameter_X`, doesn't reference any global variables, you set the value of the global contract to **`null`**.

Listing 7: show_global_contracts.ads

```
1  package Show_Global_Contracts is
2
3     X, Y, Z : Natural := 0;
4
5     procedure Set_X_To_Y_Plus_Z with
6       Global => (Input  => (Y, Z), --  reads values of Y and Z
7                  Output => X);     --  modifies value of X
8
9     procedure Set_X_To_X_Plus_Y with
10      Global => (Input  => Y,  --  reads value of Y
11                 In_Out => X); --  modifies value of X and
12                               --  also reads its initial value
13
14    function Get_Value_Of_X return Natural with
15      Global => X;  -- reads the value of the global variable X
16
17    procedure Incr_Parameter_X (X : in out Natural) with
18      Global => null; -- do not reference any global variable
```

(continues on next page)

(continued from previous page)

```
19
20 end Show_Global_Contracts;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Flow_Analysis.Global_Contracts
MD5: 2cbf90f2d27b6b0043a2e29449e79df9
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
```

Note: For more details on global contracts, see the SPARK User's Guide[253].

30.3.2 Depends Contracts

You may also supply a Depends contract for a subprogram to specify dependencies between its inputs and outputs. These dependencies include not only global variables but also parameters and the function's result. When you supply a Depends contract for a subprogram, flow analysis checks that it's correct and complete, that is, for each dependency you list, the variable depends on those listed and on no others.

For example, you may want to say that the new value of each parameter of Swap, shown below, depends only on the initial value of the other parameter and that the value of X after the return of Set_X_To_Zero doesn't depend on any global variables. If you indicate this through a comment, as you often do in other languages, GNATprove can't verify that this is actually the case.

```
package Show_Depends_Contracts is

   type T is new Integer;

   procedure Swap (X, Y : in out T);
   --  The value of X (resp. Y) after the call depends only
   --  on the value of Y (resp. X) before the call

   X : Natural;
   procedure Set_X_To_Zero;
   --  The value of X after the call depends on no input

end Show_Depends_Contracts;
```

Like Global contracts, you specify a Depends contract in subprogram declarations using an aspect. Its value is a list of one or more dependency relations between the outputs and inputs of the subprogram. Each relation is represented as two lists of variable names separated by an arrow. On the left of each arrow are variables whose final value depends on the initial value of the variables you list on the right.

For example, here we indicate that the final value of each parameter of Swap depends only on the initial value of the other parameter. If the subprogram is a function, we list its result as an output, using the Result attribute, as we do for Get_Value_Of_X below.

[253] https://docs.adacore.com/live/wave/spark2014/html/spark2014_ug/en/source/subprogram_contracts.html#data-dependencies

Listing 8: show_depends_contracts.ads

```
package Show_Depends_Contracts is

   type T is new Integer;

   X, Y, Z : T := 0;

   procedure Swap (X, Y : in out T) with
     Depends => (X => Y,
                 --  X depends on the initial value of Y
                 Y => X);
                 --  Y depends on the initial value of X

   function Get_Value_Of_X return T with
     Depends => (Get_Value_Of_X'Result => X);
                 --  result depends on the initial value of X

   procedure Set_X_To_Y_Plus_Z with
     Depends => (X => (Y, Z));
                 --  X depends on the initial values of Y and Z

   procedure Set_X_To_X_Plus_Y with
     Depends => (X =>+ Y);
              --  X depends on Y and X's initial value

   procedure Do_Nothing (X : T) with
     Depends => (null => X);
                 --  no output is affected by X

   procedure Set_X_To_Zero with
     Depends => (X => null);
                 --  X depends on no input

end Show_Depends_Contracts;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Flow_Analysis.Depends_Contracts
MD5: 290866c4208b6deff717a402bc2aef34
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
```

Often, the final value of a variable depends on its own initial value. You can specify this in a concise way using the `+` character, as we did in the specification of `Set_X_To_X_Plus_Y` above. If there's more than one variable on the left of the arrow, a `+` means each variables depends on itself, not that they all depend on each other. You can write the corresponding dependency with (=> +) or without (=>+) whitespace.

If you have a program where an input isn't used to compute the final value of any output, you express that by writting **`null`** on the left of the dependency relation, as we did for the `Do_Nothing` subprogram above. You can only write one such dependency relation, which lists all unused inputs of the subprogram, and it must be written last. Such an annotation also silences flow analysis' warning about unused parameters. You can also write **`null`** on the right of a dependency relation to indicate that an output doesn't depend on any input. We do that above for the procedure `Set_X_To_Zero`.

Note: For more details on depends contracts, see the SPARK User's Guide[254].

30.4 Shortcomings

30.4.1 Modularity

Flow analysis is sound, meaning that if it doesn't output a message on some analyzed SPARK code, you can be assured that none of the errors it tests for can occur in that code. On the other hand, flow analysis often issues messages when there are, in fact, no errors. The first, and probably most common reason for this relates to modularity.

To scale flow analysis to large projects, verifications are usually done on a per-subprogram basis, including detection of uninitialized variables. To analyze this modularly, flow analysis needs to assume the initialization of inputs on subprogram entry and modification of outputs during subprogram execution. Therefore, each time a subprogram is called, flow analysis checks that global and parameter inputs are initialized and each time a subprogram returns, it checks that global and parameter outputs were modified.

This can produce error messages on perfectly correct subprograms. An example is `Set_X_To_Y_Plus_Z` below, which only sets its **`out`** parameter `X` when `Overflow` is **`False`**.

Listing 9: set_x_to_y_plus_z.adb

```
procedure Set_X_To_Y_Plus_Z
  (Y, Z      :     Natural;
   X         : out Natural;
   Overflow : out Boolean)
is
begin
   if Natural'Last - Z < Y then
      Overflow := True; -- X should be initialized on every path
   else
      Overflow := False;
      X := Y + Z;
   end if;
end Set_X_To_Y_Plus_Z;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Flow_Analysis.Set_X_To_Y_Plus_Z
MD5: be47cd769d2a7267c0bd1bb2ef0d6328
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
set_x_to_y_plus_z.adb:3:04: medium: "X" might not be initialized in "Set_X_To_Y_
 ↪Plus_Z" [reason for check: OUT parameter should be initialized on return]␣
 ↪[possible fix: initialize "X" on all paths or make "X" an IN OUT parameter]
gnatprove: unproved check messages considered as errors
```

The message means that flow analysis wasn't able to verify that the program didn't read an uninitialized variable. To solve this problem, you can either set `X` to a dummy value when there's an overflow or manually verify that `X` is never used after a call to `Set_X_To_Y_Plus_Z` that returned **`True`** as the value of `Overflow`.

[254] https://docs.adacore.com/live/wave/spark2014/html/spark2014_ug/en/source/subprogram_contracts.html#flow-dependencies

30.4.2 Composite Types

Another common cause of false alarms is caused by the way flow analysis handles composite types. Let's start with arrays.

Flow analysis treats an entire array as single object instead of one object per element, so it considers modifying a single element to be a modification of the array as a whole. Obviously, this makes reasoning about which global variables are accessed less precise and hence the dependencies of those variables are also less precise. This also affects the ability to accurately detect reads of uninitialized data.

It's sometimes impossible for flow analysis to determine if an entire array object has been initialized. For example, after we write code to initialize every element of an unconstrained array A in chunks, we may still receive a message from flow analysis claiming that the array isn't initialized. To resolve this issue, you can either use a simpler loop over the full range of the array, or (even better) an aggregate assignment, or, if that's not possible, verify initialization of the object manually.

Listing 10: show_composite_types_shortcoming.ads

```
package Show_Composite_Types_Shortcoming is

   type T is array (Natural range <>) of Integer;

   procedure Init_Chunks (A : out T);
   procedure Init_Loop (A : out T);
   procedure Init_Aggregate (A : out T);

end Show_Composite_Types_Shortcoming;
```

Listing 11: show_composite_types_shortcoming.adb

```
package body Show_Composite_Types_Shortcoming is

   procedure Init_Chunks (A : out T) is
   begin
      A (A'First) := 0;
      for I in A'First + 1 .. A'Last loop
         A (I) := 0;
      end loop;
      --  flow analysis doesn't know that A is initialized
   end Init_Chunks;

   procedure Init_Loop (A : out T) is
   begin
      for I in A'Range loop
         A (I) := 0;
      end loop;
      --  flow analysis knows that A is initialized
   end Init_Loop;

   procedure Init_Aggregate (A : out T) is
   begin
      A := (others => 0);
      --  flow analysis knows that A is initialized
   end Init_Aggregate;

end Show_Composite_Types_Shortcoming;
```

 ↪return] [possible fix: initialize "A" on all paths, make "A" an IN OUT parameter␣
 ↪or annotate it with aspect Relaxed_Initialization]
gnatprove: unproved check messages considered as errors
```

Flow analysis is more precise on record objects because it tracks the value of each component of a record separately within a single subprogram. So when a record object is initialized by successive assignments of its components, flow analysis knows that the entire object is initialized. However, record objects are still treated as single objects when analyzed as an input or output of a subprogram.

Listing 12: show_record_flow_analysis.ads

```
1  package Show_Record_Flow_Analysis is
2
3     type Rec is record
4        F1 : Natural;
5        F2 : Natural;
6     end record;

```

Flow analysis complains when a procedure call initializes only some components of a record object. It'll notify you of uninitialized components, as we see in subprogram `Init_F2` below.

Listing 14: show_record_flow_analysis.ads

```
package Show_Record_Flow_Analysis is

   type Rec is record
      F1 : Natural;
      F2 : Natural;
   end record;

   procedure Init (R : out Rec);
   procedure Init_F2 (R : in out Rec);

end Show_Record_Flow_Analysis;
```

Listing 15: show_record_flow_analysis.adb

```
package body Show_Record_Flow_Analysis is

   procedure Init_F2
     (R : in out Rec) is
   begin
      R.F2 := 0;
   end Init_F2;

   procedure Init (R : out Rec) is
   begin
      R.F1 := 0;
      Init_F2 (R); -- R should be initialized before this call
   end Init;

end Show_Record_Flow_Analysis;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Flow_Analysis.Record_Flow_Analysis_2

```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
show_record_flow_analysis.adb:12:16: high: "R.F2" is not initialized
gnatprove: unproved check messages considered as errors
```

30.4.3 Value Dependency

Flow analysis is not value-dependent: it never reasons about the values of expressions, only whether they have been set to some value or not. As a consequence, if some execution path in a subprogram is impossible, but the impossibility can only be determined by looking at the values of expressions, flow analysis still considers that path feasible and may emit messages based on it believing that execution along such a path is possible.

For example, in the version of `Absolute_Value` below, flow analysis computes that `R` is uninitialized on a path that enters neither of the two conditional statements. Because it doesn't consider values of expressions, it can't know that such a path is impossible.

Listing 16: absolute_value.adb

```
procedure Absolute_Value
  (X :     Integer;
   R : out Natural)
is
begin
   if X < 0 then
      R := -X;
   end if;
   if X >= 0 then
      R := X;
   end if;
   --  flow analysis doesn't know that R is initialized
end Absolute_Value;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Flow_Analysis.Absolute_Value_1
MD5: 69c233d22afdfdac679bf379b353a8d4
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
absolute_value.adb:3:04: medium: "R" might not be initialized in "Absolute_Value"␣
 ↪[reason for check: OUT parameter should be initialized on return] [possible fix:␣
 ↪initialize "R" on all paths or make "R" an IN OUT parameter]
gnatprove: unproved check messages considered as errors
```

To avoid this problem, you should make the control flow explicit, as in this second version of Absolute_Value:

Listing 17: absolute_value.adb

```
procedure Absolute_Value
  (X :     Integer;
   R : out Natural)
is
begin
   if X < 0 then
      R := -X;
   else
      R := X;
   end if;
   --  flow analysis knows that R is initialized
end Absolute_Value;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Flow_Analysis.Absolute_Value_2
MD5: 9c773547f81e82a7aa1b45132b105937
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
```

30.4.4 Contract Computation

The final cause of unexpected flow messages that we'll discuss also comes from inaccuracy in computations of contracts. As we explained earlier, both `Global` and `Depends` contracts are optional, but GNATprove uses their data for some of its analysis.

For example, flow analysis can't detect reads from uninitialized variables without knowing the set of variables accessed. It needs to analyze and check both the `Depends` contracts you wrote for a subprogram and those you wrote for callers of that subprogram. Since each flow contract on a subprogram depends on the flow contracts of all the subprograms called inside its body, this computation can often be quite time-consuming. Therefore, flow analysis sometimes trades-off the precision of this computation against the time a more precise computation would take.

This is the case for `Depends` contracts, where flow analysis simply assumes the worst, that each subprogram's output depends on all of that subprogram's inputs. To avoid this assumption, all you have to do is supply contracts when default ones are not precise enough. You may also want to supply `Global` contracts to further speed up flow analysis on larger programs.

30.5 Code Examples / Pitfalls

30.5.1 Example #1

The procedure `Search_Array` searches for an occurrence of element `E` in an array `A`. If it finds one, it stores the index of the element in `Result`. Otherwise, it sets `Found` to **`False`**.

Listing 18: show_search_array.ads

```
package Show_Search_Array is

   type Array_Of_Positives is array (Natural range <>) of Positive;

   procedure Search_Array
     (A      :     Array_Of_Positives;
      E      :     Positive;
      Result : out Integer;
      Found  : out Boolean);

end Show_Search_Array;
```

Listing 19: show_search_array.adb

```
package body Show_Search_Array is

   procedure Search_Array
     (A      :     Array_Of_Positives;
      E      :     Positive;
      Result : out Integer;
      Found  : out Boolean) is
   begin
      for I in A'Range loop
         if A (I) = E then
            Result := I;
            Found  := True;
            return;
         end if;
      end loop;
```

(continues on next page)

(continued from previous page)

```
16       Found := False;
17    end Search_Array;
18
19 end Show_Search_Array;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Flow_Analysis.Example_01
MD5: d2a27a5bde247767e2f6cd2d42a2d629
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
show_search_array.ads:8:07: medium: "Result" might not be initialized in "Search_
 ↪Array" [reason for check: OUT parameter should be initialized on return]␣
 ↪[possible fix: initialize "Result" on all paths or make "Result" an IN OUT␣
 ↪parameter]
gnatprove: unproved check messages considered as errors
```

GNATprove produces a message saying that `Result` is possibly uninitialized on return. There are perfectly legal uses of the function `Search_Array`, but flow analysis detects that `Result` is not initialized on the path that falls through from the loop. Even though this program is correct, you shouldn't ignore the message: it means flow analysis cannot guarantee that `Result` is always initialized at the call site and so assumes any read of `Result` at the call site will read initialized data. Therefore, you should either initialize `Result` when Found is false, which silences flow analysis, or verify this assumption at each call site by other means.

30.5.2 Example #2

To avoid the message previously issued by GNATprove, we modify `Search_Array` to raise an exception when E isn't found in A:

Listing 20: show_search_array.ads

```
1  package Show_Search_Array is
2
3     type Array_Of_Positives is array (Natural range <>) of Positive;
4
5     Not_Found : exception;
6
7     procedure Search_Array
8       (A      :     Array_Of_Positives;
9        E      :     Positive;
10       Result : out Integer);
11 end Show_Search_Array;
```

Listing 21: show_search_array.adb

```
1  package body Show_Search_Array is
2
3     procedure Search_Array
4       (A      :     Array_Of_Positives;
5        E      :     Positive;
6        Result : out Integer) is
7     begin
8        for I in A'Range loop
```

(continues on next page)

(continued from previous page)

```
         if A (I) = E then
            Result := I;
            return;
         end if;
      end loop;
      raise Not_Found;
   end Search_Array;

end Show_Search_Array;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Flow_Analysis.Example_02
MD5: fa159faeb68974b1af3de2112e086b16
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
show_search_array.adb:14:07: medium: exception might be raised
gnatprove: unproved check messages considered as errors
```

Flow analysis doesn't emit any messages in this case, meaning it can verify that `Result` can't be read in SPARK code while uninitialized. But why is that, since `Result` is still not initialized when E is not in A? This is because the exception, `Not_Found`, can never be caught within SPARK code (SPAK doesn't allow exception handlers). However, the GNATprove tool also tries to ensure the absence of runtime errors in SPARK code, so tries to prove that `Not_Found` is never raised. When it can't do that here, it produces a different message.

30.5.3 Example #3

In this example, we're using a discriminated record for the result of `Search_Array` instead of conditionally raising an exception. By using such a structure, the place to store the index at which E was found exists only when E was indeed found. So if it wasn't found, there's nothing to be initialized.

Listing 22: show_search_array.ads

```
package Show_Search_Array is

   type Array_Of_Positives is array (Natural range <>) of Positive;

   type Search_Result (Found : Boolean := False) is record
      case Found is
         when True =>
            Content : Integer;
         when False => null;
      end case;
   end record;

   procedure Search_Array
     (A      :     Array_Of_Positives;
      E      :     Positive;
      Result : out Search_Result)
   with Pre => not Result'Constrained;

end Show_Search_Array;
```

Listing 23: show_search_array.adb

```
package body Show_Search_Array is

   procedure Search_Array
     (A      :     Array_Of_Positives;
      E      :     Positive;
      Result : out Search_Result) is
   begin
      for I in A'Range loop
         if A (I) = E then
            Result := (Found   => True,
                       Content => I);
            return;
         end if;
      end loop;
      Result := (Found => False);
   end Search_Array;

end Show_Search_Array;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Flow_Analysis.Example_03
MD5: 1d5ec5d78185fd75499b90b3d21f8ae2
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
show_search_array.adb:10:20: info: discriminant check proved
show_search_array.adb:15:14: info: discriminant check proved
show_search_array.ads:16:07: info: initialization of "Result" proved
```

This example is correct and flow analysis doesn't issue any message: it can verify both that no uninitialized variables are read in `Search_Array`'s body, and that all its outputs are set on return. We've used the attribute `Constrained` in the precondition of `Search_Array` to indicate that the value of the `Result` in argument can be set to any variant of the record type `Search_Result`, specifically to either the variant where `E` was found and where it wasn't.

30.5.4 Example #4

The function `Size_Of_Biggest_Increasing_Sequence` is supposed to find all sequences within its parameter `A` that contain elements with increasing values and returns the length of the longest one. To do this, it calls a nested procedure `Test_Index` iteratively on all the elements of `A`. `Test_Index` checks if the sequence is still increasing. If so, it updates the largest value seen so far in this sequence. If not, it means it's found the end of a sequence, so it computes the size of that sequence and stores it in `Size_Of_Seq`.

Listing 24: show_biggest_increasing_sequence.ads

```
package Show_Biggest_Increasing_Sequence is

   type Array_Of_Positives is array (Integer range <>) of Positive;

   function Size_Of_Biggest_Increasing_Sequence (A : Array_Of_Positives)
      return Natural;
```

(continues on next page)

(continued from previous page)

```
7
8  end Show_Biggest_Increasing_Sequence;
```

Listing 25: show_biggest_increasing_sequence.adb

```
1  package body Show_Biggest_Increasing_Sequence is
2
3     function Size_Of_Biggest_Increasing_Sequence (A : Array_Of_Positives)
4        return Natural
5     is
6        Max         : Natural;
7        End_Of_Seq  : Boolean;
8        Size_Of_Seq : Natural;
9        Beginning   : Integer;
10
11       procedure Test_Index (Current_Index : Integer) is
12       begin
13          if A (Current_Index) >= Max then
14             Max := A (Current_Index);
15             End_Of_Seq := False;
16          else
17             Max         := 0;
18             End_Of_Seq  := True;
19             Size_Of_Seq := Current_Index - Beginning;
20             Beginning   := Current_Index;
21          end if;
22       end Test_Index;
23
24       Biggest_Seq : Natural := 0;
25
26    begin
27       for I in A'Range loop
28          Test_Index (I);
29          if End_Of_Seq then
30             Biggest_Seq := Natural'Max (Size_Of_Seq, Biggest_Seq);
31          end if;
32       end loop;
33       return Biggest_Seq;
34    end Size_Of_Biggest_Increasing_Sequence;
35
36 end Show_Biggest_Increasing_Sequence;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Flow_Analysis.Example_04

```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
show_biggest_increasing_sequence.adb:13:34: medium: "Max" might not be initialized,
 ↪ in call inlined at show_biggest_increasing_sequence.adb:28
show_biggest_increasing_sequence.adb:19:44: medium: "Beginning" might not be␣
 ↪initialized, in call inlined at show_biggest_increasing_sequence.adb:28
show_biggest_increasing_sequence.adb:30:41: medium: "Size_Of_Seq" might not be␣
 ↪initialized
gnatprove: unproved check messages considered as errors
```

However, this example is not correct. Flow analysis emits messages for `Test_Index` stating that `Max`, `Beginning`, and `Size_Of_Seq` should be initialized before being read. Indeed,

when you look carefully, you see that both Max and Beginning are missing initializations because they are read in Test_Index before being written. As for Size_Of_Seq, we only read its value when End_Of_Seq is true, so it actually can't be read before being written, but flow analysis isn't able to verify its initialization by using just flow information.

The call to Test_Index is automatically inlined by GNATprove, which leads to another messages above. If GNATprove couldn't inline the call to Test_Index, for example if it was defined in another unit, the same messages would be issued on the call to Test_Index.

30.5.5 Example #5

In the following example, we model permutations as arrays where the element at index I is the position of the I'th element in the permutation. The procedure Init initializes a permutation to the identity, where the I'th elements is at the I'th position. Cyclic_Permutation calls Init and then swaps elements to construct a cyclic permutation.

Listing 26: show_permutation.ads

```
package Show_Permutation is

   type Permutation is array (Positive range <>) of Positive;

   procedure Swap (A    : in out Permutation;
                   I, J : Positive);

   procedure Init (A : out Permutation);

   function Cyclic_Permutation (N : Natural) return Permutation;

end Show_Permutation;
```

Listing 27: show_permutation.adb

```
package body Show_Permutation is

   procedure Swap (A    : in out Permutation;
                   I, J : Positive)
   is
      Tmp : Positive := A (I);
   begin
      A (I) := A (J);
      A (J) := Tmp;
   end Swap;

   procedure Init (A : out Permutation) is
   begin
      A (A'First) := A'First;
      for I in A'First + 1 .. A'Last loop
         A (I) := I;
      end loop;
   end Init;

   function Cyclic_Permutation (N : Natural) return Permutation is
      A : Permutation (1 .. N);
   begin
      Init (A);
      for I in A'First .. A'Last - 1 loop
         Swap (A, I, I + 1);
      end loop;
      return A;
```

(continues on next page)

(continued from previous page)

```
28    end Cyclic_Permutation;
29
30 end Show_Permutation;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Flow_Analysis.Example_05
MD5: 219b06617c636c18543128d77f90fcee
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
show_permutation.ads:8:20: medium: "A" might not be initialized in "Init" [reason␣
↪for check: OUT parameter should be fully initialized on return] [possible fix:␣
↪initialize "A" on all paths, make "A" an IN OUT parameter or annotate it with␣
↪aspect Relaxed_Initialization]
gnatprove: unproved check messages considered as errors
```

This program is correct. However, flow analysis will nevertheless still emit messages because it can't verify that every element of A is initialized by the loop in `Init`. This message is a false alarm. You can either ignore it or justify it safely.

30.5.6 Example #6

This program is the same as the previous one except that we've changed the mode of A in the specification of `Init` to **`in out`** to avoid the message from flow analysis on array assignment.

Listing 28: show_permutation.ads

```
1  package Show_Permutation is
2
3     type Permutation is array (Positive range <>) of Positive;
4
5     procedure Swap (A    : in out Permutation;
6                     I, J : Positive);
7
8     procedure Init (A : in out Permutation);
9
10    function Cyclic_Permutation (N : Natural) return Permutation;
11
12 end Show_Permutation;
```

Listing 29: show_permutation.adb

```
1  package body Show_Permutation is
2
3     procedure Swap (A    : in out Permutation;

Phase 2 of 2: analysis of data and information flow ...
show_permutation.adb:23:13: high: "A" is not initialized
gnatprove: unproved check messages considered as errors
```

This program is not correct. Changing the mode of a parameter that should really be **out** to **in out** to silence a false alarm is not a good idea. Not only does this obfuscate the specification of `Init`, but flow analysis emits a message on the procedure where `A` is not initialized, as shown by the message in `Cyclic_Permutation`.

30.5.7 Example #7

`Incr_Step_Function` takes an array `A` as an argument and iterates through `A` to increment every element by the value of `Increment`, saturating at a specified threshold value. We specified a `Global` contract for `Incr_Until_Threshold`.

Listing 30: show_increments.ads

```
package Show_Increments is

   type Array_Of_Positives is array (Natural range <>) of Positive;

   Increment : constant Natural := 10;

   procedure Incr_Step_Function (A : in out Array_Of_Positives);

end Show_Increments;
```

Listing 31: show_increments.adb

```

```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
show_increments.adb:8:09: info: data dependencies proved
```

Everything is fine here. Specifically, the `Global` contract is correct. It mentions both `Threshold`, which is read but not written in the procedure, and `A`, which is both read and written. The fact that `A` is a parameter of an enclosing unit doesn't prevent us from using it inside the `Global` contract; it really is global to `Incr_Until_Threshold`. We didn't mention `Increment` since it's a static constant.

30.5.8 Example #8

We now go back to the procedure `Test_Index` from *Example #4* (page 1008) and correct the missing initializations. We want to know if the `Global` contract of `Test_Index` is correct.

Listing 32: show_biggest_increasing_sequence.ads

show_biggest_increasing_sequence.adb:14:30: error: global item cannot reference␣
 ↪parameter of subprogram "Test_Index"
gnatprove: error during generation of Global contracts
```

The contract in this example is not correct: `Current_Index` is a parameter of `Test_Index`, so we shouldn't reference it as a global variable. Also, we should have listed variable `A` from the outer scope as an `Input` in the `Global` contract.

30.5.9 Example #9

Next, we change the `Global` contract of `Test_Index` into a `Depends` contract. In general, we don't need both contracts because the set of global variables accessed can be deduced from the `Depends` contract.

Listing 34: show_biggest_increasing_sequence.ads

```
package Show_Biggest_Increasing_Sequence is

   type Array_Of_Positives is array (Integer range <>) of Positive;

   function Size_Of_Biggest_Increasing_Sequence (A : Array_Of_Positives)
      return Natural;

show_biggest_increasing_sequence.adb:11:17: info: initialization of "End_Of_Seq"␣
 ↪proved
show_biggest_increasing_sequence.adb:12:09: info: flow dependencies proved
```

This example is correct. Some of the dependencies, such as `Size_Of_Seq` depending on `Beginning`, come directly from the assignments in the subprogram. Since the control flow influences the final value of all of the outputs, the variables that are being read, `A`, `Current_Index`, and `Max`, are present in every dependency relation. Finally, the dependencies of `Size_Of_Eq` and `Beginning` on themselves are because they may not be modified by the subprogram execution.

30.5.10 Example #10

The subprogram `Identity` swaps the value of its parameter two times. Its `Depends` contract says that the final value of `X` only depends on its initial value and likewise for `Y`.

Listing 36: show_swap.ads

```
1  package Show_Swap is
2
3     procedure Swap (X, Y : in out Positive);
4
5     procedure Identity (X, Y : in out Positive) with
6       Depends => (X => X,
7                   Y => Y);
8
9  end Show_Swap;
```

Listing 37: show_swap.adb

```

show_swap.ads:6:18: medium: missing dependency "X => Y"
show_swap.ads:7:18: medium: missing dependency "Y => X"
gnatprove: unproved check messages considered as errors
```

This code is correct, but flow analysis can't verify the `Depends` contract of `Identity` because we didn't supply a `Depends` contract for `Swap`. Therefore, flow analysis assumes that all outputs of `Swap`, `X` and `Y`, depend on all its inputs, both `X` and `Y`'s initial values. To prevent this, we should manually specify a `Depends` contract for `Swap`.

CHAPTER

THIRTYONE

PROOF OF PROGRAM INTEGRITY

This section presents the proof capability of GNATprove, a major tool for the SPARK language. We focus here on the simpler proofs that you'll need to write to verify your program's integrity. The primary objective of performing proof of your program's integrity is to ensure the absence of runtime errors during its execution.

The analysis steps discussed here are only sound if you've previously performed *Flow Analysis* (page 993). You shouldn't proceed further if you still have unjustified flow analysis messages for your program.

31.1 Runtime Errors

There's always the potential for errors that aren't detected during compilation to occur during a program's execution. These errors, called runtime errors, are those targeted by GNATprove.

There are various kinds of runtime errors, the most common being references that are out of the range of an array (buffer overflow[255] in Ada), subtype range violations, overflows in computations, and divisions by zero. The code below illustrates many examples of possible runtime errors, all within a single statement. Look at the assignment statement setting the `I + J`'th cell of an array `A` to the value `P /Q`.

Listing 1: show_runtime_errors.ads

```
package Show_Runtime_Errors is

   type Nat_Array is array (Integer range <>) of Natural;

   procedure Update (A : in out Nat_Array; I, J, P, Q : Integer);

end Show_Runtime_Errors;
```

Listing 2: show_runtime_errors.adb

```
package body Show_Runtime_Errors is

   procedure Update (A : in out Nat_Array; I, J, P, Q : Integer) is
   begin
      A (I + J) := P / Q;
   end Update;

end Show_Runtime_Errors;
```

 ↪subprogram at show_runtime_errors.ads:5]
gnatprove: unproved check messages considered as errors
```

There are quite a number of errors that may occur when executing this code. If we don't know anything about the values of `I`, `J`, `P`, and `Q`, we can't rule out any of those errors.

First, the computation of `I + J` can overflow, for example if `I` is `Integer'Last` and `J` is positive.

```
A (Integer'Last + 1) := P / Q;
```

Next, the sum, which is used as an array index, may not be in the range of the index of the array.

```
A (A'Last + 1) := P / Q;
```

On the other side of the assignment, the division may also overflow, though only in the very special case where `P` is `Integer'First` and `Q` is -1 because of the asymmetric range of signed integer types.

```
A (I + J) := Integer'First / -1;
```

The division is also not allowed if `Q` is 0.

```
A (I + J) := P / 0;
```

Finally, since the array contains natural numbers, it's also an error to store a negative value in it.

```
A (I + J) := 1 / -1;
```

The compiler generates checks in the executable code corresponding to each of those run-time errors. Each check raises an exception if it fails. For the above assignment statement, we can see examples of exceptions raised due to failed checks for each of the different cases above.

```
A (Integer'Last + 1) := P / Q;
-- raised CONSTRAINT_ERROR : overflow check failed

A (A'Last + 1) := P / Q;
-- raised CONSTRAINT_ERROR : index check failed

A (I + J) := Integer'First / (-1);
-- raised CONSTRAINT_ERROR : overflow check failed

A (I + J) := 1 / (-1);
-- raised CONSTRAINT_ERROR : range check failed

A (I + J) := P / 0;
-- raised CONSTRAINT_ERROR : divide by zero
```

These runtime checks are costly, both in terms of program size and execution time. It may be appropriate to remove them if we can statically ensure they aren't needed at runtime, in other words if we can prove that the condition tested for can never occur.

This is where the analysis done by GNATprove comes in. It can be used to demonstrate statically that none of these errors can ever occur at runtime. Specifically, GNATprove logically interprets the meaning of every instruction in the program. Using this interpretation, GNATprove generates a logical formula called a *verification condition* for each check that would otherwise be required by the Ada (and hence SPARK) language.

```
A (Integer'Last + 1) := P / Q;
-- medium: overflow check might fail

A (A'Last + 1) := P / Q;
-- medium: array index check might fail

A (I + J) := Integer'First / (-1);
-- medium: overflow check might fail

A (I + J) := 1 / (-1);
-- medium: range check might fail

A (I + J) := P / 0;
-- medium: divide by zero might fail
```

GNATprove then passes these verification conditions to an automatic prover, stated as conditions that must be true to avoid the error. If every such condition can be validated by a prover (meaning that it can be mathematically shown to always be true), we've been able to prove that no error can ever be raised at runtime when executing that program.

31.2 Modularity

To scale to large programs, GNATprove performs proofs on a per-subprogram basis by relying on preconditions and postconditions to properly summarize the input and output state of each subprogram. More precisely, when verifying the body of a subprogram, GNATprove assumes it knows nothing about the possible initial values of its parameters and of the global variables it accesses except what you state in the subprogram's precondition. If you don't specify a precondition, it can't make any assumptions.

For example, the following code shows that the body of `Increment` can be successfully verified: its precondition constrains the value of its parameter `X` to be less than `Integer'Last` so we know the overflow check is always false.

In the same way, when a subprogram is called, GNATprove assumes its **out** and **in out** parameters and the global variables it writes can be modified in any way compatible with their postconditions. For example, since Increment has no postcondition, GNATprove doesn't know that the value of X after the call is always less than **Integer**'Last. Therefore, it can't prove that the addition following the call to Increment can't overflow.

Listing 3: show_modularity.adb

```
procedure Show_Modularity is

   procedure Increment (X : in out Integer) with
     Pre => X < Integer'Last is
   begin
      X := X + 1;
      --  info: overflow check proved
   end Increment;

   X : Integer;
begin
   X := Integer'Last - 2;
   Increment (X);
   --  After the call, GNATprove no longer knows the value of X

   X := X + 1;
   --  medium: overflow check might fail
end Show_Modularity;
```

 ↪bound for X + 1 [reason for check: result of addition must fit in a 32-bits␣
 ↪machine integer] [possible fix: call at line 13 should mention X (for argument␣
 ↪X) in a postcondition]
gnatprove: unproved check messages considered as errors
```

31.2.1 Exceptions

There are two cases where GNATprove doesn't require modularity and hence doesn't make the above assumptions. First, local subprograms without contracts can be inlined if they're simple enough and are neither recursive nor have multiple return points. If we remove the contract from Increment, it fits the criteria for inlining.

Listing 4: show_modularity.adb

```
procedure Show_Modularity is

   procedure Increment (X : in out Integer) is
   begin
      X := X + 1;
      --  info: overflow check proved, in call inlined at...
```

(continues on next page)

(continued from previous page)

```
   end Increment;

   X : Integer;
begin
   X := Integer'Last - 2;
   Increment (X);
   X := X + 1;
   --  info: overflow check proved
end Show_Modularity;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Modularity_2
MD5: 448d576897c3e4606cd4b90621aad63a
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
show_modularity.adb:5:14: info: overflow check proved, in call inlined at show_
↪modularity.adb:12
show_modularity.adb:9:04: info: initialization of "X" proved
show_modularity.adb:13:11: info: overflow check proved
```

GNATprove now sees the call to `Increment` exactly as if the increment on `X` was done outside that call, so it can successfully verify that neither addition can overflow.

Note: For more details on contextual analysis of subprograms, see the SPARK User's Guide[256].

The other case involves functions. If we define a function as an expression function, with or without contracts, GNATprove uses the expression itself as the postcondition on the result of the function.

In our example, replacing `Increment` with an expression function allows GNATprove to successfully verify the overflow check in the addition.

Listing 5: show_modularity.adb

```
procedure Show_Modularity is

   function Increment (X : Integer) return Integer is
     (X + 1)
     --  info: overflow check proved
     with Pre => X < Integer'Last;

   X : Integer;
begin
   X := Integer'Last - 2;
   X := Increment (X);
   X := X + 1;
   --  info: overflow check proved
end Show_Modularity;
```

31.3 Contracts

Ada contracts are perfectly suited for formal verification, but are primarily designed to be checked at runtime. When you specify the `-gnata` switch, the compiler generates code that verifies the contracts at runtime. If an Ada contract isn't satisfied for a given subprogram call, the program raises the `Assert_Failure` exception. This switch is particularly useful during development and testing, but you may also retain run-time execution of assertions, and specifically preconditions, during the program's deployment to avoid an inconsistent state.

Consider the incorrect call to `Increment` below, which violates its precondition. One way to detect this error is by compiling the function with assertions enabled and testing it with inputs that trigger the violation. Another way, one that doesn't require guessing the needed inputs, is to run GNATprove.

Listing 6: show_precondition_violation.adb

```
procedure Show_Precondition_Violation is

   procedure Increment (X : in out Integer) with
     Pre => X < Integer'Last  is
   begin
      X := X + 1;
   end Increment;

   X : Integer;

begin
   X := Integer'Last;
   Increment (X);
end Show_Precondition_Violation;
```

Runtime output

```
raised ADA.ASSERTIONS.ASSERTION_ERROR : failed precondition from show_precondition_
↪violation.adb:4
```

Similarly, consider the incorrect implementation of function `Absolute` below, which violates its postcondition. Likewise, one way to detect this error is by compiling the function with assertions enabled and testing with inputs that trigger the violation. Another way, one which again doesn't require finding the inputs needed to demonstrate the error, is to run GNATprove.

Listing 7: show_postcondition_violation.adb

```
1  procedure Show_Postcondition_Violation is
2
3     procedure Absolute (X : in out Integer) with
4       Post => X >= 0 is
5     begin
6        if X > 0 then
7           X := -X;
8        end if;
9     end Absolute;
10
11    X : Integer;
12
13 begin
14    X := 1;
15    Absolute (X);
16 end Show_Postcondition_Violation;
```

```

Runtime output

```
raised ADA.ASSERTIONS.ASSERTION_ERROR : failed postcondition from show_
↪postcondition_violation.adb:4
```

The benefits of dynamically checking contracts extends beyond making testing easier. Early failure detection also allows an easier recovery and facilitates debugging, so you may want to enable these checks at runtime to terminate execution before some damaging or hard-to-debug action occurs.

GNATprove statically analyses preconditions and postconditions. It verifies preconditions every time a subprogram is called, which is the runtime semantics of contracts. Postconditions, on the other hand, are verified once as part of the verification of the subprogram's

body. For example, GNATprove must wait until `Increment` is improperly called to detect the precondition violation, since a precondition is really a contract for the caller. On the other hand, it doesn't need `Absolute` to be called to detect that its postcondition doesn't hold for all its possible inputs.

Note: For more details on pre and postconditions, see the SPARK User's Guide[258].

31.3.1 Executable Semantics

Expressions in Ada contracts have the same semantics as Boolean expressions elsewhere, so runtime errors can occur during their computation. To simplify both debugging of assertions and combining testing and static verification, the same semantics are used by GNATprove.

While proving programs, GNATprove verifies that no error can ever be raised during the execution of the contracts. However, you may sometimes find those semantics too heavy, in particular with respect to overflow checks, because they can make it harder to specify an appropriate precondition. We see this in the function Add below.

Listing 8: show_executable_semantics.adb

```
procedure Show_Executable_Semantics
  with SPARK_Mode => On
is
   function Add (X, Y : Integer) return Integer is (X + Y)
     with Pre => X + Y in Integer;

   X : Integer;
begin
   X := Add (Integer'Last, 1);
end Show_Executable_Semantics;
```

Code block metadata

```

show_executable_semantics.adb:9:09: medium: precondition might fail, cannot prove␣
 ↪upper bound for Add (Integer'Last, 1)
gnatprove: unproved check messages considered as errors
```

Runtime output

[258] https://docs.adacore.com/live/wave/spark2014/html/spark2014_ug/en/source/subprogram_contracts.html#preconditions

```
raised CONSTRAINT_ERROR : show_executable_semantics.adb:5 overflow check failed
```

GNATprove issues a message on this code warning about a possible overflow when computing the sum of X and Y in the precondition. Indeed, since expressions in assertions have normal Ada semantics, this addition can overflow, as you can easily see by compiling and running the code that calls Add with arguments `Integer'Last` and 1.

On the other hand, you sometimes may prefer GNATprove to use the mathematical semantics of addition in contracts while the generated code still properly verifies that no error is ever raised at runtime in the body of the program. You can get this behavior by using the compiler switch `-gnato??` (for example `-gnato13`), which allows you to independently set the overflow mode in code (the first digit) and assertions (the second digit). For both, you can either reduce the number of overflow checks (the value 2), completely eliminate them (the value 3), or preserve the default Ada semantics (the value 1).

Note: For more details on overflow modes, see the SPARK User's Guide[259].

31.3.2 Additional Assertions and Contracts

As we've seen, a key feature of SPARK is that it allows us to state properties to check using assertions and contracts. SPARK supports preconditions and postconditions as well as assertions introduced by the `Assert` pragma.

The SPARK language also includes new contract types used to assist formal verification. The new pragma `Assume` is treated as an assertion during execution but introduces an assumption when proving programs. Its value is a Boolean expression which GNATprove assumes to be true without any attempt to verify that it's true. You'll find this feature useful, but you must use it with great care. Here's an example of using it.

Listing 9: incr.adb

```
procedure Incr (X : in out Integer) is
begin
   pragma Assume (X < Integer'Last);
   X := X + 1;
end Incr;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Pragma_Assume
MD5: bfbc4b8aca259d7516b6acaee571f8c2
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
incr.adb:4:11: info: overflow check proved
```

Note: For more details on pragma `Assume`, see the SPARK User's Guide[260].

The `Contract_Cases` aspect is another construct introduced for GNATprove, but which also acts as an assertion during execution. It allows you to specify the behavior of a subprogram

[259] https://docs.adacore.com/live/wave/spark2014/html/spark2014_ug/en/source/overflow_modes.html
[260] https://docs.adacore.com/live/wave/spark2014/html/spark2014_ug/en/source/assertion_pragmas.html#pragma-assume

using a disjunction of cases. Each element of a `Contract_Cases` aspect is a *guard*, which is evaluated before the call and may only reference the subprogram's inputs, and a *consequence*. At each call of the subprogram, one and only one guard is permitted to evaluate to `True`. The consequence of that case is a contract that's required to be satisfied when the subprogram returns.

Listing 10: absolute.adb

```
procedure Absolute (X : in out Integer) with
  Pre            =>  X > Integer'First,
  Contract_Cases => (X <  0 => X = -X'Old,
                     X >= 0 => X =  X'Old)
is
begin
   if X < 0 then
      X := -X;
   end if;
end Absolute;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Absolute
MD5: 5ac868f35be18bb6fffe2444ecbea28d
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
absolute.adb:3:03: info: disjoint contract cases proved
absolute.adb:3:03: info: complete contract cases proved
absolute.adb:3:29: info: contract case proved
absolute.adb:3:36: info: overflow check proved
absolute.adb:4:29: info: contract case proved
absolute.adb:8:12: info: overflow check proved
```

Similarly to how it analyzes a subprogram's precondition, GNATprove verifies the `Contract_Cases` only once. It verifies the validity of each consequence (given the truth of its guard) and the disjointness and completeness of the guard conditions (meaning that exactly one guard must be true for each possible set of input values).

Note: For more details on `Contract_Cases`, see the SPARK User's Guide[261].

31.4 Debugging Failed Proof Attempts

GNATprove may report an error while verifying a program for any of the following reasons:

- there might be an error in the program; or
- the property may not be provable as written because more information is required; or
- the prover used by GNATprove may be unable to prove a perfectly valid property.

We spend the remainder of this section discussing the sometimes tricky task of debugging failed proof attempts.

[261] https://docs.adacore.com/live/wave/spark2014/html/spark2014_ug/en/source/subprogram_contracts.html#contract-cases

31.4.1 Debugging Errors in Code or Specification

First, let's discuss the case where there's indeed an error in the program. There are two possibilities: the code may be incorrect or, equally likely, the specification may be incorrect. As an example, there's an error in our procedure `Incr_Until` below which makes its `Contract_Cases` unprovable.

Listing 11: show_failed_proof_attempt.ads

```
package Show_Failed_Proof_Attempt is

   Incremented : Boolean := False;

   procedure Incr_Until (X : in out Natural) with
     Contract_Cases =>
       (Incremented => X > X'Old,
        others      => X = X'Old);

end Show_Failed_Proof_Attempt;
```

Listing 12: show_failed_proof_attempt.adb

```
package body Show_Failed_Proof_Attempt is

   procedure Incr_Until (X : in out Natural) is
   begin
      if X < 1000 then
         X := X + 1;
         Incremented := True;
      else
         Incremented := False;
      end if;
   end Incr_Until;

end Show_Failed_Proof_Attempt;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Failed_Proof_Attempt_1
MD5: 814636ae9df6f4f66ad69f5099a5729b
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
show_failed_proof_attempt.ads:7:21: medium: contract case might fail
show_failed_proof_attempt.ads:8:21: medium: contract case might fail
gnatprove: unproved check messages considered as errors
```

Since this is an assertion that can be executed, it may help you find the problem if you run the program with assertions enabled on representative sets of inputs. This allows you to find bugs in both the code and its contracts. In this case, testing `Incr_Until` with an input greater than 1000 raises an exception at runtime.

Listing 13: show_failed_proof_attempt.ads

```
package Show_Failed_Proof_Attempt is

   Incremented : Boolean := False;

   procedure Incr_Until (X : in out Natural) with
```

(continues on next page)

(continued from previous page)

```
     Contract_Cases =>
       (Incremented => X > X'Old,
        others      => X = X'Old);

end Show_Failed_Proof_Attempt;
```

Listing 14: show_failed_proof_attempt.adb

```
package body Show_Failed_Proof_Attempt is

   procedure Incr_Until (X : in out Natural) is
   begin
      if X < 1000 then
         X := X + 1;
         Incremented := True;
      else
         Incremented := False;
      end if;
   end Incr_Until;

end Show_Failed_Proof_Attempt;
```

Listing 15: main.adb

```
with Show_Failed_Proof_Attempt; use Show_Failed_Proof_Attempt;

procedure Main is
   Dummy : Integer;
begin
   Dummy := 0;
   Incr_Until (Dummy);

   Dummy := 1000;
   Incr_Until (Dummy);
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Failed_Proof_Attempt_2
MD5: bd87cb0f64a6468eaab3cad1678271db
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
show_failed_proof_attempt.ads:7:21: medium: contract case might fail
show_failed_proof_attempt.ads:8:21: medium: contract case might fail
gnatprove: unproved check messages considered as errors
```

Runtime output

```
raised ADA.ASSERTIONS.ASSERTION_ERROR : failed contract case at show_failed_proof_
↪attempt.ads:8
```

The error message shows that the first contract case is failing, which means that `Incremented` is **`True`**. However, if we print the value of `Incremented` before returning, we see that it's **`False`**, as expected for the input we provided. The error here is that guards of contract cases are evaluated before the call, so our specification is wrong! To correct this, we should either write `X < 1000` as the guard of the first case or use a standard postcondition with an if-expression.

31.4.2 Debugging Cases where more Information is Required

Even if both the code and the assertions are correct, GNATprove may still report that it can't prove a verification condition for a property. This can happen for two reasons:

- The property may be unprovable because the code is missing some assertion. One category of these cases is due to the modularity of the analysis which, as we discussed above, means that GNATprove only knows about the properties of your subprograms that you have explicitly written.
- There may be some information missing in the logical model of the program used by GNATprove.

Let's look at the case where the code and the specification are correct but there's some information missing. As an example, GNATprove finds the postcondition of `Increase` to be unprovable.

Listing 16: show_failed_proof_attempt.ads

```
package Show_Failed_Proof_Attempt is

   C : Natural := 100;

   procedure Increase (X : in out Natural) with
      Post => (if X'Old < C then X > X'Old else X = C);

end Show_Failed_Proof_Attempt;
```

Listing 17: show_failed_proof_attempt.adb

```
package body Show_Failed_Proof_Attempt is

   procedure Increase (X : in out Natural) is
   begin
      if X < 90 then
         X := X + 10;
      elsif X >= C then
         X := C;
      else
         X := X + 1;
      end if;
   end Increase;

end Show_Failed_Proof_Attempt;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Failed_Proof_Attempt_3
MD5: e01fc27a981bcb80757f30c94768237e
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
show_failed_proof_attempt.ads:6:49: medium: postcondition might fail, cannot prove␣
 ↪X = C
gnatprove: unproved check messages considered as errors
```

This postcondition is a conditional. It says that if the parameter (X) is less than a certain value (C), its value will be increased by the procedure while if it's greater, its value will be set to C (saturated). When C has the value 100, the code of `Increases` adds 10 to the value of X if it was initially less than 90, increments X by 1 if it was between 90 and 99, and sets

X to 100 if it was greater or equal to 100. This behavior does satisfy the postcondition, so why is the postcondition not provable?

The values in the counterexample returned by GNATprove in its message gives us a clue: `C = 0 and X = 10 and X'Old = 0`. Indeed, if C is not equal to 100, our reasoning above is incorrect: the values of 0 for C and X on entry indeed result in X being 10 on exit, which violates the postcondition!

We probably didn't expect the value of C to change, or at least not to go below 90. But, in that case, we should have stated so by either declaring C to be constant or by adding a precondition to the `Increase` subprogram. If we do either of those, GNATprove is able to prove the postcondition.

31.4.3 Debugging Prover Limitations

Finally, there are cases where GNATprove provides a perfectly valid verification condition for a property, but it's nevertheless not proved by the automatic prover that runs in the later stages of the tool's execution. This is quite common. Indeed, GNATprove produces its verification conditions in first-order logic, which is not decidable, especially in combination with the rules of arithmetic. Sometimes, the automatic prover just needs more time. Other times, the prover will abandon the search almost immediately or loop forever without reaching a conclusive answer (either a proof or a counterexample).

For example, the postcondition of our GCD function below — which calculates the value of the GCD of two positive numbers using Euclide's algorithm — can't be verified with GNATprove's default settings.

Listing 18: show_failed_proof_attempt.ads

```
package Show_Failed_Proof_Attempt is

   function GCD (A, B : Positive) return Positive with
     Post =>
       A mod GCD'Result = 0
       and B mod GCD'Result = 0;

end Show_Failed_Proof_Attempt;
```

Listing 19: show_failed_proof_attempt.adb

```
package body Show_Failed_Proof_Attempt is

   function GCD (A, B : Positive) return Positive is
   begin
      if A > B then
         return GCD (A - B, B);
      elsif B > A then
         return GCD (A, B - A);
      else
         return A;
      end if;
   end GCD;

end Show_Failed_Proof_Attempt;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Failed_Proof_Attempt_4
MD5: a6f1a39ceb0793df8a00691d59a5d9ce
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
show_failed_proof_attempt.ads:5:08: medium: postcondition might fail, cannot prove␣
↪A mod GCD'Result = 0
gnatprove: unproved check messages considered as errors
```

The first thing we try is increasing the amount of time the prover is allowed to spend on each verification condition using the `--timeout` option of GNATprove (e.g., by using the dialog box in GNAT Studio). In this example, increasing it to one minute, which is relatively high, doesn't help. We can also specify an alternative automatic prover — if we have one — using the option `--prover` of GNATprove (or the dialog box). For our postcondition, we tried Alt-Ergo, cvc5, and Z3 without any luck.

Listing 20: show_failed_proof_attempt.ads

```
1  package Show_Failed_Proof_Attempt is
2
3     function GCD (A, B : Positive) return Positive with
4       Post =>
5         A mod GCD'Result = 0
6         and B mod GCD'Result = 0;
7
8  end Show_Failed_Proof_Attempt;
```

Listing 21: show_failed_proof_attempt.adb

```
1  package body Show_Failed_Proof_Attempt is
2
3     function GCD (A, B : Positive) return Positive
4     is
5        Result : Positive;
6     begin
7        if A > B then
8           Result := GCD (A - B, B);
9           pragma Assert ((A - B) mod Result = 0);
10          --  info: assertion proved
11          pragma Assert (B mod Result = 0);
12          --  info: assertion proved
13          pragma Assert (A mod Result = 0);
14          --  medium: assertion might fail
15       elsif B > A then
16          Result := GCD (A, B - A);
17          pragma Assert ((B - A) mod Result = 0);
18          --  info: assertion proved
19       else
20          Result := A;
21       end if;
22       return Result;
23    end GCD;
24
25 end Show_Failed_Proof_Attempt;
```

Code block metadata

↪B mod GCD'Result = 0
show_failed_proof_attempt.ads:6:14: info: division check proved
gnatprove: unproved check messages considered as errors
```

To better understand the reason for the failure, we added intermediate assertions to simplify the proof and pin down the part that's causing the problem. Adding such assertions is often a good idea when trying to understand why a property is not proved. Here, provers can't verify that if both A - B and B can be divided by `Result` so can A. This may seem surprising, but non-linear arithmetic, involving, for example, multiplication, modulo, or exponentiation, is a difficult topic for provers and is not handled very well in practice by any of the general-purpose ones like Alt-Ergo, cvc5, or Z3.

Note: For more details on how to investigate unproved checks, see the SPARK User's Guide[262].

31.5 Code Examples / Pitfalls

We end with some code examples and pitfalls.

31.5.1 Example #1

The package `Lists` defines a linked-list data structure. We call `Link(I,J)` to make a link from index `I` to index `J` and call `Goes_To(I,J)` to determine if we've created a link from index `I` to index `J`. The postcondition of `Link` uses `Goes_To` to state that there must be a link between its arguments once `Link` completes.

Listing 22: lists.ads

```
1 package Lists with SPARK_Mode is
2
3    type Index is new Integer;
4
5    function Goes_To (I, J : Index) return Boolean;
6
7    procedure Link (I, J : Index) with Post => Goes_To (I, J);
8
9 private
```

(continues on next page)

[262] https://docs.adacore.com/live/wave/spark2014/html/spark2014_ug/en/source/how_to_investigate_unproved_checks.html

(continued from previous page)

```
10
11    type Cell (Is_Set : Boolean := True) is record
12       case Is_Set is
13          when True =>
14             Next : Index;
15          when False =>
16             null;
17       end case;
18    end record;
19
20    type Cell_Array is array (Index) of Cell;
21
22    Memory : Cell_Array;
23
24 end Lists;
```

Listing 23: lists.adb

```
1  package body Lists with SPARK_Mode is
2
3     function Goes_To (I, J : Index) return Boolean is
4     begin
5        if Memory (I).Is_Set then
6           return Memory (I).Next = J;
7        end if;
8        return False;
9     end Goes_To;
10
11    procedure Link (I, J : Index) is
12    begin
13       Memory (I) := (Is_Set => True, Next => J);
14    end Link;
15
16 end Lists;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Example_01
MD5: c2246948c584304d5694b49b4d1fd0fc
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
lists.ads:7:47: medium: postcondition might fail [possible fix: you should␣
 ↪consider adding a postcondition to function Goes_To or turning it into an␣
 ↪expression function]
gnatprove: unproved check messages considered as errors
```

This example is correct, but can't be verified by GNATprove. This is because Goes_To itself has no postcondition, so nothing is known about its result.

31.5.2 Example #2

We now redefine Goes_To as an expression function.

Listing 24: lists.ads

```
package Lists with SPARK_Mode is

   type Index is new Integer;

   function Goes_To (I, J : Index) return Boolean;

   procedure Link (I, J : Index) with Post => Goes_To (I, J);

private

   type Cell (Is_Set : Boolean := True) is record
      case Is_Set is
      when True =>
         Next : Index;
      when False =>
         null;
      end case;
   end record;

   type Cell_Array is array (Index) of Cell;

   Memory : Cell_Array;

   function Goes_To (I, J : Index) return Boolean is
     (Memory (I).Is_Set and then Memory (I).Next = J);

end Lists;
```

Listing 25: lists.adb

```
package body Lists with SPARK_Mode is

   procedure Link (I, J : Index) is
   begin
      Memory (I) := (Is_Set => True, Next => J);
   end Link;

end Lists;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Example_02
MD5: c65953bbe8a5f9fb77a4d94e2dd875f9
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
lists.adb:5:18: info: discriminant check proved
lists.ads:7:47: info: postcondition proved
lists.ads:25:44: info: discriminant check proved
```

GNATprove can fully prove this version: Goes_To is an expression function, so its body is available for proof (specifically, for creating the postcondition needed for the proof).

31.5.3 Example #3

The package Stacks defines an abstract stack type with a Push procedure that adds an element at the top of the stack and a function Peek that returns the content of the element at the top of the stack (without removing it).

Listing 26: stacks.ads

```
package Stacks with SPARK_Mode is

   type Stack is private;

   function  Peek (S : Stack) return Natural;
   procedure Push (S : in out Stack; E : Natural) with
     Post => Peek (S) = E;

private

   Max : constant := 10;

   type Stack_Array is array (1 .. Max) of Natural;

   type Stack is record
      Top     : Positive;
      Content : Stack_Array;
   end record;

   function Peek (S : Stack) return Natural is
     (if S.Top in S.Content'Range then S.Content (S.Top) else 0);

end Stacks;
```

Listing 27: stacks.adb

```
package body Stacks with SPARK_Mode is

   procedure Push (S : in out Stack; E : Natural) is
   begin
      if S.Top >= Max then
         return;
      end if;

      S.Top := S.Top + 1;
      S.Content (S.Top) := E;
   end Push;

end Stacks;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Example_03
MD5: 917d624916c5ef14c4e454d6c56414fd
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
stacks.ads:7:14: medium: postcondition might fail
gnatprove: unproved check messages considered as errors
```

This example isn't correct. The postcondition of Push is only satisfied if the stack isn't full when we call Push.

31.5.4 Example #4

We now change the behavior of Push so it raises an exception when the stack is full instead of returning.

Listing 28: stacks.ads

```
package Stacks with SPARK_Mode is

   type Stack is private;

   Is_Full_E : exception;

   function  Peek (S : Stack) return Natural;
   procedure Push (S : in out Stack; E : Natural) with
     Post => Peek (S) = E;

private

   Max : constant := 10;

   type Stack_Array is array (1 .. Max) of Natural;

   type Stack is record
      Top     : Positive;
      Content : Stack_Array;
   end record;

   function Peek (S : Stack) return Natural is
     (if S.Top in S.Content'Range then S.Content (S.Top) else 0);

end Stacks;
```

Listing 29: stacks.adb

```
package body Stacks with SPARK_Mode is

   procedure Push (S : in out Stack; E : Natural) is
   begin
      if S.Top >= Max then
         raise Is_Full_E;
      end if;

      S.Top := S.Top + 1;
      S.Content (S.Top) := E;
   end Push;

end Stacks;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Example_04
MD5: b573ebe93f85ea171166b6953cbb8956
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
stacks.adb:6:10: medium: exception might be raised
gnatprove: unproved check messages considered as errors
```

The postcondition of Push is now proved because GNATprove only considers execution paths

leading to normal termination. But it issues a message warning that exception `Is_Full_E` may be raised at runtime.

31.5.5 Example #5

Let's add a precondition to Push stating that the stack shouldn't be full.

Listing 30: stacks.ads

```
package Stacks with SPARK_Mode is

   type Stack is private;

   Is_Full_E : exception;

   function  Peek (S : Stack) return Natural;
   function  Is_Full (S : Stack) return Boolean;
   procedure Push (S : in out Stack; E : Natural) with
     Pre  => not Is_Full (S),
     Post => Peek (S) = E;

private

   Max : constant := 10;

   type Stack_Array is array (1 .. Max) of Natural;

   type Stack is record
      Top     : Positive;
      Content : Stack_Array;
   end record;

   function Peek (S : Stack) return Natural is
     (if S.Top in S.Content'Range then S.Content (S.Top) else 0);
   function Is_Full (S : Stack) return Boolean is (S.Top >= Max);

end Stacks;
```

Listing 31: stacks.adb

```
package body Stacks with SPARK_Mode is

   procedure Push (S : in out Stack; E : Natural) is
   begin
      if S.Top >= Max then
         raise Is_Full_E;
      end if;
      S.Top := S.Top + 1;
      S.Content (S.Top) := E;
   end Push;

end Stacks;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Example_05
MD5: 63c2dfd68dd5acd91d8d497206e7423e
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
stacks.adb:6:10: info: raise statement or expression proved unreachable
stacks.adb:8:22: info: overflow check proved
stacks.adb:9:19: info: index check proved
stacks.ads:11:14: info: postcondition proved
stacks.ads:25:52: info: index check proved
```

This example is correct. With the addition of the precondition, GNATprove can now verify that `Is_Full_E` can never be raised at runtime.

31.5.6 Example #6

The package `Memories` defines a type `Chunk` that models chunks of memory. Each element of the array, represented by its index, corresponds to one data element. The procedure `Read_Record` reads two pieces of data starting at index `From` out of the chunk represented by the value of `Memory`.

Listing 32: memories.ads

```
1  package Memories is
2
3     type Chunk is array (Integer range <>) of Integer
4       with Predicate => Chunk'Length >= 10;
5
6     function Is_Too_Coarse (V : Integer) return Boolean;
7
8     procedure Treat_Value (V : out Integer);
9
10 end Memories;
```

Listing 33: read_record.adb

```
1  with Memories; use Memories;
2
3  procedure Read_Record (Memory : Chunk; From : Integer)
4    with SPARK_Mode => On,
5         Pre => From in Memory'First .. Memory'Last - 2
6  is
7     function Read_One (First : Integer; Offset : Integer) return Integer
8       with Pre => First + Offset in Memory'Range
9     is
10       Value : Integer := Memory (First + Offset);
11    begin
12       if Is_Too_Coarse (Value) then
13          Treat_Value (Value);
14       end if;
15       return Value;
16    end Read_One;
17
18    Data1, Data2 : Integer;
19
20 begin
21    Data1 := Read_One (From, 1);
22    Data2 := Read_One (From, 2);
23 end Read_Record;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Example_06
MD5: aec8014dc291708999092fa123ee7416
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
read_record.adb:8:24: medium: overflow check might fail, cannot prove lower bound␣
 ↪for First + Offset [reason for check: result of addition must fit in a 32-bits␣
 ↪machine integer] [possible fix: use pragma Overflow_Mode or switch -gnato13 or␣
 ↪unit Ada.Numerics.Big_Numerics.Big_Integers]
gnatprove: unproved check messages considered as errors
```

This example is correct, but it can't be verified by GNATprove, which analyses Read_One on its own and notices that an overflow may occur in its precondition in certain contexts.

31.5.7 Example #7

Let's rewrite the precondition of Read_One to avoid any possible overflow.

Listing 34: memories.ads

```
1  package Memories is
2
3     type Chunk is array (Integer range <>) of Integer
4       with Predicate => Chunk'Length >= 10;
5
6     function Is_Too_Coarse (V : Integer) return Boolean;
7
8     procedure Treat_Value (V : out Integer);
9
10 end Memories;
```

Listing 35: read_record.adb

```
1  with Memories; use Memories;
2
3  procedure Read_Record (Memory : Chunk; From : Integer)
4    with SPARK_Mode => On,
5         Pre => From in Memory'First .. Memory'Last - 2
6  is
7     function Read_One (First : Integer; Offset : Integer) return Integer
8       with Pre => First >= Memory'First
9              and then Offset in 0 .. Memory'Last - First
10    is
11       Value : Integer := Memory (First + Offset);
12    begin
13       if Is_Too_Coarse (Value) then
14          Treat_Value (Value);
15       end if;
16       return Value;
17    end Read_One;
18
19    Data1, Data2 : Integer;
20
21 begin
22    Data1 := Read_One (From, 1);
23    Data2 := Read_One (From, 2);
24 end Read_Record;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Example_07
MD5: 6b4c6a41b652ad76bc7ef8934dcd9bfc
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
read_record.adb:9:49: medium: overflow check might fail, cannot prove lower bound␣
 ↪for Memory'Last - First [reason for check: result of subtraction must fit in a␣
 ↪32-bits machine integer] [possible fix: use pragma Overflow_Mode or switch -
 ↪gnato13 or unit Ada.Numerics.Big_Numerics.Big_Integers]
gnatprove: unproved check messages considered as errors
```

This example is also not correct: unfortunately, our attempt to correct Read_One's precondition failed. For example, an overflow will occur at runtime if `First` is **`Integer`**`'Last` and `Memory'Last` is negative. This is possible here because type Chunk uses **`Integer`** as base index type instead of **`Natural`** or **`Positive`**.

31.5.8 Example #8

Let's completely remove the precondition of Read_One.

Listing 36: memories.ads

```
package Memories is

   type Chunk is array (Integer range <>) of Integer
     with Predicate => Chunk'Length >= 10;

   function Is_Too_Coarse (V : Integer) return Boolean;

   procedure Treat_Value (V : out Integer);

end Memories;
```

Listing 37: read_record.adb

```
with Memories; use Memories;

procedure Read_Record (Memory : Chunk; From : Integer)
  with SPARK_Mode => On,
       Pre => From in Memory'First .. Memory'Last - 2
is
   function Read_One (First : Integer; Offset : Integer) return Integer is
      Value : Integer := Memory (First + Offset);
   begin
      if Is_Too_Coarse (Value) then
         Treat_Value (Value);
      end if;
      return Value;
   end Read_One;

   Data1, Data2 : Integer;

begin
   Data1 := Read_One (From, 1);
   Data2 := Read_One (From, 2);
end Read_Record;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Example_08
MD5: 5a806fb84b50d2dc1f2af428b1bc8d0a
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
read_record.adb:5:51: info: overflow check proved
read_record.adb:8:40: info: overflow check proved, in call inlined at read_record.
 ↪adb:19
read_record.adb:8:40: info: index check proved, in call inlined at read_record.
 ↪adb:19
read_record.adb:8:40: info: overflow check proved, in call inlined at read_record.
 ↪adb:20
read_record.adb:8:40: info: index check proved, in call inlined at read_record.
 ↪adb:20
```

This example is correct and fully proved. We could have fixed the contract of Read_One to correctly handle both positive and negative values of `Memory'Last`, but we found it simpler to let the function be inlined for proof by removing its precondition.

31.5.9 Example #9

The procedure `Compute` performs various computations on its argument. The computation performed depends on its input range and is reflected in its contract, which we express using a `Contract_Cases` aspect.

Listing 38: compute.adb

```
procedure Compute (X : in out Integer) with
  Contract_Cases => ((X in -100 .. 100) => X = X'Old * 2,
                     (X in    0 .. 199) => X = X'Old + 1,
                     (X in -199 .. 0)   => X = X'Old - 1,
                      X >=  200          => X =  200,
                      others             => X = -200)
is
begin
   if X in -100 .. 100 then
      X := X * 2;
   elsif X in 0 .. 199 then
      X := X + 1;
   elsif X in -199 .. 0 then
      X := X - 1;
   elsif X >= 200 then
      X := 200;
   else
      X := -200;
   end if;
end Compute;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Example_09
MD5: 51962d1bb6dd1b081ed498dd11559685
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
compute.adb:2:03: medium: contract cases might not be disjoint
compute.adb:3:41: medium: contract case might fail
compute.adb:4:41: medium: contract case might fail
gnatprove: unproved check messages considered as errors
```

This example isn't correct. We duplicated the content of `Compute`'s body in its contract. This is incorrect because the semantics of `Contract_Cases` require disjoint cases, just like a case statement. The counterexample returned by GNATprove shows that `X = 0` is covered by two different case-guards (the first and the second).

31.5.10 Example #10

Let's rewrite the contract of `Compute` to avoid overlapping cases.

Listing 39: compute.adb

```
procedure Compute (X : in out Integer) with
  Contract_Cases => ((X in    0 ..  199) => X >= X'Old,
                     (X in -199 ..   -1) => X <= X'Old,
                      X >=  200          => X =  200,
                      X <  -200          => X = -200)
is
begin
   if X in -100 .. 100 then
      X := X * 2;
   elsif X in 0 .. 199 then
      X := X + 1;
   elsif X in -199 .. 0 then
      X := X - 1;
   elsif X >= 200 then
      X := 200;
   else
      X := -200;
   end if;
end Compute;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Program_Integrity.Example_10
MD5: 01d33b10fd60f384ffa4ae8fea1e7d87
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
compute.adb:2:03: medium: contract cases might not be complete
gnatprove: unproved check messages considered as errors
```

This example is still not correct. GNATprove can successfully prove the different cases are disjoint and also successfully verify each case individually. This isn't enough, though: a `Contract_Cases` must cover all cases. Here, we forgot the value -200, which is what GNATprove reports in its counterexample.

CHAPTER

THIRTYTWO

STATE ABSTRACTION

Abstraction is a key concept in programming that can drastically simplify both the implementation and maintenance of code. It's particularly well suited to SPARK and its modular analysis. This section explains what state abstraction is and how you use it in SPARK. We explain how it impacts GNATprove's analysis both in terms of information flow and proof of program properties.

State abstraction allows us to:

- express dependencies that wouldn't otherwise be expressible because some data that's read or written isn't visible at the point where a subprogram is declared — examples are dependencies on data, for which we use the `Global` contract, and on flow, for which we use the `Depends` contract.
- reduce the number of variables that need to be considered in flow analysis and proof, a reduction which may be critical in order to scale the analysis to programs with thousands of global variables.

32.1 What's an Abstraction?

Abstraction is an important part of programming language design. It provides two views of the same object: an abstract one and a refined one. The abstract one — usually called *specification* — describes what the object does in a coarse way. A subprogram's specification usually describes how it should be called (e.g., parameter information such as how many and of what types) as well as what it does (e.g., returns a result or modifies one or more of its parameters).

Contract-based programming, as supported in Ada, allows contracts to be added to a subprogram's specification. You use contracts to describe the subprogram's behavior in a more fine-grained manner, but all the details of how the subprogram actually works are left to its refined view, its implementation.

Take a look at the example code shown below.

Listing 1: increase.ads

```
procedure Increase (X : in out Integer) with
  Global => null,
  Pre    => X <= 100,
  Post   => X'Old < X;
```

Listing 2: increase.adb

```
procedure Increase (X : in out Integer) is
begin
   X := X + 1;
end Increase;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.No_Abstraction
MD5: c4c8f229aeb1b5c12744d26369a8603f
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
increase.adb:3:11: info: overflow check proved
increase.ads:2:03: info: data dependencies proved
increase.ads:4:13: info: postcondition proved
```

We've written a specification of the subprogram `Increase` to say that it's called with a single argument, a variable of type **`Integer`** whose initial value is less than 100. Our contract says that the only effect of the subprogram is to increase the value of its argument.

32.2 Why is Abstraction Useful?

A good abstraction of a subprogram's implementation is one whose specification precisely and completely summarizes what its callers can rely on. In other words, a caller of that subprogram shouldn't rely on any behavior of its implementation if that behavior isn't documented in its specification.

For example, callers of the subprogram `Increase` can assume that it always strictly increases the value of its argument. In the code snippet shown below, this means the loop must terminate.

Listing 3: increase.ads

```
procedure Increase (X : in out Integer) with
  Global => null,
  Pre    => X <= 100,
  Post   => X'Old < X;
```

Listing 4: client.adb

```
with Increase;
procedure Client is
   X : Integer := 0;
begin
   while X <= 100 loop      --  The loop will terminate
      Increase (X);         --  Increase can be called safely
   end loop;
   pragma Assert (X = 101); --  Will this hold?
end Client;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Using_Abstraction
MD5: 9cd07cb04ae2194343931f0561693be4
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
client.adb:8:19: medium: assertion might fail
gnatprove: unproved check messages considered as errors
```

Callers can also assume that the implementation of `Increase` won't cause any runtime errors when called in the loop. On the other hand, nothing in the specification guarantees that the assertion show above is correct: it may fail if `Increase`'s implementation is changed.

If you follow this basic principle, abstraction can bring you significant benefits. It simplifies both your program's implementation and verification. It also makes maintenance and code reuse much easier since changes to the implementation of an object shouldn't affect the code using this object. Your goal in using it is that it should be enough to understand the specification of an object in order to use that object, since understanding the specification is usually much simpler than understanding the implementation.

GNATprove relies on the abstraction defined by subprogram contracts and therefore doesn't prove the assertion after the loop in `Client` above.

32.3 Abstraction of a Package's State

Subprograms aren't the only objects that benefit from abstraction. The state of a package — the set of persistent variables defined in it — can also be hidden from external users. You achieve this form of abstraction — called *state abstraction* — by defining variables in the body or private part of a package so they can only be accessed through subprogram calls. For example, our `Stack` package shown below provides an abstraction for a `Stack` object which can only be modified using the `Pop` and `Push` procedures.

```
package Stack is
   procedure Pop  (E : out Element);
   procedure Push (E : in  Element);
end Stack;

package body Stack is
   Content : Element_Array (1 .. Max);
   Top     : Natural;
   ...
end Stack;
```

The fact that we implemented it using an array is irrelevant to the caller. We could change that without impacting our callers' code.

32.4 Declaring a State Abstraction

Hidden state influences a program's behavior, so SPARK allows that state to be declared. You can use the `Abstract_State` aspect, an abstraction that names a state, to do this, but you aren't required to use it even for a package with hidden state. You can use several state abstractions to declare the hidden state of a single package or you can use it for a package with no hidden state at all. However, since SPARK doesn't allow aliasing, different state abstractions must always refer to disjoint sets of variables. A state abstraction isn't a variable: it doesn't have a type and can't be used inside expressions, either those in bodies or contracts.

As an example of the use of this aspect, we can optionally define a state abstraction for the entire hidden state of the `Stack` package like this:

```
package Stack with
  Abstract_State => The_Stack
is
  ...
```

Alternatively, we can define a state abstraction for each hidden variable:

```
package Stack with
  Abstract_State => (Top_State, Content_State)
is
  ...
```

Remember: a state abstraction isn't a variable (it has no type) and can't be used inside expressions. For example:

```
pragma Assert (Stack.Top_State = ...);
-- compilation error: Top_State is not a variable
```

32.5 Refining an Abstract State

Once you've declared an abstract state in a package, you must refine it into its constituents using a `Refined_State` aspect. You must place the `Refined_State` aspect on the package body even if the package wouldn't otherwise have required a body. For each state abstraction you've declared for the package, you list the set of variables represented by that state abstraction in its refined state.

If you specify an abstract state for a package, it must be complete, meaning you must have listed every hidden variable as part of some state abstraction. For example, we must add a `Refined_State` aspect on our `Stack` package's body linking the state abstraction (`The_Stack`) to the entire hidden state of the package, which consists of both `Content` and `Top`.

Listing 5: stack.ads

```
1  package Stack with
2    Abstract_State => The_Stack
3  is
4     type Element is new Integer;
5
6     procedure Pop  (E : out Element);
7     procedure Push (E : Element);
8
9  end Stack;
```

Listing 6: stack.adb

```
1  package body Stack with
2    Refined_State => (The_Stack => (Content, Top))
3  is
4     Max : constant := 100;
5
6     type Element_Array is array (1 .. Max) of Element;
7
8     Content : Element_Array := (others => 0);
9     Top     : Natural range 0 .. Max := 0;
10    --  Both Content and Top must be listed in the list of
11    --  constituents of The_Stack
12
13    procedure Pop (E : out Element) is
14    begin
15       E   := Content (Top);
16       Top := Top - 1;
17    end Pop;
18
19    procedure Push (E : Element) is
```

32.6 Representing Private Variables

You can refine state abstractions in the package body, where all the variables are visible. When only the package's specification is available, you need a way to specify which state abstraction each private variable belongs to. You do this by adding the `Part_Of` aspect to the variable's declaration.

`Part_Of` annotations are mandatory: if you gave a package an abstract state annotation, you must link all the hidden variables defined in its private part to a state abstraction. For example:

Listing 7: stack.ads

```
package Stack with
  Abstract_State => The_Stack
is
   type Element is new Integer;

   procedure Pop  (E : out Element);
   procedure Push (E : Element);

private

   Max : constant := 100;

   type Element_Array is array (1 .. Max) of Element;

   Content : Element_Array          with Part_Of => The_Stack;
   Top     : Natural range 0 .. Max with Part_Of => The_Stack;

end Stack;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Private_Variables
MD5: 3b5f7edca8a4511071d2397197b01fda
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
```

Since we chose to define `Content` and `Top` in `Stack`'s private part instead of its body, we had to add a `Part_Of` aspect to both of their declarations, associating them with the state abstraction The_Stack, even though it's the only state abstraction. However, we still need to list them in the `Refined_State` aspect in `Stack`'s body.

```
package body Stack with
  Refined_State => (The_Stack => (Content, Top))
```

32.7 Additional State

32.7.1 Nested Packages

So far, we've only discussed hidden variables. But variables aren't the only component of a package's state. If a package P contains a nested package, the nested package's state is also part of P's state. If the nested package is hidden, its state is part of P's hidden state and must be listed in P's state refinement.

We see this in the example below, where the package `Hidden_Nested`'s hidden state is part of P's hidden state.

Listing 8: p.ads

```
1  package P with
2     Abstract_State => State
3  is
4     package Visible_Nested with
5        Abstract_State => Visible_State
6     is
7        procedure Get (E : out Integer);
8     end Visible_Nested;
9  end P;
```

Listing 9: p.adb

```
1  package body P with
2     Refined_State => (State => Hidden_Nested.Hidden_State)
3  is
4     package Hidden_Nested with
5        Abstract_State => Hidden_State,
6        Initializes    => Hidden_State
7     is
8        function Get return Integer;
9     end Hidden_Nested;
10
11    package body Hidden_Nested with
12       Refined_State => (Hidden_State => Cnt)
13    is
14       Cnt : Integer := 0;
15
16       function Get return Integer is (Cnt);
17    end Hidden_Nested;
18
19    package body Visible_Nested with
20       Refined_State => (Visible_State => Checked)
```

(continues on next page)

(continued from previous page)

```
   is
      Checked : Boolean := False;

      procedure Get (E : out Integer) is
      begin
         Checked := True;
         E := Hidden_Nested.Get;
      end Get;
   end Visible_Nested;
end P;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Nested_Packages
MD5: 8260089cbd651de296dd790506c76fd8
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
p.adb:6:07: info: flow dependencies proved
p.ads:7:22: info: initialization of "E" proved
```

Any visible state of `Hidden_Nested` would also have been part of P's hidden state. However, if P contains a visible nested package, that nested package's state isn't part of P's hidden state. Instead, you should declare that package's hidden state in a separate state abstraction on its own declaration, like we did above for `Visible_Nested`.

32.7.2 Constants that Depend on Variables

Some constants are also possible components of a state abstraction. These are constants whose value depends either on a variable or a subprogram parameter. They're handled as variables during flow analysis because they participate in the flow of information between variables throughout the program. Therefore, GNATprove considers these constants to be part of a package's state just like it does for variables.

If you've specified a state abstraction for a package, you must list such hidden constants declared in that package in the state abstraction refinement. However, constants that don't depend on variables don't participate in the flow of information and must not appear in a state refinement.

Let's look at this example.

Listing 10: stack.ads

```
package Stack with
  Abstract_State => The_Stack
is
   type Element is new Integer;

   procedure Pop  (E : out Element);
   procedure Push (E : Element);
end Stack;
```

Listing 11: configuration.ads

```
package Configuration with
  Initializes => External_Variable
is
```

(continues on next page)

(continued from previous page)

```
   External_Variable : Positive with Volatile;
end Configuration;
```

Listing 12: stack.adb

```
with Configuration;
pragma Elaborate (Configuration);

package body Stack with
  Refined_State => (The_Stack => (Content, Top, Max))
  --  Max has variable inputs. It must appear as a
  --  constituent of The_Stack
is
   Max : constant Positive := Configuration.External_Variable;

   type Element_Array is array (1 .. Max) of Element;

   Content : Element_Array := (others => 0);
   Top     : Natural range 0 .. Max := 0;

   procedure Pop (E : out Element) is
   begin
      E   := Content (Top);
      Top := Top - 1;
   end Pop;

   procedure Push (E : Element) is
   begin
      Top           := Top + 1;
      Content (Top) := E;
   end Push;

end Stack;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Constants_And_Variables
MD5: 109a6340ef0f3b0dc88e0fe5888b9a53
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
stack.ads:6:20: info: initialization of "E" proved
configuration.ads:2:03: info: flow dependencies proved
```

Here, Max — the maximum number of elements that can be stored in the stack — is initialized from a variable in an external package. Because of this, we must include Max as part of the state abstraction The_Stack.

Note: For more details on state abstractions, see the SPARK User's Guide[263].

[263] https://docs.adacore.com/live/wave/spark2014/html/spark2014_ug/en/source/package_contracts.html#state-abstraction

32.8 Subprogram Contracts

32.8.1 Global and Depends

Hidden variables can only be accessed through subprogram calls, so you document how state abstractions are modified during the program's execution via the contracts of those subprograms. You use `Global` and `Depends` contracts to specify which of the state abstractions are used by a subprogram and how values flow through the different variables. The `Global` and `Depends` contracts that you write when referring to state abstractions are often less precise than contracts referring to visible variables since the possibly different dependencies of the hidden variables contained within a state abstraction are collapsed into a single dependency.

Let's add `Global` and `Depends` contracts to the `Pop` procedure in our stack.

Listing 13: stack.ads

```
package Stack with
   Abstract_State => (Top_State, Content_State)
is
   type Element is new Integer;

   procedure Pop (E : out Element) with
     Global  => (Input  => Content_State,
                 In_Out => Top_State),
     Depends => (Top_State => Top_State,
                 E         => (Content_State, Top_State));

end Stack;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Global_Depends
MD5: a7b383c35508d6a8294bf7cf0fe332ac
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
```

In this example, the `Pop` procedure only modifies the value of the hidden variable `Top`, while `Content` is unchanged. By using distinct state abstractions for the two variables, we're able to preserve this semantic in the contract.

Let's contrast this example with a different representation of `Global` and `Depends` contracts, this time using a single abstract state.

Listing 14: stack.ads

```
package Stack with
  Abstract_State => The_Stack
is
   type Element is new Integer;

   procedure Pop  (E : out Element) with
     Global  => (In_Out => The_Stack),
     Depends => ((The_Stack, E) => The_Stack);

end Stack;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Global_Single_Abstract_State
MD5: f89f6026fa5ee3c18baf0af9d7c3dbca
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
```

Here, Top_State and Content_State are merged into a single state abstraction, The_Stack. By doing so, we've hidden the fact that Content isn't modified (though we're still showing that Top may be modified). This loss in precision is reasonable here, since it's the whole point of the abstraction. However, you must be careful not to aggregate unrelated hidden state because this risks their annotations becoming meaningless.

Even though imprecise contracts that consider state abstractions as a whole are perfectly reasonable for users of a package, you should write Global and Depends contracts that are as precise as possible within the package body. To allow this, SPARK introduces the notion of *refined contracts*, which are precise contracts specified on the bodies of subprograms where state refinements are visible. These contracts are the same as normal Global and Depends contracts except they refer directly to the hidden state of the package.

When a subprogram is called inside the package body, you should write refined contracts instead of the general ones so that the verification can be as precise as possible. However, refined Global and Depends are optional: if you don't specify them, GNATprove will compute them to check the package's implementation.

For our Stack example, we could add refined contracts as shown below.

Listing 15: stack.ads

```
1  package Stack with
2    Abstract_State => The_Stack
3  is
4     type Element is new Integer;
5
6     procedure Pop  (E : out Element) with
7       Global  => (In_Out => The_Stack),
8       Depends => ((The_Stack, E) => The_Stack);
9
10    procedure Push (E : Element) with
11      Global  => (In_Out    => The_Stack),
12      Depends => (The_Stack => (The_Stack, E));
13
14 end Stack;
```

Listing 16: stack.adb

```
1  package body Stack with
2    Refined_State => (The_Stack => (Content, Top))
3  is
4     Max : constant := 100;
5
6     type Element_Array is array (1 .. Max) of Element;
7
8     Content : Element_Array := (others => 0);
9     Top     : Natural range 0 .. Max := 0;
10
11    procedure Pop (E : out Element) with
12      Refined_Global  => (Input  => Content,
13                          In_Out => Top),
14      Refined_Depends => (Top => Top,
```

(continues on next page)

(continued from previous page)

```
                          E   => (Content, Top))
   is
   begin
      E   := Content (Top);
      Top := Top - 1;
   end Pop;

   procedure Push (E : Element) with
     Refined_Global  => (In_Out => (Content, Top)),
     Refined_Depends => (Content =>+ (Content, Top, E),
                         Top     => Top) is
   begin
     Top := Top + 1;
     Content (Top) := E;
   end Push;

end Stack;
```

Phase 2 of 2: analysis of data and information flow ...
```

32.8.2 Preconditions and Postconditions

We mostly express functional properties of subprograms using preconditions and postconditions. These are standard Boolean expressions, so they can't directly refer to state abstractions. To work around this restriction, we can define functions to query the value of hidden variables. We then use these functions in place of the state abstraction in the contract of other subprograms.

For example, we can query the state of the stack with functions `Is_Empty` and `Is_Full` and call these in the contracts of procedures Pop and Push:

Listing 17: stack.ads

```
package Stack is
   type Element is new Integer;

   function Is_Empty return Boolean;
   function Is_Full  return Boolean;

   procedure Pop (E : out Element) with
     Pre  => not Is_Empty,
     Post => not Is_Full;

   procedure Push (E : Element) with
     Pre  => not Is_Full,
     Post => not Is_Empty;

end Stack;
```

Listing 18: stack.adb

```
package body Stack is

   Max : constant := 100;

   type Element_Array is array (1 .. Max) of Element;

   Content : Element_Array := (others => 0);
   Top     : Natural range 0 .. Max := 0;

   function Is_Empty return Boolean is (Top = 0);
   function Is_Full  return Boolean is (Top = Max);

   procedure Pop (E : out Element) is
   begin
      E   := Content (Top);
      Top := Top - 1;
   end Pop;

   procedure Push (E : Element) is
   begin
      Top           := Top + 1;
      Content (Top) := E;
   end Push;

end Stack;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Pre_Postconditions_1
MD5: fe9d4b65ba1beeabc7cf0feda29b8b3c
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
stack.adb:15:23: info: index check proved
stack.adb:16:18: info: range check proved
stack.adb:21:28: info: range check proved
stack.adb:22:16: info: index check proved
stack.ads:7:19: info: initialization of "E" proved
stack.ads:9:14: info: postcondition proved
stack.ads:13:14: info: postcondition proved
```

Just like we saw for `Global` and `Depends` contracts, you may often find it useful to have a more precise view of functional contracts in the context where the hidden variables are visible. You do this using expression functions in the same way we did for the functions `Is_Empty` and `Is_Full` above. As expression function, bodies act as contracts for GNATprove, so they automatically give a more precise version of the contracts when their implementation is visible.

You may often need a more constraining contract to verify the package's implementation but want to be less strict outside the abstraction. You do this using the `Refined_Post` aspect. This aspect, when placed on a subprogram's body, provides stronger guarantees to internal callers of a subprogram. If you provide one, the refined postcondition must imply the subprogram's postcondition. This is checked by GNATprove, which reports a failing postcondition if the refined postcondition is too weak, even if it's actually implied by the subprogram's body. SPARK doesn't peform a similar verification for normal preconditions.

For example, we can refine the postconditions in the bodies of Pop and Push to be more detailed than what we wrote for them in their specification.

Listing 19: stack.ads

```
package Stack is
   type Element is new Integer;

   function Is_Empty return Boolean;
   function Is_Full  return Boolean;

   procedure Pop (E : out Element) with
     Pre  => not Is_Empty,
     Post => not Is_Full;

   procedure Push (E : Element) with
     Pre  => not Is_Full,
     Post => not Is_Empty;

end Stack;
```

Listing 20: stack.adb

```
package body Stack is

   Max : constant := 100;

   type Element_Array is array (1 .. Max) of Element;

   Content : Element_Array := (others => 0);
   Top     : Natural range 0 .. Max := 0;

   function Is_Empty return Boolean is (Top = 0);
   function Is_Full  return Boolean is (Top = Max);

   procedure Pop (E : out Element) with
     Refined_Post => not Is_Full and E = Content (Top)'Old
   is
   begin
      E   := Content (Top);
      Top := Top - 1;
   end Pop;

   procedure Push (E : Element) with
     Refined_Post => not Is_Empty and E = Content (Top)
   is
   begin
      Top           := Top + 1;
      Content (Top) := E;
   end Push;

end Stack;
```

```

Note: For more details on refinement in contracts, see the SPARK User's Guide[264].

32.9 Initialization of Local Variables

As part of flow analysis, GNATprove checks for the proper initialization of variables. Therefore, flow analysis needs to know which variables are initialized during the package's elaboration.

You can use the `Initializes` aspect to specify the set of visible variables and state abstractions that are initialized during the elaboration of a package. An `Initializes` aspect can't refer to a variable that isn't defined in the unit since, in SPARK, a package can only initialize variables declared immediately within the package.

`Initializes` aspects are optional. If you don't supply any, they'll be derived by GNATprove.

For our `Stack` example, we could add an `Initializes` aspect.

Listing 21: stack.ads

```
1  package Stack with
2    Abstract_State => The_Stack,
3    Initializes    => The_Stack
4  is
5     type Element is new Integer;
6
7     procedure Pop  (E : out Element);
8
9  end Stack;
```

Listing 22: stack.adb

```
1  package body Stack with
2    Refined_State => (The_Stack => (Content, Top))
3  is
4     Max : constant := 100;
5
6     type Element_Array is array (1 .. Max) of Element;
7
8     Content : Element_Array := (others => 0);
9     Top     : Natural range 0 .. Max := 0;
10
11    procedure Pop (E : out Element) is
12    begin
13       E   := Content (Top);
```

(continues on next page)

[264] https://docs.adacore.com/live/wave/spark2014/html/spark2014_ug/en/source/subprogram_contracts.html#state-abstraction-and-contracts

(continued from previous page)

```
14       Top := Top - 1;
15    end Pop;
16
17 end Stack;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Local_Init
MD5: 710e74959fd2ef8f5089c4636d7ec13b
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
stack.ads:3:03: info: flow dependencies proved
stack.ads:7:20: info: initialization of "E" proved
```

Flow analysis also checks for dependencies between variables, so it must be aware of how information flows through the code that performs the initialization of states. We discussed one use of the `Initializes` aspect above. But you also can use it to provide flow information. If the initial value of a variable or state abstraction is dependent on the value of another visible variable or state abstraction from another package, you must list this dependency in the `Initializes` contract. You specify the list of entities on which a variable's initial value depends using an arrow following that variable's name.

Let's look at this example:

Listing 23: q.ads

```
1 package Q is
2    External_Variable : Integer := 2;
3 end Q;
```

Listing 24: p.ads

```
1 with Q;
2 package P with
3   Initializes => (V1, V2 => Q.External_Variable)
4 is
5    V1 : Integer := 0;
6    V2 : Integer := Q.External_Variable;
7 end P;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Initializes
MD5: c8aa7f21729f3b926bf3d25a826cccb2
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
p.ads:3:03: info: flow dependencies proved
```

Here we indicated that V2's initial value depends on the value of `Q.External_Variable` by including that dependency in the `Initializes` aspect of P. We didn't list any dependency for V1 because its initial value doesn't depend on any external variable. We could also have stated that lack of dependency explicitly by writing `V1 => null`.

GNATprove computes dependencies of initial values if you don't supply an `Initializes` aspect. However, if you do provide an `Initializes` aspect for a package, it must be com-

plete: you must list every initialized state of the package, along with all its external dependencies.

Note: For more details on `Initializes`, see the SPARK User's Guide[265].

32.10 Code Examples / Pitfalls

This section contains some code examples to illustrate potential pitfalls.

32.10.1 Example #1

Package `Communication` defines a hidden local package, `Ring_Buffer`, whose capacity is initialized from an external configuration during elaboration.

Listing 25: configuration.ads

```
package Configuration is

   External_Variable : Natural := 1;

end Configuration;
```

Listing 26: communication.ads

```
with Configuration;

package Communication with
  Abstract_State => State,
  Initializes    => (State => Configuration.External_Variable)
is
   function Get_Capacity return Natural;

private

   package Ring_Buffer with
     Initializes => (Capacity => Configuration.External_Variable)
   is
      Capacity : constant Natural := Configuration.External_Variable;
   end Ring_Buffer;

end Communication;
```

Listing 27: communication.adb

```
package body Communication with
  Refined_State => (State => Ring_Buffer.Capacity)
is

   function Get_Capacity return Natural is
   begin
      return Ring_Buffer.Capacity;
   end Get_Capacity;
```

(continues on next page)

[265] https://docs.adacore.com/live/wave/spark2014/html/spark2014_ug/en/source/package_contracts.html#package-initialization

(continued from previous page)

```
9
10 end Communication;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Example_01
MD5: 207e999f85a5b39fa2b9aebbc836b479
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
communication.adb:2:41: error: "Capacity" cannot act as constituent of state "State
 ↪"
communication.adb:2:41: error: missing Part_Of indicator at communication.ads:14␣
 ↪should specify encapsulator "State"
gnatprove: error during generation of Global contracts
```

This example isn't correct. `Capacity` is declared in the private part of `Communication`. Therefore, we should have linked it to `State` by using the `Part_Of` aspect in its declaration.

32.10.2 Example #2

Let's add `Part_Of` to the state of hidden local package `Ring_Buffer`, but this time we hide variable `Capacity` inside the private part of `Ring_Buffer`.

Listing 28: configuration.ads

```
1  package Configuration is
2
3     External_Variable : Natural := 1;
4
5  end Configuration;
```

Listing 29: communication.ads

```
1  with Configuration;
2
3  package Communication with
4    Abstract_State => State
5  is
6  private
7
8     package Ring_Buffer with
9       Abstract_State => (B_State with Part_Of => State),
10      Initializes    => (B_State => Configuration.External_Variable)
11    is
12       function Get_Capacity return Natural;
13    private
14       Capacity : constant Natural := Configuration.External_Variable
15         with Part_Of => B_State;
16    end Ring_Buffer;
17
18 end Communication;
```

Listing 30: communication.adb

```

```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
communication.ads:10:06: info: flow dependencies proved
```

This program is correct and GNATprove is able to verify it.

32.10.3 Example #3

Package `Counting` defines two counters: `Black_Counter` and `Red_Counter`. It provides separate initialization procedures for each, both called from the main procedure.

Listing 31: counting.ads

```
package Counting with
  Abstract_State => State
is
   procedure Reset_Black_Count;
   procedure Reset_Red_Count;
end Counting;
```

Listing 32: counting.adb

```
package body Counting with
  Refined_State => (State => (Black_Counter, Red_Counter))
is
   Black_Counter, Red_Counter : Natural;

   procedure Reset_Black_Count is
   begin
      Black_Counter := 0;
   end Reset_Black_Count;

   procedure Reset_Red_Count is
   begin
      Red_Counter := 0;
   end Reset_Red_Count;
end Counting;
```

Listing 33: main.adb

```
with Counting; use Counting;

procedure Main is
begin
   Reset_Black_Count;
   Reset_Red_Count;
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Example_03
MD5: bc2d7ccd7419d34f7156a16dfc484229
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
main.adb:5:04: medium: "Counting.State" might not be initialized after elaboration␣
 ↪of main program "Main"
counting.ads:2:21: warning: no procedure exists that can initialize abstract state
 ↪"Counting.State"
gnatprove: unproved check messages considered as errors
```

This program doesn't read any uninitialized data, but GNATprove fails to verify that. This is because we provided a state abstraction for package `Counting`, so flow analysis computes the effects of subprograms in terms of this state abstraction and thus considers `State` to be an in-out global consisting of both `Black_Counter` and `Red_Counter`. So it issues the message requiring that `State` be initialized after elaboration as well as the warning that no procedure in package `Counting` can initialize its state.

32.10.4 Example #4

Let's remove the abstract state on package `Counting`.

Listing 34: counting.ads

```
package Counting is
   procedure Reset_Black_Count;
   procedure Reset_Red_Count;
end Counting;
```

Listing 35: counting.adb

```
package body Counting is
   Black_Counter, Red_Counter : Natural;

   procedure Reset_Black_Count is
   begin
      Black_Counter := 0;
   end Reset_Black_Count;

   procedure Reset_Red_Count is
   begin
      Red_Counter := 0;
   end Reset_Red_Count;
end Counting;
```

Listing 36: main.adb

```
with Counting; use Counting;

procedure Main is
begin
   Reset_Black_Count;
   Reset_Red_Count;
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Example_04
MD5: 3ddd934b6ede6df7b823e46828694d12
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
```

This example is correct. Because we didn't provide a state abstraction, GNATprove reasons in terms of variables, instead of states, and proves data initialization without any problem.

32.10.5 Example #5

Let's restore the abstract state to package `Counting`, but this time provide a procedure `Reset_All` that calls the initialization procedures `Reset_Black_Counter` and `Reset_Red_Counter`.

Listing 37: counting.ads

```
package Counting with
  Abstract_State => State
is
   procedure Reset_Black_Count with Global => (In_Out => State);
   procedure Reset_Red_Count   with Global => (In_Out => State);
   procedure Reset_All         with Global => (Output => State);
end Counting;
```

Listing 38: counting.adb

```
package body Counting with
  Refined_State => (State => (Black_Counter, Red_Counter))
is
   Black_Counter, Red_Counter : Natural;

   procedure Reset_Black_Count is
   begin
      Black_Counter := 0;
   end Reset_Black_Count;

   procedure Reset_Red_Count is
   begin
      Red_Counter := 0;
   end Reset_Red_Count;

   procedure Reset_All is
   begin
      Reset_Black_Count;
```

(continues on next page)

(continued from previous page)

```
      Reset_Red_Count;
   end Reset_All;
end Counting;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Example_05
MD5: d123ccc644fe6999699388708f2ecf89
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
counting.ads:4:37: info: data dependencies proved
counting.ads:5:37: info: data dependencies proved
counting.ads:6:14: info: initialization of "Black_Counter" constituent of "State"␣
↪proved
counting.ads:6:14: info: initialization of "Red_Counter" constituent of "State"␣
↪proved
counting.ads:6:37: info: data dependencies proved
```

This example is correct. Flow analysis computes refined versions of `Global` contracts for internal calls and uses these to verify that `Reset_All` indeed properly initializes `State`. The `Refined_Global` and `Global` annotations are not mandatory and can be computed by GNATprove.

32.10.6 Example #6

Let's consider yet another version of our abstract stack unit.

Listing 39: stack.ads

```
package Stack with
  Abstract_State => The_Stack
is
   pragma Unevaluated_Use_Of_Old (Allow);

   type Element is new Integer;

   type Element_Array is array (Positive range <>) of Element;
   Max : constant Natural := 100;
   subtype Length_Type is Natural range 0 .. Max;

   procedure Push (E : Element) with
     Post =>
       not Is_Empty and
       (if Is_Full'Old then The_Stack = The_Stack'Old else Peek = E);

   function Peek     return Element with Pre => not Is_Empty;
   function Is_Full  return Boolean;
   function Is_Empty return Boolean;
end Stack;
```

Listing 40: stack.adb

```
package body Stack with
  Refined_State => (The_Stack => (Top, Content))
is
   Top     : Length_Type := 0;
```

(continues on next page)

(continued from previous page)

```
   Content : Element_Array (1 .. Max) := (others => 0);

   procedure Push (E : Element) is
   begin
      Top           := Top + 1;
      Content (Top) := E;
   end Push;

   function  Peek     return Element is (Content (Top));
   function  Is_Full  return Boolean is (Top >= Max);
   function  Is_Empty return Boolean is (Top = 0);
end Stack;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Example_06
MD5: 9da2b74da203a639dc66b2d33cbd500d
```

Build output

```
stack.ads:15:39: error: there is no applicable operator "=" for package or␣
 ↪procedure name
gprbuild: *** compilation phase failed
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
stack.ads:15:39: error: there is no applicable operator "=" for package or␣
 ↪procedure name
gnatprove: error during generation of Global contracts
```

This example isn't correct. There's a compilation error in Push's postcondition: The_Stack is a state abstraction, not a variable, and therefore can't be used in an expression.

32.10.7 Example #7

In this version of our abstract stack unit, a copy of the stack is returned by function Get_Stack, which we call in the postcondition of Push to specify that the stack shouldn't be modified if it's full. We also assert that after we push an element on the stack, either the stack is unchanged (if it was already full) or its top element is equal to the element just pushed.

Listing 41: stack.ads

```
package Stack with
  Abstract_State => The_Stack
is
   pragma Unevaluated_Use_Of_Old (Allow);

   type Stack_Model is private;

   type Element is new Integer;
   type Element_Array is array (Positive range <>) of Element;
   Max : constant Natural := 100;
   subtype Length_Type is Natural range 0 .. Max;

   function Peek      return Element with Pre => not Is_Empty;
   function Is_Full   return Boolean;
   function Is_Empty  return Boolean;
```

(continues on next page)

(continued from previous page)

```
   function Get_Stack return Stack_Model;

   procedure Push (E : Element) with
     Post => not Is_Empty and
       (if Is_Full'Old then Get_Stack = Get_Stack'Old else Peek = E);

private

   type Stack_Model is record
      Top     : Length_Type := 0;
      Content : Element_Array (1 .. Max) := (others => 0);
   end record;

end Stack;
```

Listing 42: stack.adb

```
package body Stack with
  Refined_State => (The_Stack => (Top, Content))
is
   Top     : Length_Type := 0;
   Content : Element_Array (1 .. Max) := (others => 0);

   procedure Push (E : Element) is
   begin
      if Top >= Max then
         return;
      end if;
      Top             := Top + 1;
      Content (Top) := E;
   end Push;

   function Peek     return Element is (Content (Top));
   function Is_Full  return Boolean is (Top >= Max);
   function Is_Empty return Boolean is (Top = 0);

   function Get_Stack return Stack_Model is (Stack_Model'(Top, Content));

end Stack;
```

Listing 43: use_stack.adb

```
with Stack; use Stack;

procedure Use_Stack (E : Element) with
  Pre => not Is_Empty
is
   F : Element := Peek;
begin
   Push (E);
   pragma Assert (Peek = E or Peek = F);
end Use_Stack;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Example_07
MD5: 4831aa7f018f2e2d4e6d102095f8f631
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
use_stack.adb:9:19: medium: assertion might fail [possible fix: precondition of␣
 ↪subprogram at line 3 should mention E]
gnatprove: unproved check messages considered as errors
```

This program is correct, but GNATprove can't prove the assertion in Use_Stack. Indeed, even if Get_Stack is an expression function, its body isn't visible outside of Stack's body, where it's defined.

32.10.8 Example #8

Let's move the definition of Get_Stack and other expression functions inside the private part of the spec of Stack.

Listing 44: stack.ads

```
package Stack with
  Abstract_State => The_Stack
is
   pragma Unevaluated_Use_Of_Old (Allow);

   type Stack_Model is private;

   type Element is new Integer;
   type Element_Array is array (Positive range <>) of Element;
   Max : constant Natural := 100;
   subtype Length_Type is Natural range 0 .. Max;

   function Peek      return Element with Pre => not Is_Empty;
   function Is_Full   return Boolean;
   function Is_Empty  return Boolean;
   function Get_Stack return Stack_Model;

   procedure Push (E : Element) with
     Post => not Is_Empty and
       (if Is_Full'Old then Get_Stack = Get_Stack'Old else Peek = E);

private

   Top     : Length_Type              := 0 with Part_Of => The_Stack;
   Content : Element_Array (1 .. Max) := (others => 0) with
     Part_Of => The_Stack;

   type Stack_Model is record
      Top     : Length_Type := 0;
      Content : Element_Array (1 .. Max) := (others => 0);
   end record;

   function Peek      return Element     is (Content (Top));
   function Is_Full   return Boolean     is (Top >= Max);
   function Is_Empty  return Boolean     is (Top = 0);

   function Get_Stack return Stack_Model is (Stack_Model'(Top, Content));

end Stack;
```

Listing 45: stack.adb

```
package body Stack with
  Refined_State => (The_Stack => (Top, Content))
is

   procedure Push (E : Element) is
   begin
      if Top >= Max then
         return;
      end if;
      Top             := Top + 1;
      Content (Top) := E;
   end Push;

end Stack;
```

Listing 46: use_stack.adb

```
with Stack; use Stack;

procedure Use_Stack (E : Element) with
  Pre => not Is_Empty
is
   F : Element := Peek;
begin
   Push (E);
   pragma Assert (Peek = E or Peek = F);
end Use_Stack;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Example_08
MD5: 7e5204d3f69e71c212e7263906a89da4
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
use_stack.adb:6:19: info: precondition proved
use_stack.adb:9:19: info: precondition proved
use_stack.adb:9:19: info: assertion proved
use_stack.adb:9:31: info: precondition proved
stack.adb:10:30: info: range check proved
stack.adb:11:16: info: index check proved
stack.ads:19:14: info: postcondition proved
stack.ads:20:60: info: precondition proved
stack.ads:33:55: info: index check proved
```

This example is correct. GNATprove can verify the assertion in Use_Stack because it has visibility to Get_Stack's body.

32.10.9 Example #9

Package Data defines three variables, Data_1, Data_2 and Data_3, that are initialized at elaboration (in Data's package body) from an external interface that reads the file system.

Listing 47: external_interface.ads

```
package External_Interface with
  Abstract_State => File_System,
  Initializes    => File_System
is
   type Data_Type_1 is new Integer;
   type Data_Type_2 is new Integer;
   type Data_Type_3 is new Integer;

   type Data_Record is record
      Field_1 : Data_Type_1;
      Field_2 : Data_Type_2;
      Field_3 : Data_Type_3;
   end record;

   procedure Read_Data (File_Name : String; Data : out Data_Record)
     with Global => File_System;
end External_Interface;
```

Listing 48: data.ads

```
with External_Interface; use External_Interface;

package Data with
  Initializes => (Data_1, Data_2, Data_3)
is
   pragma Elaborate_Body;

   Data_1 : Data_Type_1;
   Data_2 : Data_Type_2;
   Data_3 : Data_Type_3;

end Data;
```

Listing 49: data.adb

```
with External_Interface;
pragma Elaborate_All (External_Interface);

package body Data is
begin
   declare
      Data_Read : Data_Record;
   begin
      Read_Data ("data_file_name", Data_Read);
      Data_1 := Data_Read.Field_1;
      Data_2 := Data_Read.Field_2;
      Data_3 := Data_Read.Field_3;
   end;
end Data;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Example_09
MD5: 0ca44501f0c991865ea50d2ef663d992
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
data.adb:9:07: high: "External_Interface.File_System" must be mentioned as an␣
 ↪input of the Initializes aspect of "Data" (SPARK RM 7.1.5(11))
gnatprove: unproved check messages considered as errors
```

This example isn't correct. The dependency between Data_1's, Data_2's, and Data_3's initial values and File_System must be listed in Data's Initializes aspect.

32.10.10 Example #10

Let's remove the Initializes contract on package Data.

Listing 50: external_interface.ads

```
1  package External_Interface with
2    Abstract_State => File_System,
3    Initializes    => File_System
4  is
5     type Data_Type_1 is new Integer;
6     type Data_Type_2 is new Integer;
7     type Data_Type_3 is new Integer;
8
9     type Data_Record is record
10       Field_1 : Data_Type_1;
11       Field_2 : Data_Type_2;
12       Field_3 : Data_Type_3;
13    end record;
14
15    procedure Read_Data (File_Name : String; Data : out Data_Record)
16      with Global => File_System;
17 end External_Interface;
```

Listing 51: data.ads

```
1  with External_Interface; use External_Interface;
2
3  package Data is
4     pragma Elaborate_Body;
5
6     Data_1 : Data_Type_1;
7     Data_2 : Data_Type_2;
8     Data_3 : Data_Type_3;
9
10 end Data;
```

Listing 52: data.adb

```
1  with External_Interface;
2  pragma Elaborate_All (External_Interface);
3
4  package body Data is
5  begin
6     declare
7        Data_Read : Data_Record;
8     begin
9        Read_Data ("data_file_name", Data_Read);
10       Data_1 := Data_Read.Field_1;
```

(continues on next page)

(continued from previous page)

```
      Data_2 := Data_Read.Field_2;
      Data_3 := Data_Read.Field_3;
   end;
end Data;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.State_Abstraction.Example_10
MD5: 60cba2c920c7b1031d13c82a982ed0e9
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
data.adb:7:07: info: initialization of "Data_Read" proved
external_interface.ads:3:03: info: flow dependencies proved
```

This example is correct. Since `Data` has no `Initializes` aspect, GNATprove computes the set of variables initialized during its elaboration as well as their dependencies.

CHAPTER

THIRTYTHREE

PROOF OF FUNCTIONAL CORRECTNESS

This section is dedicated to the functional correctness of programs. It presents advanced proof features that you may need to use for the specification and verification of your program's complex properties.

33.1 Beyond Program Integrity

When we speak about the *correctness* of a program or subprogram, we mean the extent to which it complies with its specification. Functional correctness is specifically concerned with properties that involve the relations between the subprogram's inputs and outputs, as opposed to other properties such as running time or memory consumption.

For functional correctness, we usually specify stronger properties than those required to just prove program integrity. When we're involved in a certification processes, we should derive these properties from the requirements of the system, but, especially in non-certification contexts, they can also come from more informal sources, such as the program's documentation, comments in its code, or test oracles.

For example, if one of our goals is to ensure that no runtime error is raised when using the result of the function `Find` below, it may be enough to know that the result is either 0 or in the range of `A`. We can express this as a postcondition of `Find`.

Listing 1: show_find.ads

```
package Show_Find is

   type Nat_Array is array (Positive range <>) of Natural;

   function Find (A : Nat_Array; E : Natural) return Natural with
     Post => Find'Result in 0 | A'Range;

end Show_Find;
```

Listing 2: show_find.adb

```
package body Show_Find is

   function Find (A : Nat_Array; E : Natural) return Natural is
   begin
      for I in A'Range loop
         if A (I) = E then
            return I;
         end if;
      end loop;
      return 0;
   end Find;
```

(continues on next page)

(continued from previous page)

```
12
13 end Show_Find;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Find_1
MD5: d8f4ace6620fd46af170977c29947289
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
show_find.adb:7:20: info: range check proved
show_find.ads:6:14: info: postcondition proved
```

In this case, it's automatically proved by GNATprove.

However, to be sure that Find performs the task we expect, we may want to verify more complex properties of that function. For example, we want to ensure it returns an index of A where E is stored and returns 0 only if E is nowhere in A. Again, we can express this as a postcondition of Find.

Listing 3: show_find.ads

```
1  package Show_Find is
2
3     type Nat_Array is array (Positive range <>) of Natural;
4
5     function Find (A : Nat_Array; E : Natural) return Natural with
6       Post =>
7         (if (for all I in A'Range => A (I) /= E)
8            then Find'Result = 0
9          else Find'Result in A'Range and then A (Find'Result) = E);
10
11 end Show_Find;
```

Listing 4: show_find.adb

```
1  package body Show_Find is
2
3     function Find (A : Nat_Array; E : Natural) return Natural is
4     begin
5        for I in A'Range loop
6           if A (I) = E then
7              return I;
8           end if;
9        end loop;
10       return 0;
11    end Find;
12
13 end Show_Find;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Find_2
MD5: 8c12b9768228a3ea45ca02199f65057b
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
```

(continues on next page)

(continued from previous page)

```
show_find.ads:9:14: medium: postcondition might fail, cannot prove Find'Result in A
 ↪'range
gnatprove: unproved check messages considered as errors
```

This time, GNATprove can't prove this postcondition automatically, but we'll see later that we can help GNATprove by providing a loop invariant, which is checked by GNATprove and allows it to automatically prove the postcondition for `Find`.

Writing at least part of your program's specification in the form of contracts has many advantages. You can execute those contracts during testing, which improves the maintainability of the code by detecting discrepancies between the program and its specification in earlier stages of development. If the contracts are precise enough, you can use them as oracles to decide whether a given test passed or failed. In that case, they can allow you to verify the outputs of specific subprograms while running a larger block of code. This may, in certain contexts, replace the need for you to perform unit testing, instead allowing you to run integration tests with assertions enabled. Finally, if the code is in SPARK, you can also use GNATprove to formally prove these contracts.

The advantage of a formal proof is that it verifies all possible execution paths, something which isn't always possible by running test cases. For example, during testing, the postcondition of the subprogram `Find` shown below is checked dynamically for the set of inputs for which `Find` is called in that test, but just for that set.

Listing 5: show_find.ads

```
package Show_Find is

   type Nat_Array is array (Positive range <>) of Natural;

   function Find (A : Nat_Array; E : Natural) return Natural with
     Post =>
       (if (for all I in A'Range => A (I) /= E)
          then Find'Result = 0
        else Find'Result in A'Range and then A (Find'Result) = E);

end Show_Find;
```

However, if `Find` is formally verified, that verification checks its postcondition for all possible inputs. During development, you can attempt such verification earlier than testing since it's performed modularly on a per-subprogram basis. For example, in the code shown above, you can formally verify `Use_Find` even before you write the body for subprogram `Find`.

33.2 Advanced Contracts

Contracts for functional correctness are usually more complex than contracts for program integrity, so they more often require you to use the new forms of expressions introduced by the Ada 2012 standard. In particular, quantified expressions, which allow you to specify properties that must hold for all or for at least one element of a range, come in handy when specifying properties of arrays.

As contracts become more complex, you may find it useful to introduce new abstractions to improve the readability of your contracts. Expression functions are a good means to this end because you can retain their bodies in your package's specification.

Finally, some properties, especially those better described as invariants over data than as properties of subprograms, may be cumbersome to express as subprogram contracts. Type predicates, which must hold for every object of a given type, are usually a better match for this purpose. Here's an example.

Listing 8: show_sort.ads

```
package Show_Sort is

   type Nat_Array is array (Positive range <>) of Natural;

   function Is_Sorted (A : Nat_Array) return Boolean is
     (for all I in A'Range =>
        (if I < A'Last then A (I) <= A (I + 1)));
   --  Returns True if A is sorted in increasing order.

```

(continues on next page)

(continued from previous page)

```
10    subtype Sorted_Nat_Array is Nat_Array with
11      Dynamic_Predicate => Is_Sorted (Sorted_Nat_Array);
12    --  Elements of type Sorted_Nat_Array are all sorted.
13
14    Good_Array : Sorted_Nat_Array := (1, 2, 4, 8, 42);
15 end Show_Sort;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Sort
MD5: d3b3d26d62074d11b19d9282cc548c1b
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
show_sort.ads:7:32: info: index check proved
show_sort.ads:7:43: info: overflow check proved
show_sort.ads:7:43: info: index check proved
show_sort.ads:14:37: info: range check proved
show_sort.ads:14:37: info: predicate check proved
```

We can use the subtype `Sorted_Nat_Array` as the type of a variable that must remain sorted throughout the program's execution. Specifying that an array is sorted requires a rather complex expression involving quantifiers, so we abstract away this property as an expression function to improve readability. `Is_Sorted`'s body remains in the package's specification and allows users of the package to retain a precise knowledge of its meaning when necessary. (You must use `Nat_Array` as the type of the operand of `Is_Sorted`. If you use `Sorted_Nat_Array`, you'll get infinite recursion at runtime when assertion checks are enabled since that function is called to check all operands of type `Sorted_Nat_Array`.)

33.2.1 Ghost Code

As the properties you need to specify grow more complex, you may have entities that are only needed because they are used in specifications (contracts). You may find it important to ensure that these entities can't affect the behavior of the program or that they're completely removed from production code. This concept, having entities that are only used for specifications, is usually called having *ghost* code and is supported in SPARK by the `Ghost` aspect.

You can use `Ghost` aspects to annotate any entity including variables, types, subprograms, and packages. If you mark an entity as `Ghost`, GNATprove ensures it can't affect the program's behavior. When the program is compiled with assertions enabled, ghost code is executed like normal code so it can execute the contracts using it. You can also instruct the compiler to not generate code for ghost entities.

Consider the procedure `Do_Something` below, which calls a complex function on its input, X, and wants to check that the initial and modified values of X are related in that complex way.

Listing 9: show_ghost.ads

```
1  package Show_Ghost is
2
3     type T is record
4        A, B, C, D, E : Boolean;
5     end record;
6
```

(continues on next page)

(continued from previous page)

```
   function Formula (X : T) return Boolean is
     ((X.A and X.B) or (X.C and (X.D or X.E)));

   function Is_Correct (X, Y : T) return Boolean is
     (Formula (X) = Formula (Y));

   procedure Do_Something (X : in out T);

end Show_Ghost;
```

Listing 10: show_ghost.adb

```
package body Show_Ghost is

   procedure Do_Some_Complex_Stuff (X : in out T) is
   begin
      X := T'(X.B, X.A, X.C, X.E, X.D);
   end Do_Some_Complex_Stuff;

   procedure Do_Something (X : in out T) is
      X_Init : constant T := X with Ghost;
   begin
      Do_Some_Complex_Stuff (X);
      pragma Assert (Is_Correct (X_Init, X));
      --  It is OK to use X_Init inside an assertion.
   end Do_Something;

end Show_Ghost;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Ghost_1
MD5: 0a6caaec950b3b043a53c18bab3cb39b
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
show_ghost.adb:12:22: info: assertion proved
```

`Do_Something` stores the initial value of `X` in a ghost constant, `X_Init`. We reference it in an assertion to check that the computation performed by the call to `Do_Some_Complex_Stuff` modified the value of `X` in the expected manner.

However, `X_Init` can't be used in normal code, for example to restore the initial value of `X`.

Listing 11: show_ghost.ads

```
package Show_Ghost is

   type T is record
      A, B, C, D, E : Boolean;
   end record;

   function Formula (X : T) return Boolean is
     ((X.A and X.B) or (X.C and (X.D or X.E)));

   function Is_Correct (X, Y : T) return Boolean is
     (Formula (X) = Formula (Y));

```

(continues on next page)

(continued from previous page)

```
13    procedure Do_Something (X : in out T);
14
15 end Show_Ghost;
```

Listing 12: show_ghost.adb

```
1  package body Show_Ghost is
2
3     procedure Do_Some_Complex_Stuff (X : in out T) is
4     begin
5        X := T'(X.B, X.A, X.C, X.E, X.D);
6     end Do_Some_Complex_Stuff;
7
8     procedure Do_Something (X : in out T) is
9        X_Init : constant T := X with Ghost;
10    begin
11       Do_Some_Complex_Stuff (X);
12       pragma Assert (Is_Correct (X_Init, X));
13
14       X := X_Init; -- ERROR
15
16    end Do_Something;
17
18 end Show_Ghost;
```

Listing 13: use_ghost.adb

```
1 with Show_Ghost; use Show_Ghost;
2
3 procedure Use_Ghost is
4    X : T := (True, True, False, False, True);
5 begin
6    Do_Something (X);
7 end Use_Ghost;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Ghost_2
MD5: 464bb4bc355a648e2b92940ec80b4717
```

Build output

```
show_ghost.adb:14:12: error: ghost entity cannot appear in this context
gprbuild: *** compilation phase failed
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
show_ghost.adb:14:12: error: ghost entity cannot appear in this context
gnatprove: error during generation of Global contracts
```

When compiling this example, the compiler flags the use of `X_Init` as illegal, but more complex cases of interference between ghost and normal code may sometimes only be detected when you run GNATprove.

33.2.2 Ghost Functions

Functions used only in specifications are a common occurrence when writing contracts for functional correctness. For example, expression functions used to simplify or factor out common patterns in contracts can usually be marked as ghost.

But ghost functions can do more than improve readability. In real-world programs, it's often the case that some information necessary for functional specification isn't accessible in the package's specification because of abstraction.

Making this information available to users of the packages is generally out of the question because that breaks the abstraction. Ghost functions come in handy in that case since they provide a way to give access to that information without making it available to normal client code.

Let's look at the following example.

Listing 14: stacks.ads

```
package Stacks is

   pragma Unevaluated_Use_Of_Old (Allow);

   type Stack is private;

   type Element is new Natural;
   type Element_Array is array (Positive range <>) of Element;
   Max : constant Natural := 100;

   function Get_Model (S : Stack) return Element_Array with Ghost;
   --  Returns an array as a model of a stack.

   procedure Push (S : in out Stack; E : Element) with
     Pre  => Get_Model (S)'Length < Max,
     Post => Get_Model (S) = Get_Model (S)'Old & E;

private

   subtype Length_Type is Natural range 0 .. Max;

   type Stack is record
      Top     : Length_Type := 0;
      Content : Element_Array (1 .. Max) := (others => 0);
   end record;

end Stacks;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Ghost_Functions
MD5: e287612bd66753f07ac3eecb36c693de
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
```

Here, the type Stack is private. To specify the expected behavior of the Push procedure, we need to go inside this abstraction and access the values of the elements stored in S. For this, we introduce a function Get_Model that returns an array as a representation of the stack. However, we don't want code that uses the Stack package to use Get_Model in normal code since this breaks our stack's abstraction.

Here's an example of trying to break that abstraction in the subprogram Peek below.

Listing 15: stacks.ads

```
package Stacks is

   pragma Unevaluated_Use_Of_Old (Allow);

   type Stack is private;

   type Element is new Natural;
   type Element_Array is array (Positive range <>) of Element;
   Max : constant Natural := 100;

   function Get_Model (S : Stack) return Element_Array with Ghost;
   --  Returns an array as a model of a stack.

   procedure Push (S : in out Stack; E : Element) with
     Pre  => Get_Model (S)'Length < Max,
     Post => Get_Model (S) = Get_Model (S)'Old & E;

   function Peek (S : Stack; I : Positive) return Element is
     (Get_Model (S) (I)); -- ERROR

private

   subtype Length_Type is Natural range 0 .. Max;

   type Stack is record
      Top     : Length_Type := 0;
      Content : Element_Array (1 .. Max) := (others => 0);
   end record;

end Stacks;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Ghost_Model
MD5: c00b5d86c9d0b665ccdda7f68f16f07a
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
stacks.ads:19:07: error: ghost entity cannot appear in this context
gnatprove: error during generation of Global contracts
```

We see that marking the function as `Ghost` achieves this goal: it ensures that the subprogram `Get_Model` is never used in production code.

33.2.3 Global Ghost Variables

Though it happens less frequently, you may have specifications requiring you to store additional information in global variables that isn't needed in normal code. You should mark these global variables as ghost, allowing the compiler to remove them when assertions aren't enabled. You can use these variables for any purpose within the contracts that make up your specifications. A common scenario is writing specifications for subprograms that modify a complex or private global data structure: you can use these variables to provide a model for that structure that's updated by the ghost code as the program modifies the data structure itself.

You can also use ghost variables to store information about previous runs of subprograms

to specify temporal properties. In the following example, we have two procedures, one that accesses a state A and the other that accesses a state B. We use the ghost variable Last_Accessed_Is_A to specify that B can't be accessed twice in a row without accessing A in between.

Listing 16: call_sequence.ads

```
package Call_Sequence is

   type T is new Integer;

   Last_Accessed_Is_A : Boolean := False with Ghost;

   procedure Access_A with
     Post => Last_Accessed_Is_A;

   procedure Access_B with
     Pre  => Last_Accessed_Is_A,
     Post => not Last_Accessed_Is_A;
   --  B can only be accessed after A

end Call_Sequence;
```

Listing 17: call_sequence.adb

```
package body Call_Sequence is

   procedure Access_A is
   begin
      --  ...
      Last_Accessed_Is_A := True;
   end Access_A;

   procedure Access_B is
   begin
      --  ...
      Last_Accessed_Is_A := False;
   end Access_B;

end Call_Sequence;
```

Listing 18: main.adb

```
with Call_Sequence; use Call_Sequence;

procedure Main is
begin
   Access_A;
   Access_B;
   Access_B; -- ERROR
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Global_Ghost_Vars
MD5: f33fa2ad2bd31eb03d4400c78f22eb71
```

gnatprove: unproved check messages considered as errors
```

Runtime output

```
raised ADA.ASSERTIONS.ASSERTION_ERROR : failed precondition from call_sequence.
↪ads:11
```

Let's look at another example. The specification of a subprogram's expected behavior is sometimes best expressed as a sequence of actions it must perform. You can use global ghost variables that store intermediate values of normal variables to write this sort of specification more easily.

For example, we specify the subprogram `Do_Two_Things` below in two steps, using the ghost variable `V_Interm` to store the intermediate value of `V` between those steps. We could also express this using an existential quantification on the variable `V_Interm`, but it would be impractical to iterate over all integers at runtime and this can't always be written in SPARK because quantification is restricted to **`for ... loop`** patterns.

Finally, supplying the value of the variable may help the prover verify the contracts.

Listing 19: action_sequence.ads

```
1  package Action_Sequence is
2
3     type T is new Integer;
4
5     V_Interm : T with Ghost;
6
7     function First_Thing_Done (X, Y : T) return Boolean with Ghost;
8     function Second_Thing_Done (X, Y : T) return Boolean with Ghost;
9
10    procedure Do_Two_Things (V : in out T) with
11      Post => First_Thing_Done (V'Old, V_Interm)
12        and then Second_Thing_Done (V_Interm, V);
13
14 end Action_Sequence;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Intermediate_Values
MD5: 2ffbd2cb187c0a81423c78e0989d62f0
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
```

Note: For more details on ghost code, see the SPARK User's Guide[266].

[266] https://docs.adacore.com/live/wave/spark2014/html/spark2014_ug/en/source/specification_features.html#ghost-code

33.3 Guide Proof

Since properties of interest for functional correctness are more complex than those involved in proofs of program integrity, we expect GNATprove to initially be unable to verify them even though they're valid. You'll find the techniques we discussed in *Debugging Failed Proof Attempts* (page 1028) to come in handy here. We now go beyond those techniques and focus on more ways of improving results in the cases where the property is valid but GNATprove can't prove it in a reasonable amount of time.

In those cases, you may want to try and guide GNATprove to either complete the proof or strip it down to a small number of easily-reviewable assumptions. For this purpose, you can add assertions to break complex proofs into smaller steps.

```
pragma Assert (Assertion_Checked_By_The_Tool);
--  info: assertion proved

pragma Assert (Assumption_Validated_By_Other_Means);
--  medium: assertion might fail

pragma Assume (Assumption_Validated_By_Other_Means);
--  The tool does not attempt to check this expression.
--  It is recorded as an assumption.
```

One such intermediate step you may find useful is to try to prove a theoretically-equivalent version of the desired property, but one where you've simplified things for the prover, such as by splitting up different cases or inlining the definitions of functions.

Some intermediate assertions may not be proved by GNATprove either because it's missing some information or because the amount of information available is confusing. You can verify these remaining assertions by other means such as testing (since they're executable) or by review. You can then choose to instruct GNATprove to ignore them, either by turning them into assumptions, as in our example, or by using a **pragma** *Annotate*. In both cases, the compiler generates code to check these assumptions at runtime when you enable assertions.

33.3.1 Local Ghost Variables

You can use ghost code to enhance what you can express inside intermediate assertions in the same way we did above to enhance our contracts in specifications. In particular, you'll commonly have local variables or constants whose only purpose is to be used in assertions. You'll mostly use these ghost variables to store previous values of variables or expressions you want to refer to in assertions. They're especially useful to refer to initial values of parameters and expressions since the `'Old` attribute is only allowed in postconditions.

In the example below, we want to help GNATprove verify the postcondition of P. We do this by introducing a local ghost constant, `X_Init`, to represent this value and writing an assertion in both branches of an **if** statement that repeats the postcondition, but using `X_Init`.

Listing 20: show_local_ghost.ads

```
1  package Show_Local_Ghost is
2
3     type T is new Natural;
4
5     function F (X, Y : T) return Boolean is (X > Y) with Ghost;
6
7     function Condition (X : T) return Boolean is (X mod 2 = 0);
8
```

(continues on next page)

(continued from previous page)

```
   procedure P (X : in out T) with
     Pre  => X < 1_000_000,
     Post => F (X, X'Old);

end Show_Local_Ghost;
```

Listing 21: show_local_ghost.adb

```
package body Show_Local_Ghost is

   procedure P (X : in out T) is
      X_Init : constant T := X with Ghost;
   begin
      if Condition (X) then
         X := X + 1;
         pragma Assert (F (X, X_Init));
      else
         X := X * 2;
         pragma Assert (F (X, X_Init));
      end if;
   end P;

end Show_Local_Ghost;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Local_Ghost
MD5: 071ee53a06a6b5880eee6e9ea06dbcf3
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
show_local_ghost.adb:7:17: info: overflow check proved
show_local_ghost.adb:8:25: info: assertion proved
show_local_ghost.adb:10:17: info: overflow check proved
show_local_ghost.adb:11:25: info: assertion proved
show_local_ghost.ads:7:52: info: division check proved
show_local_ghost.ads:11:14: info: postcondition proved
```

You can also use local ghost variables for more complex purposes such as building a data structure that serves as witness for a complex property of a subprogram. In our example, we want to prove that the `Sort` procedure doesn't create new elements, that is, that all the elements present in `A` after the sort were in `A` before the sort. This property isn't enough to ensure that a call to `Sort` produces a value for `A` that's a permutation of its value before the call (or that the values are indeed sorted). However, it's already complex for a prover to verify because it involves a nesting of quantifiers. To help GNATprove, you may find it useful to store, for each index `I`, an index `J` that has the expected property.

```
procedure Sort (A : in out Nat_Array) with
  Post => (for all I in A'Range =>
             (for some J in A'Range => A (I) = A'Old (J)))
is
   Permutation : Index_Array := (1 => 1, 2 => 2, ...) with Ghost;
begin
   ...
end Sort;
```

33.3.2 Ghost Procedures

Ghost procedures can't affect the value of normal variables, so they're mostly used to perform operations on ghost variables or to group together a set of intermediate assertions.

Abstracting away the treatment of assertions and ghost variables inside a ghost procedure has several advantages. First, you're allowed to use these variables in any way you choose in code inside ghost procedures. This isn't the case outside ghost procedures, where the only ghost statements allowed are assignments to ghost variables and calls to ghost procedures.

As an example, the `for` loop contained in `Increase_A` couldn't appear by itself in normal code.

Listing 22: show_ghost_proc.ads

```
package Show_Ghost_Proc is

   type Nat_Array is array (Integer range <>) of Natural;

   A : Nat_Array (1 .. 100) with Ghost;

   procedure Increase_A with
     Ghost,
     Pre => (for all I in A'Range => A (I) < Natural'Last);

end Show_Ghost_Proc;
```

Listing 23: show_ghost_proc.adb

```
package body Show_Ghost_Proc is

   procedure Increase_A is
   begin
      for I in A'Range loop
         A (I) := A (I) + 1;
      end loop;
   end Increase_A;

end Show_Ghost_Proc;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Ghost_Proc
MD5: 4b9cfe25011169a0cd3b4a3b03135dc4
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
show_ghost_proc.adb:6:25: info: overflow check proved
```

Using the abstraction also improves readability by hiding complex code that isn't part of the functional behavior of the subprogram. Finally, it can help GNATprove by abstracting away assertions that would otherwise make its job more complex.

In the example below, calling `Prove_P` with `X` as an operand only adds `P (X)` to the proof context instead of the larger set of assertions required to verify it. In addition, the proof of `P` need only be done once and may be made easier not having any unnecessary information present in its context while verifying it. Also, if GNATprove can't fully verify `Prove_P`, you can review the remaining assumptions more easily since they're in a smaller context.

```
procedure Prove_P (X : T) with Ghost,
  Global => null,
  Post   => P (X);
```

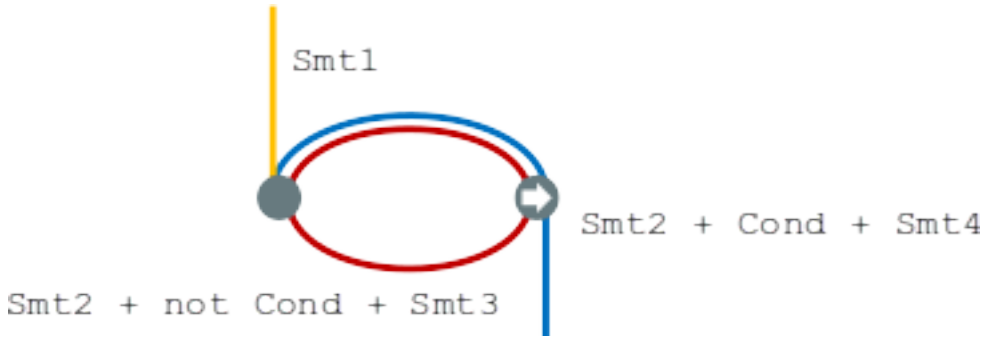
33.3.3 Handling of Loops

When the program involves a loop, you're almost always required to provide additional annotations to allow GNATprove to complete a proof because the verification techniques used by GNATprove don't handle cycles in a subprogram's control flow. Instead, loops are flattened by dividing them into several acyclic parts.

As an example, let's look at a simple loop with an exit condition.

```
Stmt1;
loop
  Stmt2;
  exit when Cond;
  Stmt3;
end loop;
Stmt4;
```

As shown below, the control flow is divided into three parts.



The first, shown in yellow, starts earlier in the subprogram and enters the loop statement. The loop itself is divided into two parts. Red represents a complete execution of the loop's body: an execution where the exit condition isn't satisfied. Blue represents the last execution of the loop, which includes some of the subprogram following it. For that path, the exit condition is assumed to hold. The red and blue parts are always executed after the yellow one.

GNATprove analyzes these parts independently since it doesn't have a way to track how variables may have been updated by an iteration of the loop. It forgets everything it knows about those variables from one part when entering another part. However, values of constants and variables that aren't modified in the loop are not an issue.

In other words, handling loops in that way makes GNATprove imprecise when verifying a subprogram involving a loop: it can't verify a property that relies on values of variables modified inside the loop. It won't forget any information it had on the value of constants or unmodified variables, but it nevertheless won't be able to deduce new information about them from the loop.

For example, consider the function `Find` which iterates over the array `A` and searches for an element where `E` is stored in `A`.

Listing 24: show_find.ads

```
1 package Show_Find is
2
```

(continues on next page)

```

At the end of each loop iteration, GNATprove knows that the value stored at index I in A must not be E. (If it were, the loop wouldn't have reached the end of the interation.) This proves the second assertion. But it's unable to aggregate this information over multiple loop iterations to deduce that it's true for all the indexes smaller than I, so it can't prove the first assertion.

33.3.4 Loop Invariants

To overcome these limitations, you can provide additional information to GNATprove in the form of a *loop invariant*. In SPARK, a loop invariant is a Boolean expression which holds true at every iteration of the loop. Like other assertions, you can have it checked at runtime by compiling the program with assertions enabled.

The major difference between loop invariants and other assertions is the way it's treated for proofs. GNATprove performs the proof of a loop invariant in two steps: first, it checks that it holds for the first iteration of the loop and then it checks that it holds in an arbitrary iteration assuming it held in the previous iteration. This is called proof by induction[267].

As an example, let's add a loop invariant to the Find function stating that the first element of A is not E.

Listing 26: show_find.ads

```
package Show_Find is

   type Nat_Array is array (Positive range <>) of Natural;

   function Find (A : Nat_Array; E : Natural) return Natural;

end Show_Find;
```

Listing 27: show_find.adb

```
package body Show_Find is

   function Find (A : Nat_Array; E : Natural) return Natural is
   begin
      for I in A'Range loop
         pragma Loop_Invariant (A (A'First) /= E);
         --  loop invariant not proved in first iteration
         --  but preservation of loop invariant is proved
         if A (I) = E then
            return I;
         end if;
      end loop;
      return 0;
   end Find;

end Show_Find;
```

```

[267] https://en.wikipedia.org/wiki/Mathematical_induction

To verify this invariant, GNATprove generates two checks. The first checks that the assertion holds in the first iteration of the loop. This isn't verified by GNATprove. And indeed there's no reason to expect the first element of A to always be different from E in this iteration. However, the second check is proved: it's easy to deduce that if the first element of A was not E in a given iteration it's still not E in the next. However, if we move the invariant to the end of the loop, then it is successfully verified by GNATprove.

Not only do loop invariants allow you to verify complex properties of loops, but GNATprove also uses them to verify other properties, such as the absence of runtime errors over both the loop's body and the statements following the loop. More precisely, when verifying a runtime check or other assertion there, GNATprove assumes that the last occurrence of the loop invariant preceding the check or assertion is true.

Let's look at a version of Find where we use a loop invariant instead of an assertion to state that none of the array elements seen so far are equal to E.

Listing 28: show_find.ads

```
package Show_Find is

   type Nat_Array is array (Positive range <>) of Natural;

   function Find (A : Nat_Array; E : Natural) return Natural;

end Show_Find;
```

Listing 29: show_find.adb

```
package body Show_Find is

   function Find (A : Nat_Array; E : Natural) return Natural is
   begin
      for I in A'Range loop
         pragma Loop_Invariant
           (for all J in A'First .. I - 1 => A (J) /= E);
         if A (I) = E then
            return I;
         end if;
      end loop;
      pragma Assert (for all I in A'Range => A (I) /= E);
      return 0;
   end Find;

end Show_Find;
```

This version is fully verified by GNATprove! This time, it proves that the loop invariant holds

in every iteration of the loop (separately proving this property for the first iteration and then for the following iterations). It also proves that none of the elements of A are equal to E after the loop exits by assuming that the loop invariant holds in the last iteration of the loop.

Note: For more details on loop invariants, see the SPARK User's Guide[268].

Finding a good loop invariant can turn out to be quite a challenge. To make this task easier, let's review the four good properties of a good loop invariant:

Property	Description
INIT	It should be provable in the first iteration of the loop.
INSIDE	It should allow proving the absence of run-time errors and local assertions inside the loop.
AFTER	It should allow proving absence of run-time errors, local assertions, and the subprogram postcondition after the loop.
PRESERVE	It should be provable after the first iteration of the loop.

Let's look at each of these in turn. First, the loop invariant should be provable in the first iteration of the loop (INIT). If your invariant fails to achieve this property, you can debug the loop invariant's initialization like any failing proof attempt using strategies for *Debugging Failed Proof Attempts* (page 1028).

Second, the loop invariant should be precise enough to allow GNATprove to prove absence of runtime errors in both statements from the loop's body (INSIDE) and those following the loop (AFTER). To do this, you should remember that all information concerning a variable modified in the loop that's not included in the invariant is forgotten by GNATprove. In particular, you should take care to include in your invariant what's usually called the loop's *frame condition*, which lists properties of variables that are true throughout the execution of the loop even though those variables are modified by the loop.

Finally, the loop invariant should be precise enough to prove that it's preserved through successive iterations of the loop (PRESERVE). This is generally the trickiest part. To understand why GNATprove hasn't been able to verify the preservation of a loop invariant you provided, you may find it useful to repeat it as local assertions throughout the loop's body to determine at which point it can no longer be proved.

As an example, let's look at a loop that iterates through an array A and applies a function F to each of its elements.

Listing 30: show_map.ads

```
1  package Show_Map is
2
3     type Nat_Array is array (Positive range <>) of Natural;
4
5     function F (V : Natural) return Natural is
6       (if V /= Natural'Last then V + 1 else V);
7
8     procedure Map (A : in out Nat_Array);
9
10 end Show_Map;
```

[268] https://docs.adacore.com/live/wave/spark2014/html/spark2014_ug/en/source/assertion_pragmas.html#loop-invariants

Listing 31: show_map.adb

```
package body Show_Map is

   procedure Map (A : in out Nat_Array) is
      A_I : constant Nat_Array := A with Ghost;
   begin
      for K in A'Range loop
         A (K) := F (A (K));
         pragma Loop_Invariant
           (for all J in A'First .. K => A (J) = F (A'Loop_Entry (J)));
      end loop;
      pragma Assert (for all K in A'Range => A (K) = F (A_I (K)));
   end Map;

end Show_Map;
```

After the loop, each element of A should be the result of applying F to its previous value. We want to prove this. To specify this property, we copy the value of A before the loop into a ghost variable, A_I. Our loop invariant states that the element at each index less than K has been modified in the expected way. We use the Loop_Entry attribute to refer to the value of A on entry of the loop instead of using A_I.

Does our loop invariant have the four properties of a good loop-invariant? When launching GNATprove, we see that INIT is fulfilled: the invariant's initialization is proved. So are INSIDE and AFTER: no potential runtime errors are reported and the assertion following the loop is successfully verified.

The situation is slightly more complex for the PRESERVE property. GNATprove manages to prove that the invariant holds after the first iteration thanks to the automatic generation of frame conditions. It was able to do this because it completes the provided loop invariant with the following frame condition stating what part of the array hasn't been modified so far:

```
pragma Loop_Invariant
  (for all J in K .. A'Last => A (J) = (if J > K then A'Loop_Entry (J)));
```

GNATprove then uses both our and the internally-generated loop invariants to prove PRESERVE. However, in more complex cases, the heuristics used by GNATprove to generate the frame condition may not be sufficient and you'll have to provide one as a loop invariant. For example, consider a version of Map where the result of applying F to an element at index K is stored at index K-1:

Listing 32: show_map.ads

```
package Show_Map is

   type Nat_Array is array (Positive range <>) of Natural;

   function F (V : Natural) return Natural is
     (if V /= Natural'Last then V + 1 else V);

   procedure Map (A : in out Nat_Array);

end Show_Map;
```

Listing 33: show_map.adb

```
package body Show_Map is

   procedure Map (A : in out Nat_Array) is
      A_I : constant Nat_Array := A with Ghost;
   begin
      for K in A'Range loop
         if K /= A'First then
            A (K - 1) := F (A (K));
         end if;
         pragma Loop_Invariant
           (for all J in A'First .. K =>
             (if J /= A'First then A (J - 1) = F (A'Loop_Entry (J))));
         --  pragma Loop_Invariant
         --  (for all J in K .. A'Last => A (J) = A'Loop_Entry (J));
      end loop;
      pragma Assert (for all K in A'Range =>
                       (if K /= A'First then A (K - 1) = F (A_I (K))));
   end Map;

end Show_Map;
```

You need to uncomment the second loop invariant containing the frame condition in order to prove the assertion after the loop.

Note: For more details on how to write a loop invariant, see the SPARK User's Guide[269].

33.4 Code Examples / Pitfalls

This section contains some code examples and pitfalls.

33.4.1 Example #1

We implement a ring buffer inside an array `Content`, where the contents of a ring buffer of length `Length` are obtained by starting at index `First` and possibly wrapping around the end of the buffer. We use a ghost function `Get_Model` to return the contents of the ring buffer for use in contracts.

Listing 34: ring_buffer.ads

```
package Ring_Buffer is

   Max_Size : constant := 100;

   type Nat_Array is array (Positive range <>) of Natural;

   function Get_Model return Nat_Array with Ghost;

   procedure Push_Last (E : Natural) with
     Pre  => Get_Model'Length < Max_Size,
     Post => Get_Model'Length = Get_Model'Old'Length + 1;

end Ring_Buffer;
```

Listing 35: ring_buffer.adb

```
package body Ring_Buffer is

   subtype Length_Range is Natural range 0 .. Max_Size;
   subtype Index_Range  is Natural range 1 .. Max_Size;

   Content : Nat_Array (1 .. Max_Size) := (others => 0);
   First   : Index_Range               := 1;
   Length  : Length_Range              := 0;

   function Get_Model return Nat_Array with
     Refined_Post => Get_Model'Result'Length = Length
   is
      Size   : constant Length_Range := Length;
      Result : Nat_Array (1 .. Size) := (others => 0);
   begin
      if First + Length - 1 <= Max_Size then
         Result := Content (First .. First + Length - 1);
      else
         declare
            Len : constant Length_Range := Max_Size - First + 1;
         begin
            Result (1 .. Len) := Content (First .. Max_Size);
```

(continues on next page)

[269] https://docs.adacore.com/live/wave/spark2014/html/spark2014_ug/en/source/how_to_write_loop_invariants.html

(continued from previous page)

```
            Result (Len + 1 .. Length) := Content (1 .. Length - Len);
         end;
      end if;
      return Result;
   end Get_Model;

   procedure Push_Last (E : Natural) is
   begin
      if First + Length <= Max_Size then
         Content (First + Length) := E;
      else
         Content (Length - Max_Size + First) := E;
      end if;
      Length := Length + 1;
   end Push_Last;

end Ring_Buffer;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Example_01

ring_buffer.adb:34:37: info: index check proved
ring_buffer.adb:36:24: info: range check proved
ring_buffer.ads:11:14: info: postcondition proved
```

This is correct: `Get_Model` is used only in contracts. Calls to `Get_Model` make copies of the buffer's contents, which isn't efficient, but is fine because `Get_Model` is only used for verification, not in production code. We enforce this by making it a ghost function. We'll produce the final production code with appropriate compiler switches (i.e., not using `-gnata`) that ensure assertions are ignored.

33.4.2 Example #2

Instead of using a ghost function, Get_Model, to retrieve the contents of the ring buffer, we're now using a global ghost variable, Model.

Listing 36: ring_buffer.ads

```
package Ring_Buffer is

   Max_Size : constant := 100;
   subtype Length_Range is Natural range 0 .. Max_Size;
   subtype Index_Range  is Natural range 1 .. Max_Size;

   type Nat_Array is array (Positive range <>) of Natural;

   type Model_Type (Length : Length_Range := 0) is record
      Content : Nat_Array (1 .. Length);
   end record
     with Ghost;

   Model : Model_Type with Ghost;

   function Valid_Model return Boolean;

   procedure Push_Last (E : Natural) with
     Pre  => Valid_Model
       and then Model.Length < Max_Size,
     Post => Model.Length = Model.Length'Old + 1;

end Ring_Buffer;
```

Listing 37: ring_buffer.adb

```
package body Ring_Buffer is

   Content : Nat_Array (1 .. Max_Size) := (others => 0);
   First   : Index_Range               := 1;
   Length  : Length_Range              := 0;

   function Valid_Model return Boolean is
      (Model.Content'Length = Length);

   procedure Push_Last (E : Natural) is
   begin
      if First + Length <= Max_Size then
         Content (First + Length) := E;
      else
         Content (Length - Max_Size + First) := E;
      end if;
      Length := Length + 1;
   end Push_Last;

end Ring_Buffer;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Example_02
MD5: 144f58bd95cd460e4ed388d4f3351fe3
```

Build output

```
ring_buffer.adb:8:08: error: ghost entity cannot appear in this context
gprbuild: *** compilation phase failed
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
ring_buffer.adb:8:08: error: ghost entity cannot appear in this context
gnatprove: error during generation of Global contracts
```

This example isn't correct. `Model`, which is a ghost variable, must not influence the return value of the normal function `Valid_Model`. Since `Valid_Model` is only used in specifications, we should have marked it as `Ghost`. Another problem is that `Model` needs to be updated inside `Push_Last` to reflect the changes to the ring buffer.

33.4.3 Example #3

Let's mark `Valid_Model` as `Ghost` and update `Model` inside `Push_Last`.

Listing 38: ring_buffer.ads

```
1  package Ring_Buffer is
2
3     Max_Size : constant := 100;
4     subtype Length_Range is Natural range 0 .. Max_Size;
5     subtype Index_Range  is Natural range 1 .. Max_Size;
6
7     type Nat_Array is array (Positive range <>) of Natural;
8
9     type Model_Type (Length : Length_Range := 0) is record
10       Content : Nat_Array (1 .. Length);
11    end record
12      with Ghost;
13
14    Model : Model_Type with Ghost;
15
16    function Valid_Model return Boolean with Ghost;
17
18    procedure Push_Last (E : Natural) with
19      Pre  => Valid_Model
20        and then Model.Length < Max_Size,
21      Post => Model.Length = Model.Length'Old + 1;
22
23 end Ring_Buffer;
```

Listing 39: ring_buffer.adb

```
1  package body Ring_Buffer is
2
3     Content : Nat_Array (1 .. Max_Size) := (others => 0);
4     First   : Index_Range               := 1;
5     Length  : Length_Range              := 0;
6
7     function Valid_Model return Boolean is
8        (Model.Content'Length = Length);
9
10    procedure Push_Last (E : Natural) is
11    begin
12       if First + Length <= Max_Size then
13          Content (First + Length) := E;
```

(continues on next page)

(continued from previous page)

```
      else
         Content (Length - Max_Size + First) := E;
      end if;
      Length := Length + 1;
      Model := (Length  => Model.Length + 1,
                Content => Model.Content & E);
   end Push_Last;

end Ring_Buffer;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Example_03
MD5: 08b74f5fe560d238550a06c6323959cf
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
ring_buffer.adb:8:21: info: range check proved
ring_buffer.adb:13:25: info: index check proved
ring_buffer.adb:15:37: info: index check proved
ring_buffer.adb:17:24: info: range check proved

ring_buffer.adb:19:42: info: range check proved
ring_buffer.adb:19:42: info: length check proved
ring_buffer.ads:10:07: info: range check proved
ring_buffer.ads:21:14: info: postcondition proved
```

This example is correct. The ghost variable `Model` can be referenced both from the body of the ghost function `Valid_Model` and the non-ghost procedure `Push_Last` as long as it's only used in ghost statements.

33.4.4 Example #4

We're now modifying `Push_Last` to share the computation of the new length between the operational and ghost code.

Listing 40: ring_buffer.ads

```
package Ring_Buffer is

   Max_Size : constant := 100;
   subtype Length_Range is Natural range 0 .. Max_Size;
   subtype Index_Range  is Natural range 1 .. Max_Size;

   type Nat_Array is array (Positive range <>) of Natural;

   type Model_Type (Length : Length_Range := 0) is record
      Content : Nat_Array (1 .. Length);
   end record
     with Ghost;

   Model : Model_Type with Ghost;

   function Valid_Model return Boolean with Ghost;

   procedure Push_Last (E : Natural) with
```

(continues on next page)

(continued from previous page)

```
     Pre  => Valid_Model
       and then Model.Length < Max_Size,
     Post => Model.Length = Model.Length'Old + 1;

end Ring_Buffer;
```

Listing 41: ring_buffer.adb

```
package body Ring_Buffer is

   Content : Nat_Array (1 .. Max_Size) := (others => 0);
   First   : Index_Range               := 1;
   Length  : Length_Range              := 0;

   function Valid_Model return Boolean is
      (Model.Content'Length = Length);

   procedure Push_Last (E : Natural) is
      New_Length : constant Length_Range := Model.Length + 1;
   begin
      if First + Length <= Max_Size then
         Content (First + Length) := E;
      else
         Content (Length - Max_Size + First) := E;
      end if;
      Length := New_Length;
      Model := (Length  => New_Length,
                Content => Model.Content & E);
   end Push_Last;

end Ring_Buffer;
```

```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
ring_buffer.adb:11:45: error: ghost entity cannot appear in this context
gnatprove: error during generation of Global contracts
```

This example isn't correct. We didn't mark local constant New_Length as Ghost, so it can't be computed from the value of ghost variable Model. If we made New_Length a ghost constant, the compiler would report the problem on the assignment from New_Length to Length. The correct solution here is to compute New_Length from the value of the non-ghost variable Length.

33.4.5 Example #5

Let's move the code updating Model inside a local ghost procedure, Update_Model, but still using a local variable, New_Length, to compute the length.

Listing 42: ring_buffer.ads

```
package Ring_Buffer is

   Max_Size : constant := 100;
   subtype Length_Range is Natural range 0 .. Max_Size;
   subtype Index_Range  is Natural range 1 .. Max_Size;

   type Nat_Array is array (Positive range <>) of Natural;

   type Model_Type (Length : Length_Range := 0) is record
      Content : Nat_Array (1 .. Length);
   end record
     with Ghost;

   Model : Model_Type with Ghost;

   function Valid_Model return Boolean with Ghost;

   procedure Push_Last (E : Natural) with
     Pre  => Valid_Model
       and then Model.Length < Max_Size,
     Post => Model.Length = Model.Length'Old + 1;

end Ring_Buffer;
```

Listing 43: ring_buffer.adb

```
package body Ring_Buffer is

   Content : Nat_Array (1 .. Max_Size) := (others => 0);
   First   : Index_Range               := 1;
   Length  : Length_Range              := 0;

   function Valid_Model return Boolean is
      (Model.Content'Length = Length);

   procedure Push_Last (E : Natural) is

      procedure Update_Model with Ghost is
         New_Length : constant Length_Range := Model.Length + 1;
      begin
         Model := (Length  => New_Length,
                   Content => Model.Content & E);
      end Update_Model;

   begin
      if First + Length <= Max_Size then
         Content (First + Length) := E;
      else
         Content (Length - Max_Size + First) := E;
      end if;
      Length := Length + 1;
      Update_Model;
   end Push_Last;

end Ring_Buffer;
```

```

Everything's fine here. `Model` is only accessed inside `Update_Model`, itself a ghost procedure, so it's fine to declare local variable `New_Length` without the `Ghost` aspect: everything inside a ghost procedure body is ghost. Moreover, we don't need to add any contract to `Update_Model`: it's inlined by GNATprove because it's a local procedure without a contract.

33.4.6 Example #6

The function `Max_Array` takes two arrays of the same length (but not necessarily with the same bounds) as arguments and returns an array with each entry being the maximum values of both arguments at that index.

Listing 44: array_util.ads

```
1  package Array_Util is
2
3     type Nat_Array is array (Positive range <>) of Natural;
4
5     function Max_Array (A, B : Nat_Array) return Nat_Array with
6       Pre => A'Length = B'Length;
7
8  end Array_Util;
```

Listing 45: array_util.adb

```
1  package body Array_Util is
2
3     function Max_Array (A, B : Nat_Array) return Nat_Array is
4        R : Nat_Array (A'Range);
5        J : Integer := B'First;
6     begin
7        for I in A'Range loop
8           if A (I) > B (J) then
9              R (I) := A (I);
10          else
11             R (I) := B (J);
12          end if;
```

(continues on next page)

(continued from previous page)

```
13          J := J + 1;
14       end loop;
15       return R;
16    end Max_Array;
17
18 end Array_Util;
```

Code block metadata

```

array_util.adb:8:24: medium: array index check might fail [reason for check: value␣
 ↪must be a valid index into the array] [possible fix: loop at line 7 should␣
 ↪mention J in a loop invariant]
array_util.adb:13:17: medium: overflow check might fail, cannot prove upper bound␣
 ↪for J + 1 [reason for check: result of addition must fit in a 32-bits machine␣
 ↪integer] [possible fix: loop at line 7 should mention J in a loop invariant]
gnatprove: unproved check messages considered as errors
```

This program is correct, but GNATprove can't prove that J is always in the index range of B (the unproved index check) or even that it's always within the bounds of its type (the unproved overflow check). Indeed, when checking the body of the loop, GNATprove forgets everything about the current value of J because it's been modified by previous loop iterations. To get more precise results, we need to provide a loop invariant.

33.4.7 Example #7

Let's add a loop invariant that states that J stays in the index range of B and let's protect the increment to J by checking that it's not already the maximal integer value.

Listing 46: array_util.ads

```
1  package Array_Util is
2
3     type Nat_Array is array (Positive range <>) of Natural;
4
5     function Max_Array (A, B : Nat_Array) return Nat_Array with
6       Pre => A'Length = B'Length;
7
8  end Array_Util;
```

Listing 47: array_util.adb

```
1  package body Array_Util is
2
3     function Max_Array (A, B : Nat_Array) return Nat_Array is
4        R : Nat_Array (A'Range);
5        J : Integer := B'First;
6     begin
7        for I in A'Range loop
8           pragma Loop_Invariant (J in B'Range);
9           if A (I) > B (J) then
10             R (I) := A (I);
```

(continues on next page)

(continued from previous page)

```
         else
            R (I) := B (J);
         end if;
         if J < Integer'Last then
            J := J + 1;
         end if;
      end loop;
      return R;
   end Max_Array;

end Array_Util;
```

Code block metadata

```

Phase 2 of 2: flow analysis and proof ...
array_util.adb:8:33: medium: loop invariant might not be preserved by an arbitrary␣
 ↪iteration
gnatprove: unproved check messages considered as errors
```

The loop invariant now allows verifying that no runtime error can occur in the loop's body (property INSIDE seen in section *Loop Invariants* (page 1089)). Unfortunately, GNATprove fails to verify that the invariant stays valid after the first iteration of the loop (property PRESERVE). Indeed, knowing that J is in B'Range in a given iteration isn't enough to prove it'll remain so in the next iteration. We need a more precise invariant, linking J to the value of the loop index I, like `J = I - A'First + B'First`.

33.4.8 Example #8

We now consider a version of Max_Array which takes arguments that have the same bounds. We want to prove that Max_Array returns an array of the maximum values of both its arguments at each index.

Listing 48: array_util.ads

```
package Array_Util is

   type Nat_Array is array (Positive range <>) of Natural;

   function Max_Array (A, B : Nat_Array) return Nat_Array with
     Pre  => A'First = B'First and A'Last = B'Last,
     Post => (for all K in A'Range =>
                Max_Array'Result (K) = Natural'Max (A (K), B (K)));

end Array_Util;
```

Listing 49: array_util.adb

```
package body Array_Util is

   function Max_Array (A, B : Nat_Array) return Nat_Array is
      R : Nat_Array (A'Range) := (others => 0);
   begin
```

(continues on next page)

(continued from previous page)

```
      for I in A'Range loop
         pragma Loop_Invariant (for all K in A'First .. I =>
                                   R (K) = Natural'Max (A (K), B (K)));
         if A (I) > B (I) then
            R (I) := A (I);
         else
            R (I) := B (I);
         end if;
      end loop;
      return R;
   end Max_Array;

end Array_Util;
```

Listing 50: main.adb

```
with Array_Util; use Array_Util;

procedure Main is
   A : Nat_Array := (1, 1, 2);
   B : Nat_Array := (2, 1, 0);
   R : Nat_Array (1 .. 3);
begin
   R := Max_Array (A, B);
end Main;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Example_08
MD5: d0a04c214a632466a4fe4ec6cb7f8842
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
main.adb:8:09: medium: length check might fail [reason for check: array must be of␣
 ↪the appropriate length]
array_util.adb:8:35: medium: loop invariant might not be preserved by an arbitrary␣
 ↪iteration, cannot prove R (K) = Natural'max
array_util.adb:8:35: medium: loop invariant might fail in first iteration, cannot␣
 ↪prove R (K) = Natural'max
gnatprove: unproved check messages considered as errors
```

Runtime output

```

raised ADA.ASSERTIONS.ASSERTION_ERROR : Loop_Invariant failed at array_util.adb:7
```

Here, GNATprove doesn't manage to prove the loop invariant even for the first loop iteration (property INIT seen in section *Loop Invariants* (page 1089)). In fact, the loop invariant is incorrect, as you can see by executing the function `Max_Array` with assertions enabled: at each loop iteration, `R` contains the maximum of `A` and `B` only until `I - 1` because the `I`'th index wasn't yet handled.

33.4.9 Example #9

We now consider a procedural version of Max_Array which updates its first argument instead of returning a new array. We want to prove that Max_Array sets the maximum values of both its arguments into each index in its first argument.

Listing 51: array_util.ads

```
package Array_Util is

   type Nat_Array is array (Positive range <>) of Natural;

   procedure Max_Array (A : in out Nat_Array; B : Nat_Array) with
     Pre  => A'First = B'First and A'Last = B'Last,
     Post => (for all K in A'Range =>
                 A (K) = Natural'Max (A'Old (K), B (K)));

end Array_Util;
```

Listing 52: array_util.adb

```
package body Array_Util is

   procedure Max_Array (A : in out Nat_Array; B : Nat_Array) is
   begin
      for I in A'Range loop
         pragma Loop_Invariant
           (for all K in A'First .. I - 1 =>
              A (K) = Natural'Max (A'Loop_Entry (K), B (K)));
         pragma Loop_Invariant
           (for all K in I .. A'Last => A (K) = A'Loop_Entry (K));
         if A (I) <= B (I) then
            A (I) := B (I);
         end if;
      end loop;
   end Max_Array;

end Array_Util;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Example_09
MD5: 2de4bdd9c59d7d1eccb6259067ffdcf3
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
array_util.adb:7:13: info: loop invariant preservation proved
array_util.adb:7:13: info: loop invariant initialization proved

array_util.ads:8:20: info: index check proved
```

(continues on next page)

(continued from previous page)

```
array_util.ads:8:45: info: index check proved
array_util.ads:8:52: info: index check proved
```

Everything is proved. The first loop invariant states that the values of A before the loop index contains the maximum values of the arguments of Max_Array (referring to the input value of A with A'Loop_Entry). The second loop invariant states that the values of A beyond and including the loop index are the same as they were on entry. This is the frame condition of the loop.

33.4.10 Example #10

Let's remove the frame condition from the previous example.

Listing 53: array_util.ads

```
package Array_Util is

   type Nat_Array is array (Positive range <>) of Natural;

   procedure Max_Array (A : in out Nat_Array; B : Nat_Array) with
     Pre  => A'First = B'First and A'Last = B'Last,
     Post => (for all K in A'Range =>
                A (K) = Natural'Max (A'Old (K), B (K)));

end Array_Util;
```

Listing 54: array_util.adb

```
package body Array_Util is

   procedure Max_Array (A : in out Nat_Array; B : Nat_Array) is
   begin
      for I in A'Range loop
         pragma Loop_Invariant
           (for all K in A'First .. I - 1 =>
              A (K) = Natural'Max (A'Loop_Entry (K), B (K)));
         if A (I) <= B (I) then
            A (I) := B (I);
         end if;
      end loop;
   end Max_Array;

end Array_Util;
```

Code block metadata

```
Project: Courses.Intro_To_Spark.Proof_of_Functional_Correctness.Example_10
MD5: 8bdc8432cbb3f26f58f63457408c7172
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
array_util.adb:7:13: info: loop invariant initialization proved
array_util.adb:7:13: info: loop invariant preservation proved
array_util.adb:7:39: info: overflow check proved
array_util.adb:8:18: info: index check proved
array_util.adb:8:50: info: index check proved
```

(continues on next page)

(continued from previous page)

```
array_util.adb:8:57: info: index check proved
array_util.adb:9:25: info: index check proved
array_util.adb:10:25: info: index check proved
array_util.ads:7:14: info: postcondition proved
array_util.ads:8:20: info: index check proved
array_util.ads:8:45: info: index check proved
array_util.ads:8:52: info: index check proved
```

Everything is still proved. GNATprove internally generates the frame condition for the loop, so it's sufficient here to state that `A` before the loop index contains the maximum values of the arguments of `Max_Array`.

Part IV

Introduction to Embedded Systems Programming

This course will teach you the basics of the Embedded Systems Programming using Ada.

This document was written by Patrick Rogers, with review by Stephen Baird, Tucker Taft, Filip Gajowniczek, and Gustavo A. Hoffmann.

Note: The code examples in this course use an 80-column limit, which is a typical limit for Ada code. Note that, on devices with a small screen size, some code examples might be difficult to read.

CHAPTER

THIRTYFOUR

INTRODUCTION

This is a course about embedded systems programming. Embedded systems are everywhere today, including — just to name a few — the thermostats that control a building's temperature, the power-steering controller in modern automobiles, and the control systems in charge of jet engines.

Clearly, much can depend on these systems operating correctly. It might be only a matter of comfort if the thermostat fails. But imagine what might happen if one of the critical control systems in your car failed when you're out on the freeway. When a jet engine controller is designed to have absolute control, it is known as a Full Authority Digital Engine Controller, or FADEC for short. If a FADEC fails, the result can make international news.

Using Ada can help you get it right, and for less cost than other languages, if you use it well. Many industrial organizations developing critical embedded software use Ada for that reason. Our goal is to get you started in using it well.

The course is based on the assumption that you know some of the Ada language already, preferably even some of the more advanced concepts. You don't need to know how to use Ada constructs for embedded systems, of course, but you do need to know at least the language basics. If you need that introduction, see the course *Introduction to Ada* (page 5).

We also assume that you already have some programming experience so we won't cover CS-101.

Ideally, you also have some experience with low-level programming, because we will focus on "how to do it in Ada." If you do, feel free to gloss over the introductory material. If not, don't worry. We will cover enough for the course to be of value in any case.

34.1 So, what will we actually cover?

We will introduce you to using Ada to do low level programming, such as how to specify the layout of types, how to map variables of those types to specific addresses, when and how to do unchecked programming (and how not to), and how to determine the validity of incoming data, e.g., data from sensors that are occasionally faulty.

We will discuss development using more than Ada alone, nowadays a quite common approach. Specifically, how to interface with code and data written in other languages, and how (and why) to work with assembly language.

Embedded systems interact with the outside world via embedded devices, such as A/D converters, timers, actuators, sensors, and so forth. Frequently these devices are mapped into the target memory address space. We will cover how to define and interact with these memory-mapped devices.

Finally, we will show how to handle interrupts in Ada, using portable constructs.

34.2 Definitions

Before we go any further, what do we mean by "embedded system" anyway? It's time to be specific. We're talking about a computer that is part of a larger system, in which the capability to compute is not the larger system's primary function. These computers are said to be "embedded" in the larger system: the enclosing thermostat controlling the temperature, the power steering controller in the enclosing automobile, and the FADEC embedded in the enclosing aircraft. So these are not stand-alone computers for general purpose application execution.

As such, embedded systems typically have reduced resources available, especially power, which means reduced processor speed and reduced memory on-board. For an example at the small end of the spectrum, consider the computer embedded in a wearable device: it must run for a long time on a very little battery, with comparatively little memory available. But that's often true of bigger systems too, such as systems on aircraft where power (and heat) are directly limiting factors.

As a result, developing embedded systems software can be more difficult than general application development, not to mention that this software is potentially safety-critical.

Ada is known for use in very large, very long-lived projects (e.g., deployed for decades), but it can also be used for very small systems with tight resource constraints. We'll show you how.

We used the term "computer" above. You already know what that means, but you may be thinking of your laptop or something like that, where the processor, memory, and devices are all distinct, separate components. That can be the case for embedded systems too, albeit in a different form-factor such as rack-mounted boards. However, be sure to expand your definition to include the notion of a system-on-chip (SoC), in which the processor, memory, and various useful devices are all on a single chip. Embedded systems don't necessarily involve SoC computers but they frequently do. The techniques and information in this course work on any of these kinds of computer.

34.3 Down To The Bare Metal

Ada has always had facilities designed specifically for embedded systems. The language includes constructs for directly manipulating hardware, for example, and direct interaction with assembly language. These constructs are as effective as those of any high-level programming language (yes, including C). These constructs are expressively powerful, well-specified (so there are few surprises), efficient, and portable (within reason).

We say "within reason" because portability is a difficult goal for embedded systems. That's because the hardware is so much a part of the application itself, rather than being abstracted away as in a general-purpose application. That said, the hardware details can be managed in Ada so that portability is maximized to the extent possible for the application.

But strictly speaking, not all software can or should be absolutely portable! If a specific device is required, well, the program won't work with some other device. But to the extent possible portability is obviously a good thing.

34.4 The Ada Drivers Library

Speaking of SoC computers, there is a library of freely-available device drivers in Ada. Known as the Ada Driver Library (ADL), it supports many devices on a number of vendors' products. Device drivers for timers, I2C, SPI, A/D and D/A converters, DMA, General Purpose I/O, LCD displays, sensors, and other devices are included. The ADL is available on GitHub for both non-proprietary and commercial use here: https://github.com/AdaCore/Ada_Drivers_Library.

An extensive description of a project using the ADL is available here: https://blog.adacore.com/making-an-rc-car-with-ada-and-spark

We will refer to components of this library and use some of them as examples.

CHAPTER

THIRTYFIVE

LOW LEVEL PROGRAMMING

This section introduces a number of topics in low-level programming, in which the hardware and the compiler's representation choices are much more in view at the source code level. In comparatively high level code these topics are "abstracted away" in that the programmer can assume that the compiler does whatever is necessary on the current target machine so that their code executes as intended. That approach is not sufficient in low-level programming.

Note that we do not cover every possibility or language feature. Instead, we cover the necessary concepts, and also potential surprises or pitfalls, so that the parts not covered can be learned on your own.

35.1 Separation Principle

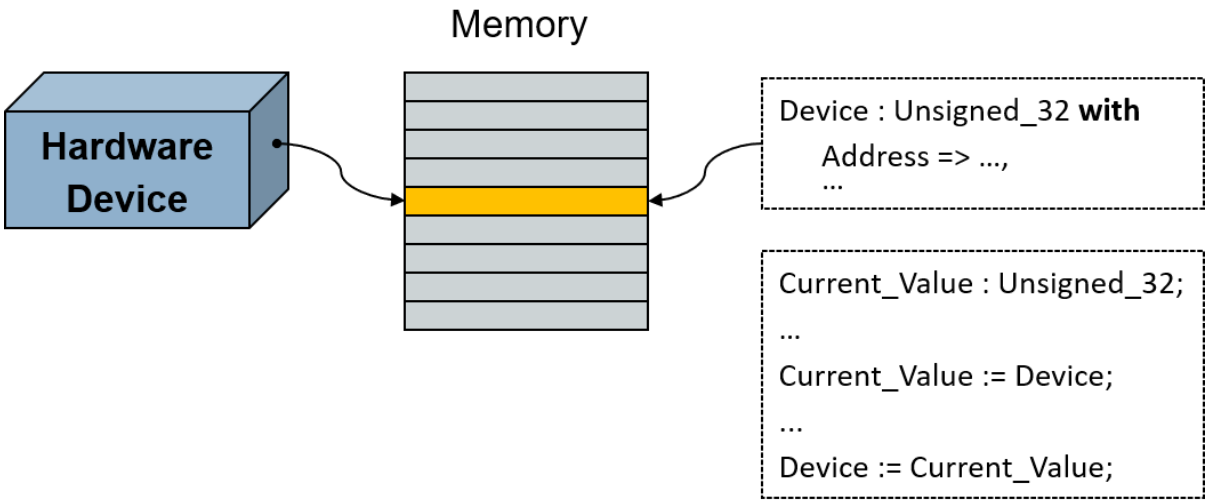
There is a language design principle underlying the Ada facilities intended for implementing embedded software. This design principle directly affects how the language is used, and therefore, the portability and readability of the resulting application code.

This language design principle is known as the "separation principle." What's being separated? The low-level, less portable aspects of some piece of code are separated from the usage of that piece of code.

Don't confuse this with hiding unnecessary implementation details via compile-time visibility control (i.e., information hiding and encapsulation). That certainly should be done too. Instead, because of the separation principle, we specify the low-level properties of something once, when we declare it. From then on, we can use regular Ada code to interact with it. That way the bulk of the code — the usage — is like any other Ada code, and doesn't propagate the low-level details all over the client code. This greatly simplifies usage and understandability as well as easing porting to new hardware-specific aspects. You change things in one place, rather than everywhere.

For example, consider a device mapped to the memory address space of the processor. To interact with the device we interact with one or more memory cells. Reading input from the device amounts to reading the value at the associated memory location. Likewise, sending output to the device amounts to writing to that location.

To represent this device mapping we declare a variable of an appropriate type and specify the starting address the object should occupy. (There are other ways too, but for a single, statically mapped object this is the simplest approach.) We'd want to specify some other characteristics as well, but let's focus on the address.



If the hardware presents an interface consisting of multiple fields within individual memory cells, we can use a record type instead of a single unsigned type representing a single word. Ada allows us to specify the exact record layout, down to the individual bit level, for any types we may need to use for the record components. When we declare the object we use that record type, again specifying the starting address. Then we can just refer to the object's record components as usual, having the compiler compute the address offsets required to access the components representing the individual hardware fields.

Note that we aren't saying that other languages cannot do this too. Many can, using good programming practices. What we're saying is that those practices are designed into the Ada way of doing it.

35.2 Guaranteed Level of Support

The Ada reference manual has an entire section dedicated to low-level programming. That's section 13, "Representation Issues," which provides facilities for developers to query and control aspects of various entities in their code, and for interfacing to hardware. Want to specify the exact layout for a record type's components? Easy, and the compiler will check your layout too. Want to specify the alignment of a type? That's easy too. And that's just the beginning. We'll talk about these facilities as we go, but there's another point to make about this section.

In particular, section 13 includes recommended levels of support to be provided by language implementations, i.e., compilers and other associated tools. Although the word "recommended" is used, the recommendations are meant to be followed.

For example, section 13.3 says that, for some entity named X, "X'`Address` should produce a useful result if X is an object that is aliased or of a by-reference type, or is an entity whose **`Address`** has been specified." So, for example, if the programmer specifies the address for a memory-mapped variable, the compiler cannot ignore that specification and instead, for the sake of performance, represent that variable using a register. The object must be represented as an addressable entity, as requested by the programmer. (Registers are not addressable.)

We mention this because, although the recommended levels of support are intended to be followed, those recommendations become **requirements** if the Systems Programming (SP) Annex is implemented by the vendor. In that case the vendor's implementation of section 13 must support at least the recommended levels. The SP Annex defines additional, optional functionality oriented toward this programming domain; you want it anyway. (Like all the annexes it adds no new syntax.) Almost all vendors, if not literally all, implement the Annex so you can rely on the recommended levels of support.

35.3 Querying Implementation Limits and Characteristics

Sometimes you need to know more about the underlying machine than is typical for general purpose applications. For example, your numerical analysis algorithm might need to know the maximum number of digits of precision that a floating-point number can have on this specific machine. For networking code, you will need to know the "endianness" of the machine so you can know whether to swap the bytes in an Ethernet packet. You'd go look in the `limits.h` file in C implementations, but in Ada we go to a package named `System` to get this information.

Clearly, these implementation values will vary with the hardware, so the package declares constants with implementation-defined values. The names of the constants are what's portable, you can count on them being the same in any Ada implementation.

However, vendors can add implementation-defined declarations to the language-defined content in package System. You might require some of those additions, but portability could then suffer when moving to a new vendor's compiler. Try not to use them unless it is unavoidable. Ideally these additions will appear in the private part of the package, so the implementation can use them but application code cannot.

For examples of the useful, language-defined constants, here are those for the numeric limits of an Ada compiler for an Arm 32-bit SoC:

```
Min_Int               : constant := Long_Long_Integer'First;
Max_Int               : constant := Long_Long_Integer'Last;

Max_Binary_Modulus    : constant := 2 ** Long_Long_Integer'Size;
Max_Nonbinary_Modulus : constant := 2 ** Integer'Size - 1;

Max_Base_Digits       : constant := Long_Long_Float'Digits;
Max_Digits            : constant := Long_Long_Float'Digits;

Max_Mantissa          : constant := 63;
Fine_Delta            : constant := 2.0 ** (-Max_Mantissa);
```

`Min_Int` and `Max_Int` supply the most-negative and most-positive integer values supported by the machine.

`Max_Binary_Modulus` is the largest power of two allowed as the modulus of a modular type definition.

But a modular type need not be defined in terms of powers of two. An arbitrary modulus is allowed, as long as it is not bigger than the machine can handle. That's specified by `Max_Nonbinary_Modulus`, the largest non-power-of-two value allowed as the modulus of a modular type definition.

`Max_Base_Digits` is the largest value allowed for the requested decimal precision in a floating-point type's definition.

We won't go over all of the above, you get the idea. Let's examine the more important contents.

Two of the most frequently referenced constants in `System` are the following, especially the first. (The values here are again for the Arm 32-bit SoC):

```
Storage_Unit : constant := 8;
Word_Size    : constant := 32;
```

`Storage_Unit` is the number of bits per memory storage element. Storage elements are the components of memory cells, and typically correspond to the individually addressable

memory elements. A "byte" would correspond to a storage element with the above constant value.

Consider a typical idiom for determining the number of whole storage elements an object named X occupies:

```
Units : constant Integer := (X'Size + Storage_Unit - 1) / Storage_Unit;
```

Remember that `'Size` returns a value in terms of bits. There are more direct ways to determine that size information but this will serve as an example of the sort of thing you might do with that constant.

A machine "word" is the largest amount of storage that can be conveniently and efficiently manipulated by the hardware, given the implementation's run-time model. A word consists of some number of storage elements, maybe one but typically more than one. As the unit the machine natively manipulates, words are expected to be independently addressable. (On some machines only words are independently addressable.)

`Word_Size` is the number of bits in the machine word. On a 32-bit machine we'd expect `Word_Size` to have a value of 32; on a 64-bit machine it would probably be 64, and so on.

`Storage_Unit` and `Word_Size` are obviously related.

Another frequently referenced declaration in package `System` is that of the type representing memory addresses, along with a constant for the null address designating no storage element.

```
type Address is private;
Null_Address : constant Address;
```

You may be wondering why type **`Address`** is a private type, since that choice means that we programmers cannot treat it like an ordinary (unsigned) integer value. Portability is of course the issue, because addressing, and thus address representation, varies among computer architectures. Not all architectures have a flat address space directly referenced by numeric values, although that is common. Some are represented by a base address plus an offset, for example. Therefore, the representation for type **`Address`** is hidden from us, the clients. Consequently we cannot simply treat address values as numeric values. Don't worry, though. The operations we need are provided.

Package *System* declares these comparison functions, for example:

```
function "<"  (Left, Right : Address) return Boolean;
function "<=" (Left, Right : Address) return Boolean;
function ">"  (Left, Right : Address) return Boolean;
function ">=" (Left, Right : Address) return Boolean;
function "="  (Left, Right : Address) return Boolean;
```

These functions are intrinsic, i.e., built-in, meaning that the compiler generates the code for them directly at the point of calls. There is no actual function body for any of them so there is no performance penalty.

Any private type directly supports the equality function, and consequently the inequality function, as well as assignment. What we don't get here is address arithmetic, again because we don't have a compile-time view of the actual representation. That functionality is provided by package `System.Storage_Elements`, a child package we will cover later. We should say though, that the need for address arithmetic in Ada is rare, especially compared to C.

Having type **`Address`** presented as a private type is not, strictly speaking, required by the language. Doing so is a good idea for the reasons given above, and is common among vendors. Not all vendors do, though.

Note that **`Address`** is the type of the result of the query attribute **`Address`**.

We mentioned potentially needing to swap bytes in networking communications software, due to the differences in the "endianness" of the machines communicating. That characteristic can be determined via a constant declared in package System as follows:

```
type Bit_Order is (High_Order_First, Low_Order_First);
Default_Bit_Order : constant Bit_Order := implementation-defined;
```

High_Order_First corresponds to "Big Endian" and Low_Order_First to "Little Endian." On a Big Endian machine, bit 0 is the most significant bit. On a Little Endian machine, bit 0 is the least significant bit.

Strictly speaking, this constant gives us the default order for bits within storage elements in record representation clauses, not the order of bytes within words. However, we can usually use it for the byte order too. In particular, if Word_Size is greater than Storage_Unit, a word necessarily consists of multiple storage elements, so the default bit ordering is the same as the ordering of storage elements in a word.

Let's take that example of swapping the bytes in a received Ethernet packet. The "wire" format is Big Endian so if we are running on a Little Endian machine we must swap the bytes received.

Suppose we want to retrieve typed values from a given buffer or bytes. We get the bytes from the buffer into a variable named Value, of the type of interest, and then swap those bytes within Value if necessary.

```
   ...
begin
   Value := ...

   if Default_Bit_Order /= High_Order_First then
      -- we're not on a Big Endian machine
      Value := Byte_Swapped (Value);
   end if;
end Retrieve_4_Bytes;
```

We have elided the code that gets the bytes into Value, for the sake of simplicity. How the bytes are actually swapped by function Byte_Swapped is also irrelevant. The point here is the if-statement: the expression compares the Default_Bit_Order constant to High_Order_First to see if this execution is on a Big Endian machine. If not, it swaps the bytes because the incoming bytes are always received in "wire-order," i.e., Big Endian order.

Another important set of declarations in package System define the values for priorities, including interrupt priorities. We will ignore them until we get to the section on interrupt handling.

Finally, and perhaps surprisingly, a few declarations in package System are almost always (if not actually always) ignored.

```
type Name is implementation-defined-enumeration-type;
System_Name : constant Name := implementation-defined;
```

Values of type Name are the names of alternative machine configurations supported by the implementation. System_Name represents the current machine configuration. We've never seen any actual use of this.

Memory_Size is an implementation-defined value that is intended to reflect the memory size of the configuration, in units of storage elements. What the value actually refers to is not specified. Is it the size of the address space, i.e., the amount possible, or is it the amount of physical memory actually on the machine, or what? In any case, the amount of memory available to a given computer is neither dependent upon, nor reflected by, this constant. Consequently, Memory_Size is not useful either.

Why have something defined in the language that nobody uses? In short, it seemed like a good idea at the time when Ada was first defined. Upward-compatibility concerns propagate these declarations forward as the language evolves, just in case somebody does use them.

35.4 Querying Representation Choices

As we mentioned in the introduction, in low-level programming the hardware and the compiler's representation choices can come to the forefront. You can, therefore, query many such choices.

For example, let's say we want to query the addresses of some objects because we are calling the imported C `memcpy` function. That function requires two addresses to be passed to the call: one for the source, and one for the destination. We can use the `'Address` attribute to get those values.

We will explore importing routines and objects implemented in other languages elsewhere. For now, just understand that we will have an Ada declaration for the imported routine that tells the compiler how it should be called. Let's assume we have an Ada function declared like so:

```
function MemCopy
  (Destination : System.Address;
   Source      : System.Address;
   Length      : Natural)
return Address
with
  Import,
  Convention => C,
  Link_Name => "memcpy",
  Pre  => Source /= Null_Address      and then
          Destination /= Null_Address and then
          not Overlapping (Destination, Source, Length),
  Post => MemCopy'Result = Destination;
--  Copies Length bytes from the object designated by Source to the object
--  designated by Destination.
```

The three aspects that do the importing are specified after the reserved word **`with`** but can be ignored for this discussion. We'll talk about them later. The preconditions make explicit the otherwise implicit requirements for the arguments passed to `memcpy`, and the postcondition specifies the expected result returned from a successful call. Neither the preconditions nor the postconditions are required for importing external entities but they are good "guard-rails" for using those entities. If we call it incorrectly the precondition will inform us, and likewise, if we misunderstand the result the postcondition will let us know (at least to the extent that the return value does that).

For a sample call to our imported routine, imagine that we have a procedure that copies the bytes of a **`String`** parameter into a `Buffer` parameter, which is just a contiguous array of bytes. We need to tell `MemCopy` the addresses of the arguments passed so we apply the `'Address` attribute accordingly:

```
procedure Put (This : in out Buffer; Start : Index; Value : String) is
   Result : System.Address with Unreferenced;
begin
   Result := MemCopy (Destination => This (Start)'Address,
                      Source      => Value'Address,
                      Length      => Value'Length);
end Put;
```

The order of the address parameters is easily confused so we use the named association format for specifying the actual parameters in the call.

Although we assign `Result` we don't otherwise use it, so we tell the compiler this is not a mistake via the `Unreferenced` aspect. And if we do turn around and reference it the compiler will complain, as it should. Note that `Unreferenced` is defined by GNAT, so usage is not necessarily portable. Other vendors may or may not implement something like it, perhaps with a different name.

(We don't show the preconditions for `Put`, but they would have specified that `Start` must be a valid index into this particular buffer, and that there must be room in the `Buffer` argument for the number of bytes in `Value` when starting at the `Start` index, so that we don't copy past the end of the `Buffer` argument.)

There are other characteristics we might want to query too.

We might want to ask the compiler what alignment it chose for a given object (or type, for all such objects).

For a type, when `Alignment` returns a non-zero value we can be sure that the compiler will allocate storage for objects of the type at correspondingly aligned addresses (unless we force it to do otherwise). Similarly, references to dynamically allocated objects of the type will be to properly aligned locations. Otherwise, an `Alignment` of zero means that the guarantee does not hold. That could happen if the type is packed down into a composite object, such as an array of `Booleans`. We'll discuss "packing" soon. More commonly, the smallest likely value is 1, meaning that any storage element's address will suffice. If the machine has no particular natural alignments, then all type alignments will probably be 1 by default. That would be somewhat rare today, though, because modern processors usually have comparatively strict alignment requirements.

We can ask for the amount of storage associated with various entities. For example, when applied to a task, `'Storage_Size` tells us the number of storage elements reserved for the task's execution. The value includes the size of the task's stack, if it has one. We aren't told if other required storage, used internally in the implementation, is also included in this number. Often that other storage is not included in this number, but it could be.

`Storage_Size` is also defined for access types. The meaning is a little complicated. Access types can be classified into those that designate only variables and constants ("access-to-object") and those that can designate subprograms. Each access-to-object type has an associated storage pool. The storage allocated by **`new`** comes from the pool, and instances of `Unchecked_Deallocation` return storage to the pool.

When applied to an access-to-object type, `Storage_Size` gives us the number of storage elements reserved for the corresponding pool.

Note that `Storage_Size` doesn't tell us how much available, unallocated space remains in a pool. It includes both allocated and unallocated space. Note, too, that although each access-to-object type has an associated pool, that doesn't mean that each one has a distinct, dedicated pool. They might all share one, by default. On an operating system, such as Linux, the default shared pool might even be implicit, consisting merely of calls to the OS routines in C.

As a result, querying `Storage_Size` for access types and tasks is not necessarily all that useful. Specifying the sizes, on the other hand, definitely can be useful.

That said, we can create our own pool types and define precisely how they are sized and how allocation and deallocation work, so in that case querying the size for access types could be more useful.

For an array type or object, `'Component_Size` provides the size in bits of the individual components.

More useful are the following two attributes that query a degree of memory sharing between objects.

Applied to an object, `'Has_Same_Storage` is a Boolean function that takes another object of any type as the argument. It indicates whether the two objects' representations occupy exactly the same bits.

Applied to an object, `'Overlaps_Storage` is a Boolean function that takes another object of any type as the argument. It indicates whether the two objects' representations share at least one bit.

Generally, though, we specify representation characteristics far more often than we query them. Rather than describe all the possibilities, we can just say that all the representation characteristics that can be specified can also be queried. We cover specifying representation characteristics next, so just assume the corresponding queries are available.

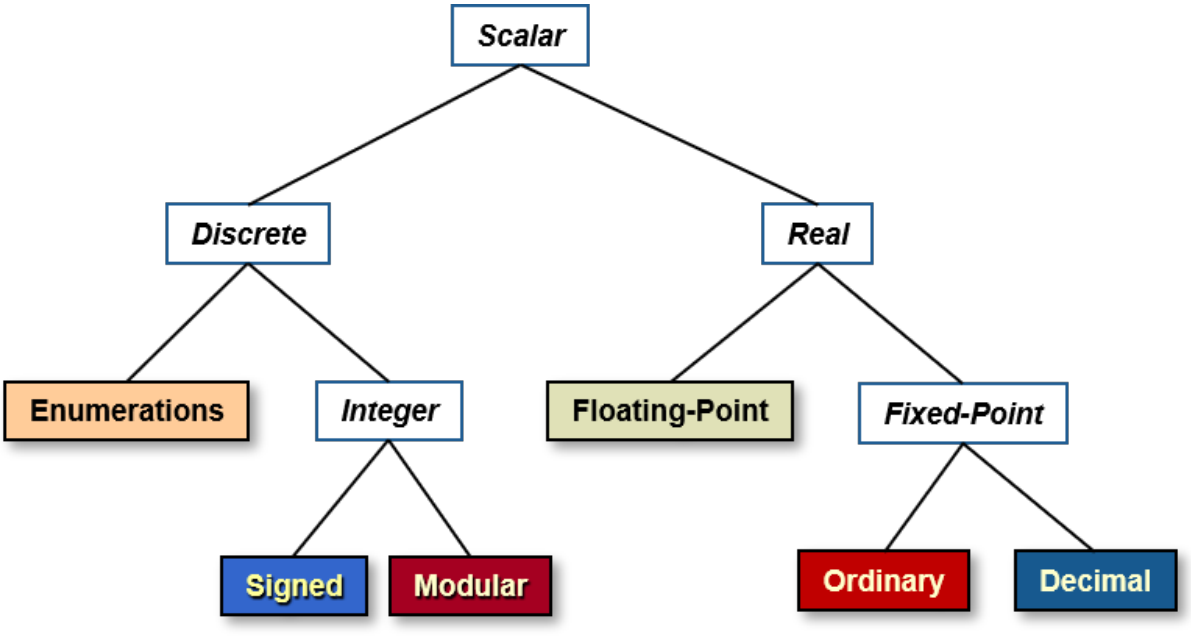
That said, there is one particular representation query we need to talk about explicitly, now, because there is a lot of confusion about it: the `'Size` attribute. The confusion stems from the fact that there are multiple contexts for applying the attribute, and multiple reasonable interpretations possible. We can apply the `'Size` attribute to a type, in an attempt to get information about all objects of the type, or we can apply it to individual objects to get specific information. In both cases, what actual information do we get? In the original version of Ada these questions weren't really answered so vendors did what they thought was correct. But they did not agree with each other, and portability became a problem.

For example, suppose you want to convert some value to a series of bytes in order to send the value over the wire. To do that you need to know how many bytes are required to represent the value. Many applications queried the size of the type to determine that, and then, when porting to a new vendor's compiler, found that their code no longer worked correctly. The new vendor's implementation wasn't wrong, it was just different.

Later versions of Ada answered these questions, where possible, so let's examine the contexts and meaning. Above all, though, remember that `'Size` returns values in terms of **bits**.

If we apply `'Size` to a type, the resulting value depends on the kind of type.

For scalar types, the attribute returns the *minimum* number of bits required to represent all the values of the type. Here's a diagram showing what the category "scalar types" includes:



Consider type `Boolean`, which has two possible values. One bit will suffice, and indeed the language standard requires `Boolean'Size` to be the value 1.

This meaning also applies to subtypes, which can constrain the number of values for a scalar type. Consider subtype `Natural`. That's a subtype defined by the language to be type `Integer` but with a range of `0 .. Integer'Last`. On a 32-bit machine we would expect `Integer` to be a native type, and thus 32-bits. On such a machine if we say `Integer'Size`

we will indeed get 32. But if we say `Natural'Size` we will get 31, not 32, because only 31 bits are needed to represent that range on that machine.

The size of objects, on the other hand, cannot be just a matter of the possible values. Consider type `Boolean` again, where `Boolean'Size` is required to be 1. No compiler is likely to allocate one bit to a `Boolean` variable, because typical machines don't support individually-addressable bits. Instead, addresses refer to storage elements, of a size indicated by the `Storage_Unit` constant. The compiler will allocate the smallest number of storage elements necessary, consistent with other considerations such as alignment. Therefore, for a machine that has `Storage_Unit` set to a value of eight, we can assume that a compiler for that machine will allocate an entire eight-bit storage element to a stand-alone `Boolean` variable. The other seven bits are simply not used by that variable. Moreover, those seven bits are not used by any other stand-alone object either, because access would be far less efficient, and such sharing would require some kind of locking to prevent tasks from interfering with each other when accessing those stand-alone objects. (Stand-alone objects are independently addressable; they wouldn't stand alone otherwise.)

By the same token (and still assuming a 32-bit machine), a compiler will allocate more than 31 bits to a variable of subtype Natural because there is no 31-bit addressable unit. The variable will get all 32-bits.

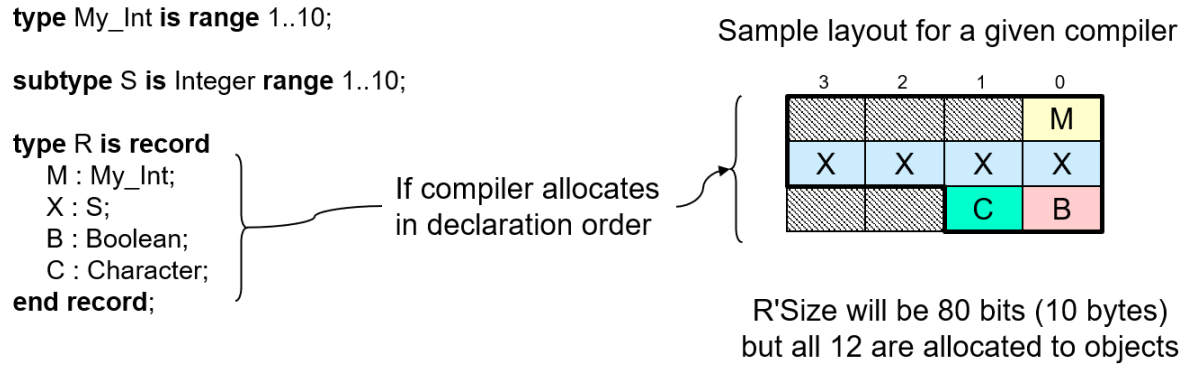
Note that we're talking about individual, stand-alone variables. Components of composite types, on the other hand, might indeed share bytes if the individual components don't require all the bits of their storage elements. You'd have to request that representation, though, with most implementations, because accessing the components at run-time would require more machine instructions. We'll go into the details of that later.

Let's talk further about sizes of types.

For record types, `'Size` gives the minimum number of bits required to represent the whole composite value. But again, that's not necessarily the number of bits required for the objects' in-memory representation. The order of the components within the record can make a difference, as well as their alignments. The compiler will respect the alignment requirements of the components, and may add padding bytes within the record and also at the end to ensure components start at addresses compatible with their alignment requirements. As a result the overall size could be larger.

Note that Ada compilers are allowed to reorder the components; the order in memory might not match the order in the source code.

For example, consider this record type and its components:



In the figure, we see a record type with some components, and a sample layout for that record type assuming the compiler does not reorder the components. Observe that some bytes allocated to objects of type R are unused (the darkly shaded ones). In this case that's because the alignment of subtype S happens to be 4 on this machine. The component X of that subtype S cannot start at byte offset 1, or 2, or 3, because those addresses would not satisfy the alignment constraint of S. (We're assuming byte 0 is at a word-aligned address.) Therefore, X starts at the object's starting address plus 4. Components B and C are of types

that have an alignment of 1, so they can start at any storage element. They immediately follow the bytes allocated to component X. Therefore, R'Size is 80, or 10 bytes. The three bytes following component M are simply not used.

But what about the two bytes following the last component C? They could be allocated to stand-alone objects if they would fit. More likely, though, the compiler will allocate those two bytes to objects of type R, that is, 12 bytes instead of 10 are allocated. As a result, 96 bits are actually used in memory. The extra, unused 16 bits are "padding."

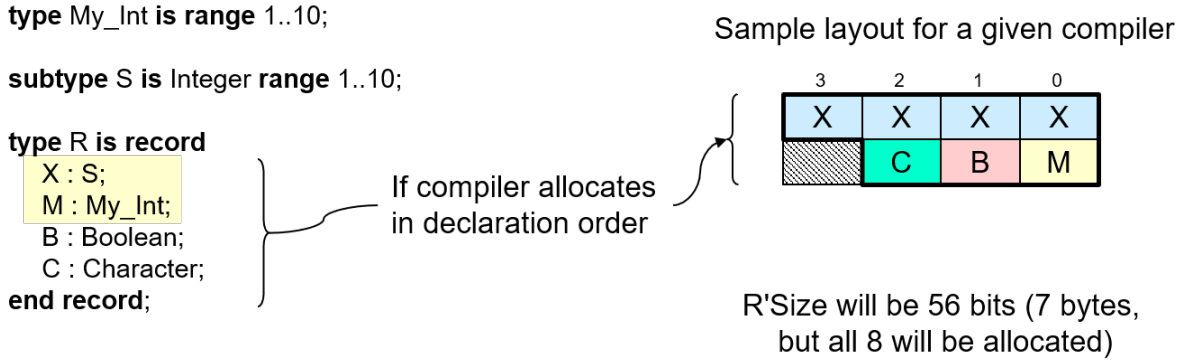
Why add unused padding? It simplifies the memory allocation of objects of type R. Suppose some array type has components of record type R. Assuming the first component is aligned properly, every following component will also be aligned properly, automatically, because the two padding bytes are considered parts of the components.

To make that work, the compiler takes the most stringent alignment of all the record type's components and uses that for the alignment of the overall record type. That way, any address that satisfies the record object's alignment will satisfy the components' alignment requirements. The alignment is component X, of subtype S, is 4. The other components have an alignment of 1, therefore R'Alignment is 4. An aligned address plus 12 will also be an aligned address.

This rounding up based on alignment is recommended behavior for the compiler, not a requirement, but is reasonable and typical among vendors. Although it can result in unused storage, that's the price paid for speed of access (or even correctness for machines that would fault on misaligned component accesses).

As you can see, alignment is a critical factor in the sizes of composite objects. If you care about the layout of the type you very likely need to care about the alignment of the components and overall record type.

Ada compilers are allowed to reorder the components of record types in order to minimize these gaps or satisfy the alignment requirements of the components. Some compilers do, some don't. Consider the type R again, this time with the first two components switched in the component declaration order:



Now R'Size will report 56 bits instead of 80. The one trailing byte will still be padding, but only that one.

What about unbounded types, for example type **String**? Querying the 'Size in that case would provide an implementation-defined result. A somewhat silly thing to do, really, since the type — by definition — doesn't specify how many components are involved.

Usually, though, you don't want to query the size of a type. Most of the time what you want is the size of objects of the type. Going back to sending values over the wire, the code should query the size of the *parameter* holding the value to be sent. That will tell you how many bits are really needed.

One last point: GNAT, and now Ada 202x, define an attribute named Object_Size. It does just what the name suggests: what 'Size does when applied to objects rather than types.

GNAT also defines another attribute, named `Value_Size`, that does what `'Size` does when applied to types. The former is far more useful so Ada has standardized it.

35.5 Specifying Representation

Recall that we said `Boolean'Size` is required to be 1, and that stand-alone objects of type `Boolean` are very likely allocated some integral number of storage elements (e.g., bytes) in memory, typically one. What about arrays of Booleans? Suppose we have an array of 16 Boolean components. How big are objects of the array type? It depends on the machine. Continuing with our hypothetical (but typical) byte-addressable machine, for the sake of efficient access each component is almost certainly allocated an individual byte rather than a single bit, just like stand-alone objects. Consequently, our array of 16 Booleans will be reported by `'Size` to be 128 bits, i.e., 16 bytes. If you wanted a bit-mask, in which each Boolean component is allocated a single bit and the total array size is 16 bits, you'd have a problem. The compiler assumes you want speed of access rather than storage minimization, and normally that would be the right assumption.

Naturally there is a solution. Ada allows us to specify the representation characteristics of types, and thus objects of those types, including their bit-wise layouts. It also allows us to specify the representation of individual objects. You should understand, though, that the compiler is not required to do what you ask, because you might ask the impossible. For example, if you specify that the array of 16 Booleans is to be represented completely in 15 bits, what can the compiler do? Rejecting that specification is the only reasonable response. But if you specify something possible, the compiler must do what you ask, absent some compelling reason to the contrary.

With that in mind, let's examine setting the size for types.

So, how do we specify that we want our array of 16 Boolean components to be allocated one bit per component, for a total allocation of 16 bits? There are a couple of ways, one somewhat better than the other.

First, you can ask that the compiler "pack" the components into as small a number of bits as it can:

```
type Bits16 is array (0 .. 15) of Boolean with
  Pack;
```

That likely does what you want: `Bits16'Size` will probably be 16.

But realize that the `Pack` aspect (and corresponding pragma) is merely a request that the compiler do its best to minimize the number of bits allocated, not necessarily that it do exactly what you expected or required.

We could set the size of the entire array type:

```
type Bits16 is array (0 .. 15) of Boolean with
  Size => 16;
```

But the language standard says that a `Size` clause on array and record types should not affect the internal layout of their components. That's Implementation Advice, so not normative, but implementations are really expected to follow the advice, absent some compelling reason. That's what the `Pack` aspect, record representation clauses, and `Component_Size` clauses are for. (We'll talk about record representation clauses momentarily.) That said, at least one other vendor's compiler would have changed the size of the array type because of the `Size` clause, so GNAT defines a configuration pragma named `Implicit_Packing` that overrides the default behavior. With that pragma applied, the `Size` clause would compile and suffice to make the overall size be 16. That's a vendor-defined pragma though, so not portable.

Therefore, the best way to set the size for the array type is to set the size of the individual components, via the `Component_Size` aspect as the Implementation Advice indicates. That will say what we really want, rather than a "best effort" request for the compiler, and is portable:

```
type Bits16 is array (0 .. 15) of Boolean with
  Component_Size => 1;
```

With this approach the compiler must either use the specified size for each component or refuse to compile the code. If it compiles, objects of the array type will be 16 bits total (plus any padding bits required to make objects have a size that is a multiple of Storage_Unit, typically zero on modern machines).

Now that we have a bit-mask array type, let's put it to use.

Let's say that you have an object that is represented as a simple signed integer because, for most usage, that's the appropriate representation. Sometimes, though, let's say you need to access individual bits of the object instead of the whole numeric value. Signed integer types don't provide bit-level access. In Ada we'd say that the "view" presented by the object's type doesn't include bit-oriented operations. Therefore, we need to add a view to the object that does provide them. A different view will require an additional type for the same object.

Applying different types, and thus their operations, to the same object is known as type punning[271] in computer programming. Realize that doing so circumvents the static strong typing we harness to protect us from ourselves and from others. Use it with care! (For example, limit the compile-time visibility to such code.)

One way to add a view is to express an "overlay," in which an object of one type is placed at the same memory location as a distinct object of a different type, thus "overlaying" one object over the other in memory. The different types present different views, therefore different operations available for the shared memory cells. Our hypothetical example uses two views, but you can overlay as many different views as needed. (That said, requiring a large number of different views of the same object would be suspect.)

There are other ways in Ada to apply different views, some more flexible than others, but an overlay is a simple one that will often suffice.

Here is an implementation of the overlay approach, using our bit-mask array type:

```
type Bits32 is array (0 .. 31) of Boolean with
  Component_Size => 1;

X : Integer;
Y : Bits32 with Address => X'Address;
```

We can query the addresses of objects, and other things too, but objects, especially variables, are the most common case. In the above, we say `X'Address` to query the starting address of object X. With that information we know what address to specify for our bit-mask overlay object Y. Now X and Y are aliases for the same memory cells, and therefore we can manipulate and query that memory as either a signed integer or as an array of bits. Reading or updating individual array components accesses the individual bits of the overlaid object.

Instead of the `Bits32` array type, we could have specified a modular type for the overlay Y to get a view providing bit-oriented operations. Overlaying such an array was a common idiom prior to the introduction of modular "unsigned" types in Ada, and remains useful for accessing individual bits. In other words, using a modular type for Y, you could indeed access an individual bit by passing a mask value to the **and** operator defined in any modular type's view. Using a bit array representation lets the compiler do that work for you, in the generated code. The source code will be both easier to read and more explicit about what it is doing when using the bit array overlay.

[271] https://en.wikipedia.org/wiki/Type_punning

One final issue remains: in our specific overlay example the compiler would likely generate code that works. But strictly speaking it might not.

The Ada language rules say that for such an overlaid object — Y in the example above — the compiler should not perform optimizations regarding Y that it would otherwise apply in the absence of aliases. That's necessary, functionally, but may imply degraded performance regarding Y, so keep it in mind. Aliasing precludes some desirable optimizations.

But what about X in the example above? We're querying that object's address, not specifying it, so the RM rule precluding optimizations doesn't apply to X. That can be problematic.

The compiler might very well place X in a register, for example, for the sake of the significant performance increase (another way of being friendly). But in that case `System.Null_Address` will be returned by the `X'Address` query and, consequently, the declaration for Y will not result in the desired overlaying.

Therefore, we should mark X as explicitly **`aliased`** to ensure that `X'Address` is well-defined:

```
type Bits32 is array (0 .. 31) of Boolean with
  Component_Size => 1;

X : aliased Integer;
Y : Bits32 with Address => X'Address;
```

The only difference in the version above is the addition of **`aliased`** in the declaration of X. Now we can be certain that the optimizer will not represent X in some way incompatible with the idiom, and `X'Address` will be well-defined.

In our example X and Y are clearly declared in the same compilation unit. Most compilers will be friendly in this scenario, representing X in such a way that querying the address will return a non-null address value even if **`aliased`** is not applied. Indeed, **`aliased`** is relatively new to Ada, and earlier compilers typically emitted code that would handle the overlay as intended.

But suppose, instead of being declared in the same declarative part, that X was declared in some other compilation unit. Let's say it is in the visible part of a package declaration. (Assume X is visible to clients for some good reason.) That package declaration can be, and usually will be, compiled independently of clients, with the result that X might be represented in some way that cannot supporting querying the address meaningfully.

Therefore, the declaration of X in the package spec should be marked as aliased, explicitly:

```
package P is
   X : aliased Integer;
end P;
```

Then, in the client code declaring the overlay, we only declare Y, assuming a with-clause for P:

```
type Bits32 is array (0 .. 31) of Boolean with
  Component_Size => 1;

Y : Bits32 with Address => P.X'Address;
```

All well and good, but how did the developer of the package know that some other unit, a client of the package, would query the address of X, such that it needed to be marked as aliased? Indeed, the package developer might not know. Yet the programmer is responsible for ensuring a valid and appropriate **`Address`** value is used in the declaration of Y. Execution is erroneous otherwise, so we can't say what would happen in that case. Maybe an exception is raised or a machine trap, maybe not.

Worse, the switches that were applied when compiling the spec for package P can make a difference: `P.X` might not be placed in a register unless the optimizer is enabled. Hence the client code using Y might work as expected when built for debugging, with the optimizer

disabled, and then not do so when re-built for the final release. You'd probably have to solve this issue by debugging the application.

On a related note, you may be asking yourself how to know that type **Integer** is 32 bits wide, so that we know what size array to use for the bit-mask. The answer is that you just have to know the target well when doing low-level programming. The hardware becomes much more visible, as we mentioned.

That said, you could at least verify the assumption:

```
pragma Compile_Time_Error (Integer'Object_Size /= 32,
                           "Integers expected to be 32 bits");
X : aliased Integer;
Y : Bits32 with Address => X'Address;
```

That's a vendor-defined pragma so this is not fully portable. It isn't an unusual pragma, though, so at least you can probably get the same functionality even if the pragma name varies.

Overlays aren't always structured like our example above, i.e., with two objects declared at the same time. We might apply a different type to the same memory locations at different times. Here's an example from the ADL to illustrate the idea. We'll elaborate on this example later, in another section.

First, a package declaration, with two functions that provide a device-specific unique identifier located in shared memory. Each function provides the same Id value in a distinct format. One format is a string of 12 characters, the other is a sequence of three 32-bit values. Hence both representations are the same size.

```
package STM32.Device_Id is

   subtype Device_Id_Image is String (1 .. 12);

   function Unique_Id return Device_Id_Image;

   type Device_Id_Tuple is array (1 .. 3) of UInt32
     with Component_Size => 32;

   function Unique_Id return Device_Id_Tuple;

end STM32.Device_Id;
```

In the package body we implement the functions as two ways to access the same shared memory, specified by `ID_Address`:

```
with System;

package body STM32.Device_Id is

   ID_Address : constant System.Address := System'To_Address (16#1FFF_7A10#);

   function Unique_Id return Device_Id_Image is
      Result : Device_Id_Image with Address => ID_Address, Import;
   begin
      return Result;
   end Unique_Id;

   function Unique_Id return Device_Id_Tuple is
      Result : Device_Id_Tuple with Address => ID_Address, Import;
   begin
      return Result;
   end Unique_Id;
```

(continues on next page)

(continued from previous page)

```
end STM32.Device_Id;
```

System'To_Address is just a convenient way to convert a numeric value into an **Address** value. The primary benefit is that the call is a static expression, but we can ignore that here. Using Import is a good idea to ensure that the Ada code does no initialization of the object, since the value is coming from the hardware via the shared memory. Doing so may not be necessary, depending on the type used, but is a good habit to develop.

The point of this example is that we have one object declaration per function, of a type corresponding to the intended function result type. Because each function places their local object at the same address, they are still overlaying the shared memory.

Now let's return, momentarily, to setting the size of entities, but now let's focus on setting the size of objects.

We've said that the size of an object is not necessarily the same as the size of the object's type. The object size won't be smaller, but it could be larger. Why? For a stand-alone object or a parameter, most implementations will round the size up to a storage element boundary, or more, so the object size might be greater than that of the type. Think back to **Boolean**, where Size is required to be 1, but stand-alone objects are probably allocated 8 bits, i.e., an entire storage element (on our hypothetical byte-addressed machine).

Likewise, recall that numeric type declarations are mapped to underlying hardware numeric types. These underlying numeric types provide at least the capabilities we request with our type declarations, e.g., the range or number of digits, perhaps more. But the mapped numeric hardware type cannot provide less than requested. If there is no underlying hardware type with at least our requested capabilities, our declarations won't compile. That mapping means that specifying the size of a numeric type doesn't necessarily affect the size of objects of the type. That numeric hardware type is the size that it is, and is fixed by the hardware.

For example, let's say we have this declaration:

```
type Device_Register is range 0 .. 2**5 - 1 with Size => 5;
```

That will compile successfully, because there will be a signed integer hardware type with at least that range. (Not necessarily, legally speaking, but realistically speaking, there will be such a hardware type.) Indeed, it may be an 8-bit signed integer, in which case Device_Register'Size will give us 5, but objects of the type will have a size of 8, unavoidably, even though we set Size to 5.

The difference between the type and object sizes can lead to potentially problematic code:

```
type Device_Register is range 0 .. 2**8 - 1 with Size => 8;

My_Device : Device_Register
  with Address => To_Address (...);
```

The code compiles successfully, and tries to map a byte to a hardware device that is physically connected to one storage element in the processor memory space. The actual address is elided as it is not important here.

That code might work too, but it might not. We might think that My_Device'Size is 8, and that My_Device'Address points at an 8-bit location. However, this isn't necessarily so, as we saw with the supposedly 5-bit example earlier. Maybe the smallest signed integer the hardware has is 16-bits wide. The code would compile because a 16-bit signed numeric type can certainly handle the 8-bit range requested. My_Device'Size would be then 16, and because 'Address gives us the *starting* storage element, My_Device'Address might designate the high-order byte of the overall 16-bit object. When the compiler reads the two bytes for My_Device what will happen? One of the bytes will be the data presented by

the hardware device mapped to the memory. The other byte will contain undefined junk, whatever happens to be in the memory cell at the time. We might have to debug the code a long time to identify that as the problem. More likely we'll conclude we have a failed device.

The correct way to write the code is to specify the size of the object instead of the type:

```
type Device_Register is range 0 .. 2**8 - 1;

My_Device : Device_Register with
  Size => 8,
  Address => To_Address (...);
```

If the compiler cannot support stand-alone 8-bit objects for the type, the code won't compile.

Alternatively, we could change the earlier `Size` clause on the type to apply `Object_Size` instead:

```
type Device_Register is range 0 .. 2**8 - 1 with Object_Size => 8;

My_Device : Device_Register with
  Address => To_Address (...);
```

The choice between the two approaches comes down to personal preference, at least if only a small number of stand-alone objects of the type are going to be declared. With either approach, if the implementation cannot support 8-bit stand-alone objects, we find out that there is a problem at compile-time. That's always cheaper than debugging.

You might conclude that setting the `Size` for a type serves no purpose. That's not an unreasonable conclusion, given what you've seen, but in fact there are reasons to do so. However, there are only a few specific cases so we will save the reasons for the discussions of the specific cases.

There is one general case, though, for setting the `'Size` of a type. Specifically, you may want to specify the size that you think is the minimum possible, and you want the compiler to confirm that belief. This would be one of the so-called "confirming" representation clauses, in which the representation detail is what the compiler would have chosen anyway, absent the specification. You're not actually changing anything, you're just getting confirmation via `Size` whether or not the compiler accepts the clause. Suppose, for example, that you have an enumeration type with 256 values. For enumeration types, the compiler allocates the smallest number of bits required to represent all the values, rounded up to the nearest storage element. (It's not like C, where enums are just named int values.) For 256 values, an eight-bit byte would suffice, so setting the size to 8 would be confirming. But suppose we actually had 257 enumerals, accidentally? Our size clause set to 8 would not compile, and we'd be told that something is amiss.

However, note that if your supposedly "confirming" size clause actually specifies a size larger than what the compiler would have chosen, you won't know, because the compiler will silently accept sizes larger than necessary. It just won't accept sizes that are too small.

There are other confirming representation clauses as well. Thinking again of enumeration types, the underlying numeric values are integers, starting with zero and consecutively increasing from there up to N-1, where N is the total number of enumeral values.

For example:

```
type Commands is (Off, On);

for Commands use (Off => 0, On => 1);
```

As a result, `Off` is encoded as 0 and `On` as 1. That specific underlying encoding is guaranteed by the language, as of Ada 95, so this is just a confirming representation clause nowadays.

But it was not guaranteed in the original version of the language, so if you wanted to be sure of the encoding values you would have specified the above. It wasn't necessarily confirming before Ada 95, in other words.

But let's also say that the underlying numeric values are not what you want because you're interacting with some device and the commands are encoded with values other than 0 and 1. Maybe you want to use an enumeration type because you want to specify all the possible values actually used by clients. If you just used some numeric type instead and made up constants for `On` and `Off`, there's nothing to keep clients from using other numeric values in place of the two constants (absent some comparatively heavy code to prevent that from happening). Better to use the compiler to make that impossible in the first place, rather than debug the code to find the incorrect values used. Therefore, we could specify different encodings:

```
for Commands use (Off => 2, On => 4);
```

Now the compiler will use those encoding values instead of 0 and 1, transparently to client code.

The encoding values specified must maintain the relative ordering, otherwise the relational operators won't work correctly. For example, for type Commands above, Off is less than On, so the specified encoding value for Off must be less than that of On.

Note that the values given in the example no longer increase consecutively, i.e., there's a gap. That gap is OK, in itself. As long as we use the two enumerals the same way we'd use named constants, all is well. Otherwise, there is both a storage issue and a performance issue possible. Let's say that we use that enumeration type as the index for an array type. Perfectly legal, but how much storage is allocated to objects of this array type? Enough for exactly two components? Four, with two unused? The answer depends on the compiler, and is therefore not portable. The bigger the gaps, the bigger the overall storage difference possible. Likewise, imagine we have a for-loop iterating over the index values of one of these array objects. The for-loop parameter cannot be coded by the compiler to start at 0, clearly, because there is no index (enumeration) value corresponding to 0. Similarly, to get the next index, the compiler cannot have the code simply increment the current value. Working around that takes some extra code, and takes some extra time that would not be required if we did not have the gaps.

The performance degradation can be significant compared to the usual code generated for a for-loop. Some coding guidelines say that you shouldn't use an enumeration representation clause for this reason, with or without gaps. Now that Ada has type predicates we could limit the values used by clients for a numeric type, so an enumeration type is not the only way to get a restricted set of named, encoded values.

```
type Commands is new Integer with
   Static_Predicate => Commands in 2 | 4;

On    : constant Commands := 2;
Off   : constant Commands := 4;
```

The storage and performance issues bring us back to confirming clauses. We want the compiler to recognize them as such, so that it can generate the usual code, thereby avoiding the unnecessary portability and performance issues. Why would we have such a confirming clause now? It might be left over from the original version of the language, written before the Ada 95 change. Some projects have lifetimes of several decades, after all, and changing the code can be expensive (certified code, for example). Whether the compiler does recognize confirming clauses is a feature of the compiler implementation. We can expect a mature compiler to do so, but there's no guarantee.

Now let's turn to what is arguably the most common representation specification, that of record type layouts.

Recall from the discussion above that Ada compilers are allowed to reorder record com-

ponents in physical memory. In other words, the textual order in the source code is not necessarily the physical order in memory. That's different from, say, C, where what you write is what you get, and you better know what you're doing. On some targets a misaligned `struct` component access will perform very poorly, or even trap and halt, but that's not the C compiler's fault. In Ada you'd have to explicitly specify the problematic layout. Otherwise, if compilation is successful, the Ada compiler must find a representation that will work, either by reordering the components or by some other means. Otherwise it won't compile.

GNAT did not reorder components until relatively recently but does now, at least for the more egregious performance cases. It does this reordering silently, too, although there is a switch to have it warn you when it does. To prevent reordering, GNAT defines a pragma named `No_Component_Reorder` that does what the name suggests. You can apply it to individual record types, or globally, as a configuration pragma. But of course because the pragma is vendor defined it is not portable.

Therefore, if you care about the record components' layout in memory, the best approach is to specify the layout explicitly. For example, perhaps you are passing data to code written in C. In that case, you need the component order in memory to match the order given in the corresponding C struct declaration. That order in memory is not necessarily guaranteed from the order in the Ada source code. The Ada compiler is allowed to chose the representation unless you specify it, and it might chose a different layout from the one given. (Ordinarily, letting the compiler chose the layout is the most desirable approach, but in this case we have an external layout requirement.)

Fortunately, specifying a record type's layout is straightforward. The record layout specification consists of the storage places for some or all components, specified with a record representation clause. This clause specifies the order, position, and size of components (including discriminants, if any).

The approach is to first define the record type, as usual, using any component order you like — you're about to specify the physical layout explicitly, in the next step.

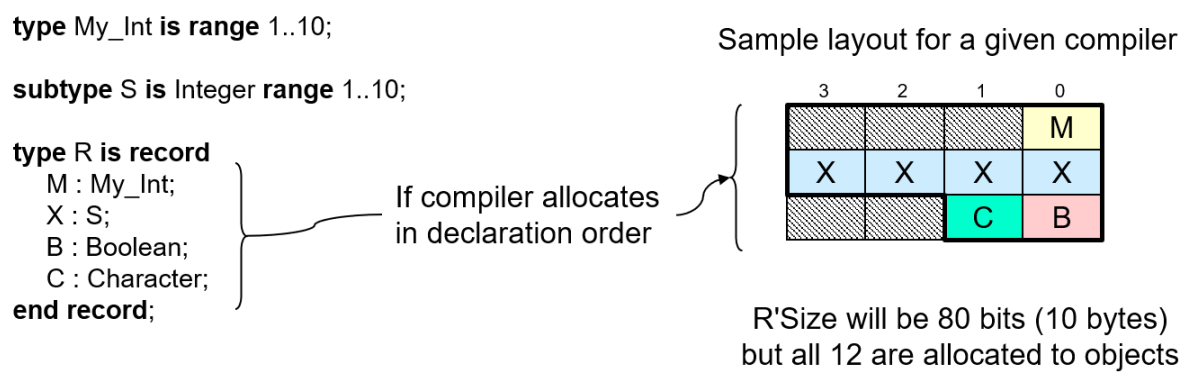
Let's reuse that record type from the earlier discussion:

```
type My_Int is range 1 .. 10;

subtype S is Integer range 1 .. 10;

type R is record
   M : My_Int;
   X : S;
   B : Boolean;
   C : Character;
end record;
```

The resulting layout might be like so, assuming the compiler doesn't reorder the components:

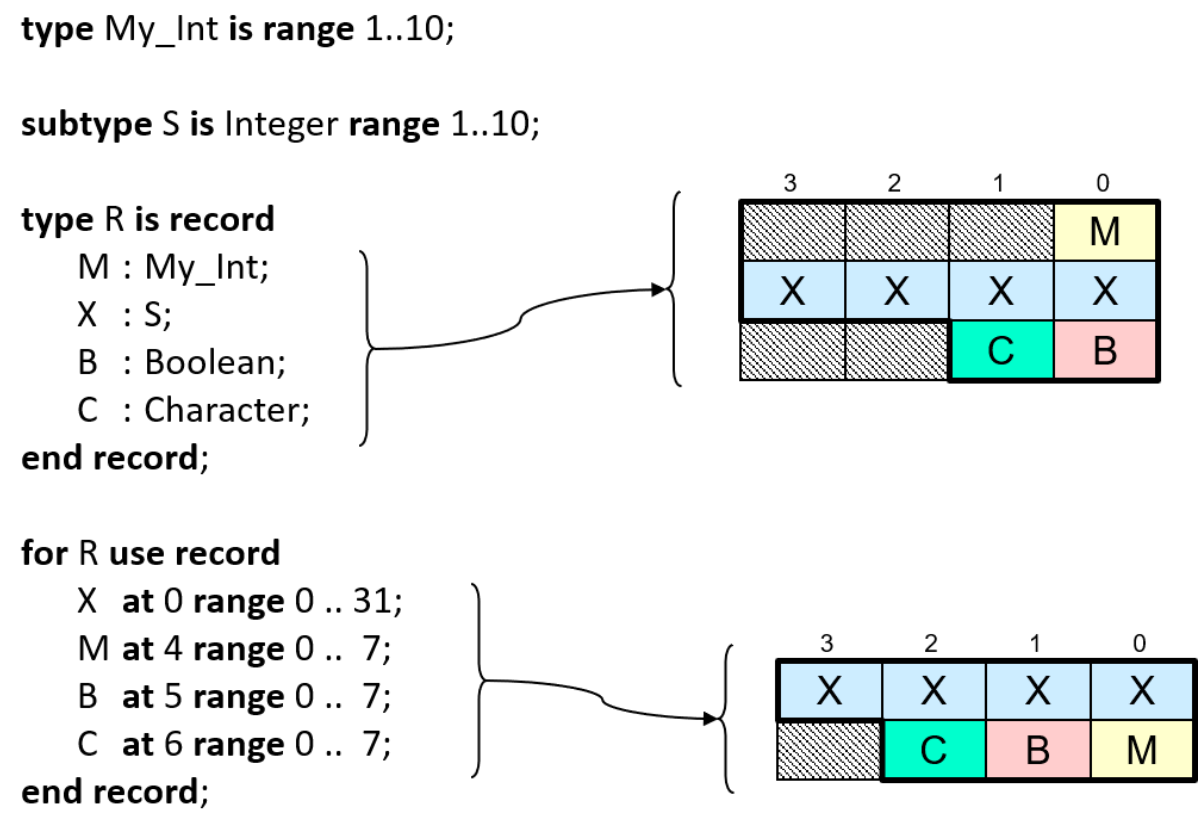


As a result, R'Size will be 80 bits (10 bytes), but those last two bytes will be will be allocated to objects, for an Object_Size of 96 bits (12 bytes). We'll change that with an explicit layout specification.

Having declared the record type, the second step consists of defining the corresponding record representation clause giving the components' layout. The clause uses syntax that somewhat mirrors that of a record type declaration. The components' names appear, as in a record type declaration. But now, we don't repeat the components' types, instead we give their relative positions within the record, in terms of a relative offset that starts at zero. We also specify the bits we want them to occupy within the storage elements starting at that offset.

```
for R use record
   X at 0 range 0 .. 31;  -- note the order swap,
   M at 4 range 0 ..  7;  -- with this component
   B at 5 range 0 ..  7;
   C at 6 range 0 ..  7;
end record;
```

Now we'll get the optimized order, and we'll always get that order, or the layout specification won't compile in the first place. In the following diagram, both layouts, the default, and the one resulting from the record representation clause, are depicted for comparison:



R'Size will be 56 bits (7 bytes), but that last padding byte will also be allocated to objects, so the Object_Size will be 64 bits (8 bytes).

Notice how we gave each component an offset, after the reserved word **at**. These offsets are in terms of storage elements, and specify their positions within the record object as a whole. They are relative to the beginning of the memory allocated to the record object so they are numbered starting at zero. We want the X component to be the very first component in the allocated memory so the offset for that one is zero. The M component, in comparison, starts at an offset of 4 because we are allocating 4 bytes to the prior component X: bytes 0 through 3 specifically. M just occupies one storage element so the next

component, B, starts at offset 5. Likewise, component C starts at offset 6.

Note that there is no requirement for the components in the record representation clause to be in any particular textual order. The offsets alone specify the components' order in memory. A good style, though, is to order the components in the representation clause so that their textual order corresponds to their order in memory. Doing so facilitates our verifying that the layout is correct because the offsets will be increasing as we read the specification.

An individual component may occupy part of a single storage element, all of a single storage element, multiple contiguous storage elements, or a combination of those (i.e., some number of whole storage elements but also part of another). The bit "range" specifies this bit-specific layout, per component, by specifying the first and last bits occupied. The X component occupies 4 complete 8-bit storage elements, so the bit range is 0 through 31, for a total of 32 bits. All the other components each occupy an entire single storage element so their bit ranges are 0 through 7, for a total of 8 bits.

The text specifying the offset and bit range is known as a "component_clause" in the syntax productions. Not all components need be specified by component_clauses, but (not surprisingly) at most one clause is allowed per component. Really none are required but it would be strange not to have some. Typically, all the components are given positions. If component_clauses are given for all components, the record_representation_clause completely specifies the representation of the type and will be obeyed exactly by the implementation.

Components not otherwise given an explicit placement are given positions chosen by the compiler. We don't say that they "follow" those explicitly positioned because there's no requirement that the explicit positions start at offset 0, although it would be unusual not to start there.

Placements must not make components overlap, except for components of variant parts, a topic covered elsewhere. You can also specify the placement of implementation-defined components, as long as you have a name to refer to them. (In addition to the components listed in the source code, the implementation can add components to help implement what you wrote explicitly.) Such names are always attribute references but the specific attributes, if any, are implementation-defined. It would be a mistake for the compiler to define such implicit components without giving you a way to refer to them. Otherwise they might go exactly where you want some other component to be placed, or overlap that place.

The positions (offsets) and the bit numbers must be static, informally meaning that they are known at compile-time. They don't have to be numeric literals, though. Numeric constants would work, but literals are the most common by far.

Note that the language does not limit support for component clauses to specific component types. They need not be one of the integer types, in particular. For example, a position can be given for components that are themselves record types, or array types. Even task types are allowed as far as the language goes, although the implementation might require a specific representation, such as the component taking no bits whatsoever (`0 .. -1`). There are restrictions that keep things sane, for example rules about how a component name can be used within the overall record layout construct, but not restrictions on the types allowed for individual components. For example, here is a record layout containing a **`String`** component, arbitrarily set to contain 11 characters:

```
type R is record
   S : String (1 .. 11);
   B : Boolean;
end record;

for R use record
   S at 0  range 0 .. 87;
   B at 11 range 0 .. 7;
end record;
```

Component S is to be the first component in memory in this example, hence the position offset is 0, for the first byte of S. Next, S is 11 characters long, or 88 bits, so the bit range is 0 .. 87. That's 11 bytes of course, so S occupies storage elements 0 .. 10. Therefore, the next component position must be at least 11, unless there is to be a gap, in which case it would be greater than 11. We'll place B immediately after the last character of S, so B is at storage element offset 11 and occupying all that one byte's bits.

We'll have more to say about record type layouts but first we need to talk about alignment.

Modern target architectures are comparatively strict about the address alignments for some of their types. If the alignment is off, an access to the memory for objects of the type can have highly undesirable consequences. Some targets will experience seriously degraded performance. On others, the target will halt altogether. As you can see, getting the alignment correct is a low-level, but vital, part of correct code on these machines.

Normally the compiler does this work for us, choosing an alignment that is both possible for the target and also optimal for speed of access. You can, however, override the compiler's alignment choice using an attribute definition clause or the `Alignment` aspect. You can do so on types other than record types, but specifying it on record types is typical. Here's our example record type with the alignment specified via the aspect:

```
type My_Int is range 1 .. 10;

subtype S is Integer range 1 .. 10;

type R is record
   M : My_Int;
   X : S;
   B : Boolean;
   C : Character;
end record with
   Alignment => 1;
```

Alignment values are in terms of storage elements. The effect of the aspect or attribute clause is to ensure that the starting address of the memory allocated to objects of the type will be a multiple of the specified value.

In fact, whenever we specify a record type layout we really should also specify the record type's alignment, even though doing so is optional. Why? The alignment makes a difference in the overall record object's size. We've seen that already, with the padding bytes: the compiler will respect the alignment requirements of the components, and may add padding bytes within the record and also at the end to ensure components start at addresses compatible with their alignment requirements. The alignment also affects the size allocated to the record type even when the components are already aligned. As a result the overall size could be larger than we want for the sake of space. Additionally, when we pass such objects to code written in other languages, we want to ensure that the starting address of these objects is aligned as the external code expects. The compiler might not choose that required alignment by default.

Specifying alignment for record types is so useful that in the first version of Ada there was no syntax to specify alignment for anything other than record types (via the obsolete **`at mod`** clause on record representation clauses).

For that reason GNAT provides a pragma named `Optimize_Alignment`. This is a configuration pragma that affects the compiler's choice of default alignments where no alignment is explicitly specified. There is a time/space trade-off in the selection of these values, as we've seen. The normal choice tries to balance these two characteristics, but with an argument to the pragma you can give more weight to one or the other. The best approach is to specify the alignments explicitly, per type, for those that require specific alignment values. The pragma has the nice property of giving general guidance to the compiler for what should be done for the other types and objects not explicitly specified.

Now let's look into the details. We'll use a case study for this purpose, including specifying sizes as well as alignments.

The code for the case study is as follows. It uses `Size` clauses to specify the `Sizes`, instead of the `Size` aspect, just to emphasize that the `Size` clause approach is not obsolete.

```
package Some_Types is

   type Temperature is range -275 .. 1_000;

   type Identity is range 1 .. 127;

   type Info is record
      T  : Temperature;
      Id : Identity;
   end record;

   for Info use record
      T  at 0 range 0 .. 15;
      Id at 2 range 0 .. 7;
   end record;

   for Info'Size use 24;

   type List is array (1 .. 3) of Info;
   for List'Size use 24 * 3;

end Some_Types;
```

When we compile this, the compiler will complain that the size for `List` is too small, i.e., that the minimum allowed is 96 bits instead of the 72 we specified. We specified 24 * 3 because we said the record size should be 24 bits, and we want our array to contain 3 record components of that size, so 72 seems right.

What's wrong? As we've shown earlier, specifying the record type size doesn't necessarily mean that objects (in this case array components) are that size. The object size could be bigger than we specified for the type. In this case, the compiler says we need 96 total bits for the array type, meaning that each of the 3 array components is 32 bits wide instead of 24.

Why is it 32 bits? Because the alignment for `Info` is 2 (on this machine). The record alignment is a multiple of the largest alignment of the enclosed components. The alignment for type `Temperature` (2), is larger than the alignment for type `Identity` (1), therefore the alignment for the whole record type is 2. We need to go from that number of storage elements to a number of bits for the size.

Here's where it gets subtle. The alignment is in terms of storage elements. Each storage element is of a size in bits given by `System.Storage_Unit`. We've said that on our hypothetical machine `Storage_Unit` is 8, so storage elements are 8 bits wide on this machine. Bytes, in other words. Therefore, to get the required size in bits, we have to find a multiple of the two 8-bit bytes (specified by the alignment) that has at least the number of bits we gave in the `Size` clause. Two bytes only provides 16 bits, so that's not big enough, we need at least 24 bits. The next multiple of 2 bytes is 4 bytes, providing 32 bits, which is indeed larger than 24. Therefore, the overall size of the record type, consistent with the alignment, is 4 bytes, or 32 bits. That's why the compiler says each array component is 32 bits wide.

But for our example let's say that we really want to use only 72 total bits for the array type (and that we want three array components). That's the size we specified, after all. So how do we get the record type to be 24 bits instead of 32? Yes, you guessed it, we change the alignment for the record type. If we change it from 2 to 1, the size of 24 bits will work. Adding this `Alignment` clause line will do that:

```
for Info'Alignment use 1;
```

An alignment of 1 means that any address will work, assuming that addresses refer to entire storage elements. (An alignment of 0 would mean that the address need not start on a storage element boundary, but we know of no such machines.)

We can even entirely replace the `Size` clause with the `Alignment` clause, because the `Size` clause specifying 24 bits is just confirming: it's the value that `'Size` would return anyway. The problem is the object size.

Now, you may be wondering why an alignment of 1 would work, given that the alignment of the `Temperature` component is 2. Wouldn't it slow down the code, or even trap? Well, maybe. It depends on the machine. If it doesn't work we would just have to use 32 bits for the record type, with the original alignment of 2, for a larger total array size. Of course, if the compiler recognizes that a representation cannot be supported it must reject the code, but the compiler might not recognize the problem.

We said earlier that there are only a small number of reasons to specify `'Size` for a type. We can mention one of them now. Setting `'Size` can be useful to give the minimum number of bits to use for a component of a packed composite type, that is, within either a record type or an array type that is explicitly packed via the aspect or pragma `Pack`. It says that the compiler, when giving its best effort, shouldn't compress components of the type any smaller than the number of bits specified. No, it isn't earth-shattering, but other uses are more valuable, to be discussed soon.

One thing we will leave unaddressed (pun intended) is the question of bit ordering and byte ordering within our record layouts. In other words, the "endian-ness". That's a subject beyond the scope of this course. Suffice it to say that GNAT provides a way to specify record layouts that are independent of the endian-ness of the machine, within some implementation-oriented limits. That's obviously useful when the code might be compiled for a different ISA in the future. On the other hand, if your code is specifically for a single ISA, e.g. Arm, even if different boards and hardware vendors are involved, there's no need to be independent of the endian-ness. It will always be the same in that case. (Those are "famous last words" though.) For an overview of the GNAT facility, an attribute named attribute `Scalar_Storage_Order` see https://www.adacore.com/papers/lady-ada-mediates-peace-treaty-in-endianness-war.

Although specifying record type layouts and alignments are perhaps the most common representation characteristics expressed, there are a couple of other useful cases. Both involve storage allocation.

One useful scenario concerns tasking. We can specify the number of storage elements reserved for the execution of a task object, or all objects of a task type. You use the `Storage_Size` aspect to do so:

```
task Servo with
  Storage_Size => 1 * 1024,
  ...
```

Or the corresponding pragma:

```
task Servo is
   pragma Storage_Size (1 * 1024);
end Servo;
```

The aspect seems textually cleaner and lighter unless you have task entries to declare as well. In that case the line for the pragma wouldn't add all that much. That's a matter of personal aesthetics anyway.

The specified number of storage elements includes the size of the task's stack (GNAT does have one, per task). The language does not specify whether or not it includes other storage associated with the task used for implementing and managing the task execution. With

GNAT, the extent of the primary stack size is the value returned, ignoring any other storage used internally in the run-time library for managing the task.

The GNAT run-time library allocates a default stack amount to each task, with different defaults depending on the underlying O.S., or lack thereof, and the target. You need to read the documentation to find the actual amount, or, with GNAT, read the code.

You would need to specify this amount in order to either increase or decrease the allocated storage. If the task won't run properly, perhaps crashing at strange and seemingly random places, there's a decent chance it is running out of stack space. That might also be the reason if you have a really deep series of subprogram calls that fails. The correction is to increase the allocation, as shown above. How much? Depends on the application code. The quick-and-dirty approach is to iteratively increase the allocation until the task runs properly. Then, reverse the approach until it starts to fail again. Add a little back until it runs, and leave it there. We'll mention a much better approach momentarily (**GNATstack**).

Even if the task doesn't seem to run out of task stack, you might want to reduce it anyway, to the extent possible, because the total amount of storage on your target might be limited. Some of the GNAT bare-metal embedded targets have very small amounts of memory available, so much so that the default task stack allocations would exhaust the memory available quickly. That's what the example above does: empirical data showed that the `Servo` task could run with just 1K bytes allocated, so we reduced it from the default accordingly. (We specified the size with that expression for the sake of readability, relative to using literals directly.)

Notice we said "empirical data" above. How do we know that we exercised the task's thread of control exhaustively, such that the arrived-at allocation value covers the worst case? We don't, not with certainty. If we really must know the allocation will suffice for all cases, say because this is a high-integrity application, we would use **GNATstack**. GNATstack is an offline tool that exploits data generated by the compiler to compute worst-case stack requirements per subprogram and per task. As a static analysis tool, its computation is based on information known at compile time. It does not rely on empirical run-time information.

The other useful scenario for allocating storage concerns access types, specifically access types whose values designate objects, as opposed to designating subprograms. (Remember, objects are either variables or constants.) There is no notion of dynamically allocating procedures and functions in Ada so access-to-subprogram types are not relevant here. But objects can be of protected types (or task types), and protected objects can "contain" entries and protected subprograms, so there's a lot of expressive power available. You just don't dynamically allocate procedures or functions as such.

First, a little background on access types, to supplement what we said earlier.

By default, the implementation chooses a standard storage pool for each named access-to-object type. The storage allocated by an allocator (i.e., **new**) for such a type comes from the associated pool.

Several access types can share the same pool. By default, the implementation might choose to have a single global storage pool, used by all such access types. This global pool might consist merely of calls to operating system routines (e.g., `malloc`), or it might be a vendor-defined pool instead. Alternatively, the implementation might choose to create a new pool for each access-to-object type, reclaiming the pool's memory when the access type goes out of scope (if ever). Other schemes are possible.

Finally, users may define new pool types, and may override the choice of pool for an access-to-object type by specifying `Storage_Pool` for the type. In this case, allocation (via **new**) takes memory from the user-defined pool and deallocation puts it back into that pool, transparently.

With that said, here's how to specify the storage to be used for an access-to-object type. There are two ways to do it.

If you specify `Storage_Pool` for an access type, you indicate a specific pool object to be used (user-defined or vendor-defined). The pool object determines how much storage is

available for allocation via **new** for that access type.

Alternatively, you can specify `Storage_Size` for the access type. In this case, an implementation-defined pool is used for the access type, and the storage available is at least the amount requested, maybe more (it might round up to some advantageous block size, for example). If the implementation cannot satisfy the request, `Storage_Error` is raised.

It should be clear that that the two alternatives are mutually exclusive. Therefore the compiler will not allow you to specify both.

Each alternative has advantages. If your only concern is the total number of allocations possible, use `Storage_Size` and let the implementation do the rest. However, maybe you also care about the behavior of the allocation and deallocation routines themselves, beyond just providing and reclaiming the storage. In that case, use `Storage_Pool` and specify a pool object of the appropriate type. For example, you (or the vendor, or someone else) might create a pool type in which the allocation routine performs in constant time, because you want to do **new** in a real-time application where predictability is essential.

Lastly, an idiom: when using `Storage_Size` you may want to specify a value of zero. That means you intend to do no allocations whatsoever, and want the compiler to reject the code if you try. Why would you want an access type that doesn't allow dynamically allocating objects? It isn't as unreasonable as it might sound. If you plan to use the access type strictly with aliased objects, never doing any allocations, you can have the compiler enforce your intent. There are application domains that prohibit dynamic allocations due to the difficulties in analyzing their behavior, including issues of fragmentation and exhaustion. Access types themselves are allowed in these domains. You'd simply use them to designate aliased objects alone. In addition, in this usage scenario, if the implementation associates an actual pool with each access type, the pool's storage would be wasted since you never intend to allocate any storage from it. Specifying a size of 0 tells the implementation not to waste that storage.

Before we end this section, there is a GNAT compiler switch you should know about. Th `-gnatR?` switch instructs the compiler to list the representation details for the types, objects and subprograms in the compiled file(s). Both implementation-defined and user-defined representation details are presented. The '?' is just a placeholder and can be one of the following characters:

```
[0|1|2|3|4][e][j][m][s]
```

Increasing numeric values provide increasing amounts of information. The default is '1' and usually will suffice. See the GNAT User's Guide for Native Platforms for the details of the switch in section 4.3.15 Debugging Control[272].

You'll have to scroll down some to find that specific switch but it is worth finding and remembering. When you cannot understand what the compiler is telling you about the representation of something, this switch is your best friend.

35.6 Unchecked Programming

Ada is designed to be a reliable language by default, based as it is on static strong typing and high-level semantics. Many of the pitfalls that a developer must keep in the back of their mind with other languages do not apply in Ada, and are typically impossible. That protection extends to low-level programming as well, e.g., the Separation Principle. Nevertheless, low-level programming occasionally does require mechanisms that allow us to go beyond the safety net provided by the type rules and high-level language constructs.

One such mechanism (unchecked conversion) provides a way to circumvent the type system, a system otherwise firmly enforced by the compiler on our behalf. Note that by "circumventing the type system" we do not include so-called "checked" conversions. These conversions have meaningful semantics, and are, therefore, allowed by the language using a specific syntax. This conversion syntax is known as "functional" syntax because it looks like a function call, except that the "function" name is a type name, and the parameter is the object or value being converted to that type. These conversions are said to be "checked" because only specific kinds of types are allowed, and the compiler checks that such conversions are indeed between these allowed types.

Instead, this section discusses "unchecked" programming, so-called because the compiler does not check for meaningful semantics. There are multiple mechanisms for unchecked programming in Ada: in addition to circumventing the type system, we can also deallocate a previously-allocated object, and can create an access value without the usual checks. In all cases the responsibility for correct meaning and behavior rests on the developer. Very few, if any, checks are done by the compiler. If we convert a value to another type that generally makes no sense, for example a task object converted to a record type, we are on our own. If we deallocate an allocated object more than once, it is our fault and Bad Things inevitably result.

Likened to "escape hatches," the facilities for unchecked programming are explicit in Ada. Their use is very clear in the source code, and is relatively heavy: each mechanism is provided by the language in the form of a generic library subprogram that must be specified in a context clause ("with-clause") at the top of the file, and then instantiated prior to use, like any generic. For an introduction to generic units in Ada, see that section in the introductory Ada course: *Introduction to Ada* (page 123)

You should understand that the explicitly unchecked facilities in Ada are no more unsafe than the implicitly unchecked facilities in other languages. There's no safety-oriented reason to "drop down" to C, for example, to do low-level programming. For that matter, the low-level programming facilities in Ada are at least as powerful as those in other languages, and probably more so.

We will explore unchecked storage deallocation in a separate book so let's focus on unchecked type conversions.

Unchecked type conversions are achieved by instantiating this language-defined generic library function, a "child" of the root package named "Ada":

```
generic
   type Source(<>) is limited private;
   type Target(<>) is limited private;
function Ada.Unchecked_Conversion (S : Source) return Target
   with Pure, Nonblocking, Convention => Intrinsic;
```

The function, once instantiated and eventually invoked, returns the caller's value passed to S (of type `Source`) as if it is a value of type `Target`. That value can then be used in any way consistent with the `Target` type.

The two generic parameters, `Source` and `Target`, are defined in a manner that makes them very permissive in terms of the types they will accept when instantiated. To understand how, you need to understand a little bit of Ada's terminology and design for generic

unit parameters. (If you are already familiar with generic formal types and how they are matched, feel free to skip this material.)

First, the terminology. The type parameters defined by a generic unit are known as "generic formal types," or "generic formals" for short. Types `Source` and `Target` are the generic formals in the unit above. When instantiating such a generic, clients must specify a type for each generic formal type. The types specified by the client are known as "generic actual types," or "generic actuals" for short. You can remember that by the fact that the actuals are the types "actually" given to the generic unit to work with when instantiated. (You may laugh, but that mnemonic works.)

Now we're ready to discuss the language design concept. The idea is that the syntax of a generic formal type indicates what kind of generic actual is required for a legal instantiation. This is known as the "Contract Model" because we can think of the formal parameters as expressing a contract between the generic unit's implementation and the client code that instantiates the generic. The contract is enforced by the compiler, in that it will reject any instantiation that attempts to specify some actual type that does not match the formal's requirements.

For example, if the generic computes some value for any floating point type, that floating-point type would be declared as a generic formal type, and would be defined so that only some floating-point type could be used for the corresponding actual type:

```
generic
   type Real is digits <>;
```

The formal parameter syntax reflects the syntax of a floating-point type declaration, except that the <> (the "box") indicates that the generic does not care how many digits are available. The generic actual will be some floating point type and it will specify the number of decimal digits.

If instead we try to match that formal with some actual that is anything other than a floating-point type the compiler will reject the instantiation. Therefore, within the generic body, the implementation code can be written with the assurance that the characteristics and capabilities required of a floating point type will be available. That's the Contract Model in full: the requirements are a matter of the generic unit's purpose and implementation, so the formal parameters reflect those requirements and the compiler ensures they will be met.

Some generic units, though, do not require specifically numeric actual types. These generics can use less specific syntax for their formal types, and as a result, more kinds of actual types are permitted in the instantiations. Remember the Contract Model and this will make sense. The contract between the generic and the clients is, in this case, more permissive: it does not require a numeric type in order to implement whatever it does.

For illustration, suppose we want a generic procedure that will exchange two values of some type. What operations does the generic unit require in the implementation in order to swap two values? There are two: assignment, as you might expect, but also the ability to declare objects of the type (the "temporary" used to hold one of the values during the swap steps). As long as the body can do that, any type will suffice, so the generic formals are written to be that permissive. What is the syntax that expresses that permissiveness, you ask? To answer that, first consider simple, non-generic private types from the user's point of view. For example:

```
package P is
   type Foo is private;
   procedure Do_Something (This : Foo);
private
   type Foo is ...  -- whatever
end P;
```

There are two "views" associated with the package: one for the "visible" part of the package

spec (declaration), known as the "partial" view, and one for the "private" part of the package spec and the package body, known as the "full" view. The differences between the two views are a function of compile-time visibility.

The partial view is what clients (i.e., users) of the package have: the ability to do things that a type name provides, such as declarations of objects, as well as some basic operations such as assignment, some functions for equality and inequality, some conversions, and whatever subprograms work on the type (the procedure `Do_Something` above). Practically speaking, that's about all that the partial view provides. That's quite a lot, in fact, and corresponds to the classic definition of an "abstract data type."

The code within the package private part and package body has the full view. This code has compile-time visibility to the full definition for type Foo, so there are additional capabilities available to this code. For example, if the full definition for Foo is as an array type, indexing will be available with the private part and body. If Foo is fully defined as some numeric type, arithmetic operations will be possible within the package, and so on.

Therefore, the full view provides capabilities for type `Foo` that users of the type cannot access via the partial view. Only the implementation for type `Foo` and procedure `Do_Something` have the potential to access them.

Now, back to the generic formal parameter. If the generic unit doesn't care what the actual type is, and just needs to be able do assignment and object declaration, a "generic formal private type" expresses exactly that:

```
generic
   type Item is private;
procedure Exchange( Left, Right : in out Item );

procedure Exchange( Left, Right : in out Item ) is
   Old_Left : Item;
begin
   Old_Left := Left;
   Left := Right;
   Right := Old_Left;
end Exchange;
```

Inside generic procedure Exchange, the view of type `Item` is as if `Item` were some private type declared in a package, with only the partial view available. But the operations provided by a partial view are sufficient to implement the body of Exchange: only assignment and object declaration are required. Any additional capabilities that the generic actual type may have — array indexing, arithmetic operators, whatever — are immaterial because they are not required. That's the Contract Model: only the specified view's required capabilities are important. Anything else the type can also do is not relevant.

But consider limited types. Those types don't allow assignment, by definition. Therefore, an instantiation that specified a limited actual type for the generic formal type Item above would be rejected by the compiler. The contract specifies the ability to do assignment so a limited type would violate the contract.

Finally, as mentioned, our Exchange generic needs to declare the "temporary" object `Old_Left`. A partial view of a private type allows that. But not all types are sufficient, by their name alone, to declare objects. Unconstrained array types, such as type **`String`**, are a familiar example: they require the bounds to be specified when declaring objects; the name **`String`** alone is insufficient. Therefore, such types would also violate the contract and, therefore, would be rejected by the compiler when attempting to instate generic procedure Exchange.

Suppose, however, that we have some other generic unit whose implementation does not need to declare objects of the formal type. In that case, a generic actual type that did not support object declaration (by the name alone) would be acceptable for an instantiation. The generic formal syntax for expressing that contract uses these tokens: (<>) in addition to the other syntax mentioned earlier:

```
generic
   type Foo(<>) is private;
```

In the above, the generic formal type Foo expresses the fact that it can allow unconstrained types — known as "indefinite types" — when instantiated because it will not attempt to use that type name to declare objects. Of course, the compiler will also allow constrained types (e.g., **Integer**, **Boolean**, etc.) in instantiations because it doesn't matter one way or the other inside the generic implementation. The Contract Model says that additional capabilities, declaring objects in this case, are allowed but not required. (There is a way to declare objects of indefinite types, but not using the type name alone. The unchecked facilities don't need to declare objects so we will not show how to do it.)

Now that you understand the Contract Model (perhaps more than you cared), we are ready to examine the generic formal type parameters for `Ada.Unchecked_Conversion`. Here's the declaration again:

```
generic
   type Source(<>) is limited private;
   type Target(<>) is limited private;
function Ada.Unchecked_Conversion (S : Source) return Target
   with Pure, Nonblocking, Convention => Intrinsic;
```

The two generic formal types, `Source`, and `Target`, are the types used for the incoming value and the returned value, respectively. Both formals are "indefinite, limited private types" in the jargon, but now you know what that means. Inside the implementation of the generic function, neither `Source` nor `Target` will be used to declare objects (the (<>) syntax). Likewise, neither type will be used in an assignment statement (the "limited" reserved word). And finally, no particular kind of type is required for `Source` or `Target` (the **private** reserved word). That's a fairly restricted usage within the generic implementation, but as a result the contract can be very permissive: the generic can be instantiated with almost any type. It doesn't matter if the actual is limited or not, private or not, and indefinite or not. The generic implementation doesn't need those capabilities to implement a conversion so they are not part of the contract expressed by the generic formal types.

What sort of type would be disallowed? Abstract types, and incomplete types. However, it is impossible to declare objects of those types, for good reasons, so unchecked conversion is never needed for them.

Note that the result value is returned by-reference whenever possible, in which case it is just a view of the `Source` bits in the formal parameter S and not a copy. For a `Source` type that is not a by-copy type, the result of an unchecked conversion will typically be returned by-reference (so that the result and the parameter S share the same storage); for a by-copy `Source` type, a copy is made.

The compiler can restrict instantiations but implementers are advised by the language standard to avoid them unless they are required by the target environment. For example, an instantiation for types for which unchecked conversion can't possibly make sense might be disallowed.

Clients can apply language- and vendor-defined restrictions as well, via pragma `Restrictions`. In particular, the language defines the `No_Dependence` restriction, meaning that no client's context clause can specify the unit specified. As a result no client can instantiate the generic for unchecked conversion:

```
pragma Restrictions (No_Dependence => Ada.Unchecked_Conversion);
```

hence there would be no use of unchecked conversion.

From the Contract Model's point of view most any type can be converted to some other type via this generic function. But practically speaking, some limitations are necessary. The following must all be true for the conversion effect to be defined by the language:

- S'Size = Target'Size
- S'Alignment is a multiple of Target'Alignment, or Target'Alignment is 0 (meaning no alignment required whatsoever)
- Target is not an unconstrained composite type
- S and Target both have a contiguous representation
- The representation of S is a representation of an object of the target subtype

We will examine these requirements in turn, but realize that they are not a matter of legality. Compilers can allow instantiations that violate these requirements. Rather, they are requirements for conversions to have the defined effect.

The first requirement is that the size (in bits) for the parameter S, of type Source, is the same as the size of the Target type. That's reasonable if you consider it. What would it mean to convert, for example, a 32-bit value to an 8-bit value? Which 8 bits should be used?

As a result, one of the few reasons for setting the size of a type (as opposed to the size of an object) is for the sake of well-defined unchecked conversions. We might make the size larger than it would need to be because we want to convert a value of that type to what would otherwise be a larger Target type.

Because converting between types that are not the same size is so open to interpretation, most compilers will issue a warning when the sizes are not the same. Some will even reject the instantiation. GNAT will issue a warning for these cases when the warnings are enabled, but will allow the instantiation. We're supposed to know what we are doing, after all. The warning is enabled via the specific -gnatwz switch or the more general -gnatwa switch. GNAT tries to be permissive. For example, in the case of discrete types, a shorter source is first zero or sign extended as necessary, and a shorter target is simply truncated on the left. See the GNAT RM for the other details.

The next requirement concerns alignment. As we mentioned earlier, modern architectures tend to have strict alignment requirements. We can meaningfully convert to a type with a stricter alignment, or to a type with no alignment requirement, but converting in the other direction would require a copy.

Next, recall that objects of unconstrained types, such as unconstrained array types or discriminated record types, must have their constraints specified when the objects are declared. We cannot just declare a **String** object, for example, we must also specify the lower and upper bounds. Those bounds are stored in memory, logically as part of the **String** object, since each object could have different bounds (that's the point, after all). What, then, would it mean to convert some value of a type that has no bounds to a type that requires bounds? The third requirement says that it is not meaningful to do so.

The next requirement is that the argument for S, and the conversion target type Target, have a contiguous representation in memory. In other words, each storage unit must be immediately adjacent, physically, to the next logical storage unit in the value. Such a representation for any given type is not required by the language, although on typical modern architectures it is common. (The type System.Storage_Elements.Storage_Array is an exception, in that a contiguous representation is guaranteed.) An instance of Ada.Unchecked_Conversion just takes the bits of S and treats them as if they are bits for a value of type Target (more or less), and does not handle issues of segmentation.

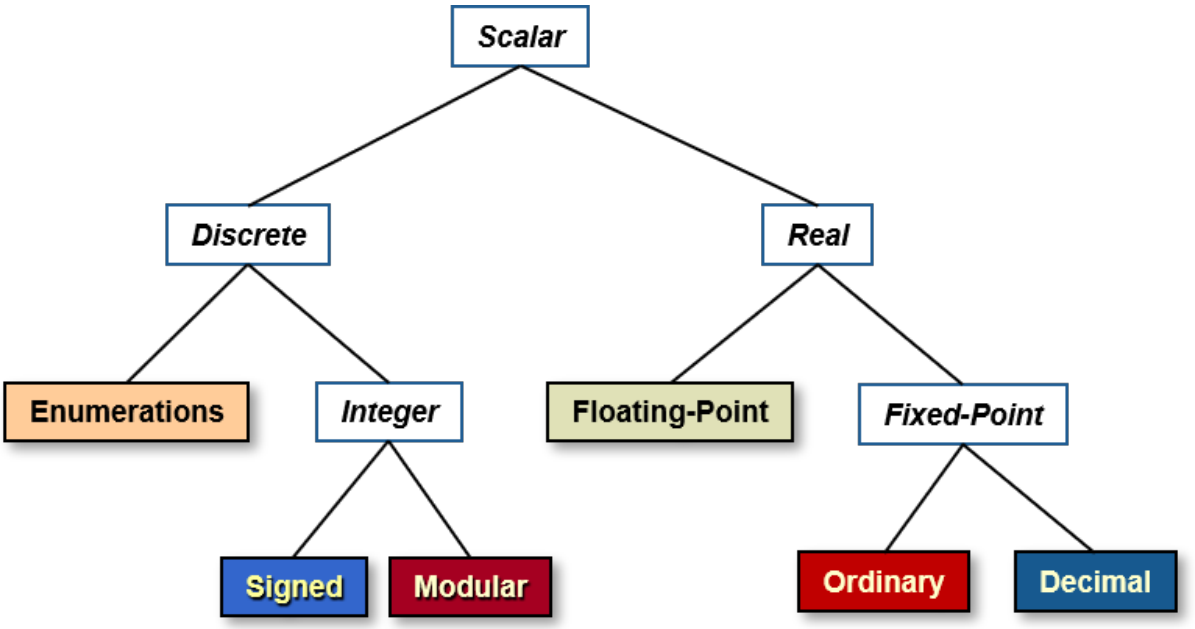
The last requirement merely states that the bits of the argument S, when treated as a value of type Target, must actually be a bit-pattern representing a value of type Target (strictly, the subtype). For example, with signed integers, any bit pattern (of the right size) represents a valid value for those types. In contrast, consider an enumeration type. By default, the underlying representational values are the same as the position values, i.e., starting at zero and increasing by one. But users can override that representation: they can start with any value and, although the values must increase, they need not increase by one:

```
type Toggle_Switch is (Off, On);
for Toggle_Switch use (Off => 0, On => 4);
```

If we covert an unsigned integer (of the right size) to a Toggle_Switch value, what would it mean if the Source value was neither 0 nor 4?

We've said that the instantiations are likely allowed, hence callable functions are created. If the above requirements are not met, what happens?

What happens depends on the Target type, that is, the result type for the conversion. Specifically, it depends on whether the target type is a "scalar" type. As we mentioned earlier, a scalar type is either a "discrete" type or a "real" type, which are themselves further defined, as the figure below indicates. Any other type is a non-scalar type, e.g., record types, access types, task types, and so on.



When the requirements for meaningful instantiations are not respected and the Target type is a scalar type, the result returned from the call is implementation defined and is potentially an invalid representation. For example, type Toggle_Switch is an enumeration type, hence it is a scalar type. Therefore, if we covert an unsigned integer (of the right size) to a Toggle_Switch value, and the Source value is neither 0 nor 4, the resulting value is an invalid representation. That's the same as an object of type Toggle_Switch that is never assigned a value. The random junk in the bits may or may not be a valid Toggle_Switch value. That's not a good situation, clearly, but it is well-defined: if it is detected, either Constraint_Error or Program_Error is raised. If the situation is not detected, execution continues using the invalid representation. In that case it may or may not be detected, near the call or later. For example:

```
with Ada.Unchecked_Conversion;
with Ada.Text_IO;  use Ada.Text_IO;
with Interfaces;   use Interfaces;

procedure Demo is

   type Toggle_Switch is (Off, On) with Size => 8;
   for Toggle_Switch use (Off => 1, On => 4);

   function As_Toggle_Switch is new Ada.Unchecked_Conversion
     (Source => Unsigned_8, Target => Toggle_Switch);
```

(continues on next page)

(continued from previous page)

```
   T1 : Toggle_Switch;
   T2 : Toggle_Switch;
begin
   T1 := As_Toggle_Switch (12);  -- neither 1 nor 4
   if T1 = Off then
      Put_Line ("T1's off");
   else
      Put_Line ("T1's on");
   end if;
   T2 := T1;
   if T2 = Off then
      Put_Line ("T2's off");
   else
      Put_Line ("T2's on");
   end if;
   Put_Line (T2'Image);
end Demo;
```

In the execution of the code above, the invalid representation value in T1 is not detected, except that it is copied into T2, where it is eventually detected when `'Image` is applied to T2. The invalid representation is not detected in the assignment statement or the comparison because we want the optimizer to be able to avoid emitting a check prior to every use of the value. Otherwise the generated code would be too slow. (The language explicitly allows this optimization.)

The evaluation of an object having an invalid representation value due to unchecked conversion is a so-called "bounded error" because the results at run-time are predictable and limited to one of those three possibilities: the two possible exceptions, or continued execution.

Continued execution might even work as hoped, but such code is not portable and should be avoided. A new vendor's compiler, or even a new version of a given vendor's compiler, might detect the situation and raise an exception. That happens, and it ends up costing developer time to make the required application code changes.

The possibilities get much worse when the result type is not a scalar type. In this case, the *effect* of the call — not the value returned by the call — is implementation defined. As a result, the possible run-time behavior is unpredictable and, consequently, from the language rules point of view anything is possible. Such execution is said to be "erroneous."

Why the difference based on scalar versus non-scalar types? Scalar types have a simple representation: their bits directly represent their values. Non-scalar types don't always have a simple representation that can be verified by examining their bits.

For example, we can have record types with discriminants that control the size of the corresponding objects because the record type contains an array component that uses the discriminant to set the upper bound. These record types might have multiple discriminants, and multiple dependent components. As a result, an implementation could have hidden, internal record components. These internal components might be used to store the starting address of the dependent components, for example, or might use pointers to provide a level of indirection. If an unchecked conversion did not provide correct values for these internal components, the effect of referencing the record object would be unpredictable.

Even a comparatively simple record type with one such dependent component is sufficient to illustrate the problem. There are no internal, hidden components involved:

```
with Ada.Unchecked_Conversion;
with Ada.Text_IO;             use Ada.Text_IO;
with System;                  use System;  -- for Storage_Unit
with System.Storage_Elements; use System.Storage_Elements;
```

(continues on next page)

(continued from previous page)

```
procedure Demo_Erroneous is

   subtype Buffer_Size is Storage_Offset range 1 .. Storage_Offset'Last;

   type Bounded_Buffer (Capacity : Buffer_Size) is record
      Content : Storage_Array (1 .. Capacity);
      Length  : Storage_Offset := 0;
   end record;

   procedure Show_Capacity (This : Bounded_Buffer);

   subtype OneK_Bounded_Buffer is Bounded_Buffer (Capacity => 1 * 1024);

   function As_OneK_Bounded_Buffer is new Ada.Unchecked_Conversion
     (Source => Storage_Array, Target => OneK_Bounded_Buffer);

   Buffer   : OneK_Bounded_Buffer;
   Sequence : Storage_Array (1 .. Buffer'Size / Storage_Unit);

   procedure Show_Capacity (This : Bounded_Buffer) is
   begin
      Put_line ("This.Capacity is" & This.Capacity'Image);
   end Show_Capacity;

begin
   Buffer := As_OneK_Bounded_Buffer (Sequence);
   Put_Line ("Buffer capacity is" & Buffer.Capacity'Image);
   Show_Capacity (Buffer);
   Put_Line ("Done");
end Demo_Erroneous;
```

In the above, the type `Bounded_Buffer` has an array component `Content` that depends on the discriminant `Capacity` for the number of array components. This is an extremely common idiom. However, unchecked conversion is only meaningful, as defined earlier, when converting to constrained target types. `Bounded_Buffer` is not constrained, so we define a constrained subtype (`OneK_Bounded_Buffer`) for the sake of the conversion.

The specific `Buffer` object is 8320 bits (1024 * 8, plus 2 * 64), as is the Sequence object, so the sizes are the same.

The alignment of `OneK_Bounded_Buffer` is 8, and `Storage_Array`'s alignment is 1, so the `Target` type is a multiple of the `Source` type, as required.

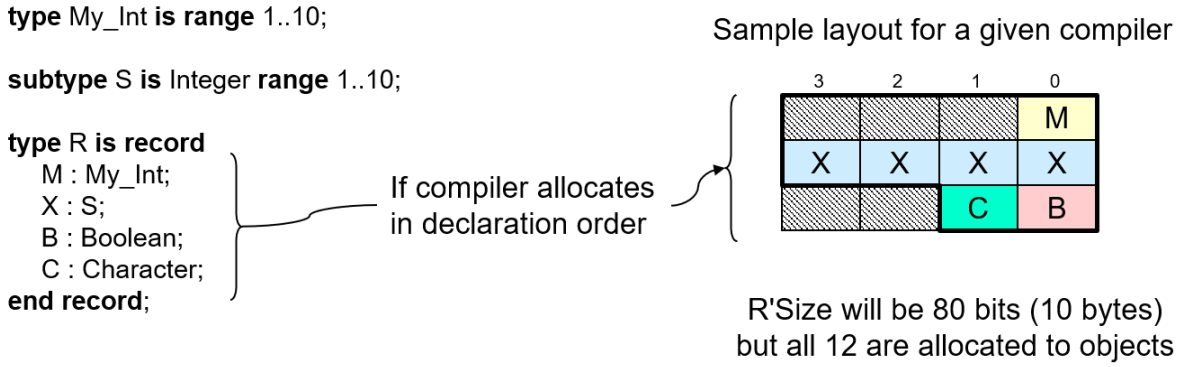
Both types have a contiguous representation, and the sequence of bytes can be a valid representation for the record type, although it certainly might not be valid. For example, if we change the discriminant from what the subtype specifies, we would have an invalid representation for that subtype.

So we can reasonably invoke an unchecked conversion between the array of bytes and the record type. However, as you can see in the code and as the compiler warns, we never assigned a value to the Sequence array object. The unchecked conversion from that Sequence of bytes includes the discriminant value, so it is very possible that we will get a discriminant value that is not 1K.

We can test that possibility by running the program. In the first call to `Put_Line`, the program prints the `Capacity` discriminant for the `Buffer` object. The compiler knew it was 1024, so it doesn't get the discriminant component from memory, it just directly prints 1024. However, we can force the compiler to query the discriminant in memory. We can pass `Buffer` to procedure `Show_Capacity`, which takes any `Bounded_Buffer`, and there query (print) the `Capacity` component under that different view. That works because the view inside the procedure `Show_Capacity` is as of `Bounded_Buffer`, in which the discriminant value is unknown at compile-time.

In the above examples, we are responsible for ensuring that the enumeration representation encoding and the record discriminant value are correct when converted from some other type. That's not too hard to recognize because we can literally see in the source code that there is something to be maintained by the conversions. However, there might be hidden implementation artifacts that we cannot see in the source code but that must be maintained nevertheless.

For example, the compiler's implementation for some record type might use dynamic memory allocations instead of directly representing some components. That would not appear in the source code. As a simpler example of invisible implementation issues, consider again our earlier record type:



As we discussed earlier, between the bytes that are allocated to the record components are some other bytes that are not used at all. As usual, the compiler must implement the language-defined equality operator for the record type. One way to implement that function would be to generate code that checks the equality for each component individually, ignoring any unused bytes. But suppose you have a large record type with many components. The code for checking record level equality will be extensive and inefficient. An alternative implementation for the compiler would be to use a "block compare" machine instruction to check the equality of the entire record at once, rather than component-by-component. That will be considerably more efficient because the block-compare instruction just compares the bits from one starting address to another ending address. But in that case the "unused" bytes are not skipped so the values within those bytes become significant. Comparison of those unused bytes will only work if their values are defined and assigned in each record object. Compilers that may use a block-comparison approach will, therefore, always set those unused bytes to a known value (typically zero). That is part of the valid representation for values of the type, and consequently must be maintained by our unchecked conversions. This being a non-scalar target type, failure to do so results in erroneous execution, i.e., undefined behavior. "There be dragons" as ancient maps of the unknown world once said.

As you can see, you should use unchecked conversions with considerable care and thought. Moreover, because unchecked programming is such a low-level activity, and has vendor-defined implementation issues, it is not only less portable than high-level coding, it is also less portable than other low-level programming. You will be well served if you limit the use of unchecked conversions overall. If your application code is performing unchecked conversions all over the code, something is very likely wrong, or at least very questionable. A well-designed Ada program should not need ubiquitous unchecked conversions.

That said, of course sometimes unchecked conversions are reasonable. But even then, it is better to isolate and hide their use via compile-time visibility controls. For example, instead of having clients invoke unchecked conversion instances many times, have a procedure that is invoked many times, and let the procedure body do the conversion. That way, the clients see a high-level specification of functionality, and, if the conversion needs to be changed later, there is only that one conversion usage (the procedure body) to change. This approach is really just another example of isolating and hiding code that might need to change in the future.

35.7 Data Validity

Our earlier demo program assigned an incorrect value via unchecked conversion into an object of an enumeration type that had non-standard representation values. The value assigned was not one of those representation values so the object had an invalid representation. Certain uses of an invalid representation value will be erroneous, and we saw that the effect of erroneous execution was unpredictable and unbounded.

That example was somewhat artificial, for the sake of illustration. But we might get an invalid value in a real-world application. For example, we could get an invalid value from a sensor. Hardware sensors are frequently unreliable and noisy. We might get an invalid value from a call to an imported function implemented in some other language. Whenever an assignment is aborted, the target of the assignment might not be fully assigned, leading to so-called "abnormal" values. Other causes are also possible. The problem is not unusual in low-level programming.

How do we avoid the resulting bounded errors and erroneous execution?

In addition to assignment statements, we can safely apply the `Valid` attribute to the object. This language-defined attribute returns a Boolean value indicating whether or not the object's value is a valid representation for the object's subtype. (More details in a moment.) There is no portable alternative to check an object's validity. Here's an example:

```
with Ada.Unchecked_Conversion;
with Ada.Text_IO;  use Ada.Text_IO;
with Interfaces;   use Interfaces;
with System;

procedure Demo_Validity_Check is

   type Toggle_Switch is (Off, On) with Size => 8;
   for Toggle_Switch use (Off => 1, On => 4);

   T1 : Toggle_Switch;

   function Sensor_Reading (Default : Toggle_Switch) return Toggle_Switch is

      function As_Toggle_Switch is new Ada.Unchecked_Conversion
        (Source => Unsigned_8, Target => Toggle_Switch);

      Result : Toggle_Switch;
      Sensor : Unsigned_8;
      --  for Sensor'Address use System'To_Address (...);

   begin
      Result := As_Toggle_Switch (Sensor);
      return (if Result'Valid then Result else Default);
   end Sensor_Reading;

begin
   T1 := Sensor_Reading (Default => Off); -- arbitrary
   Put_Line (T1'Image);
end Demo_Validity_Check;
```

In the above, `Sensor_Reading` is the high-level, functional API provided to clients. The function hides the use of the unchecked conversion, and also hides the memory-mapped hardware interface named `Sensor`. We've commented out the address clause since we don't really have a memory mapped device available. You can experiment with this program by changing the code to assign a value to `Sensor` (e.g., when it is declared). It is an unsigned 8-bit quantity so any value in the corresponding range would be allowed.

In addition to checking for a valid representation, thus preventing the bounded error, Valid

also checks that the object is not abnormal, so erroneous execution can be prevented too. (It also checks that any subtype predicate defined for the `Target` type is also satisfied, but that's a lesson for another day.)

However, the `Valid` attribute can be applied only to scalar objects. There is no language-defined attribute for checking objects of composite types. That's because it would be very hard to implement for some types, if not impossible. For example, given a typical run-time model, it is impossible to check the validity of an access value component. Therefore, you must individually check the validity of scalar record or array components.

At least, you would have to check them individually in standard Ada. GNAT defines another Boolean attribute, named `Valid_Scalars`, to check them all for us. This attribute returns **`True`** if the evaluation of `Valid` returns **`True`** for every scalar subcomponent of the enclosing composite type. It also returns **`True`** when there are no scalar subcomponents. See the GNAT RM for more information.

CHAPTER

THIRTYSIX

MULTI-LANGUAGE DEVELOPMENT

Software projects often involve more than one programming language. Typically that's because there is existing code that already does something we need done and, for that specific code, it doesn't make economic sense to redevelop it in some other language. Consider the rotor blade model in a high-fidelity helicopter simulation. Nobody touches the code for that model except for a few specialists, because the code is extraordinarily complex. (This complexity is unavoidable because a rotor blade's dynamic behavior is so complex. You can't even model it as one physical piece because the tip is traveling so much faster than the other end.) Complex and expensive models like that are a simulator company's crown jewels; their cost is meant to be amortized over as many projects as possible. Nobody would imagine redeveloping it simply because a new project is to be written in a different language.

Therefore, Ada includes extensive facilities to "import" foreign entities into Ada code, and to "export" Ada entities to code in foreign languages. The facilities are so useful that Ada has been used purely as "glue code" to allow code written in two other programming languages to be used together.

You've already seen an introduction to Ada and C code working together in the "*Interfacing*" *section of the Ada introductory course* (page 175). If you have not seen that material, be sure to see it first. We will cover some further details not already discussed there, and then go into the details of the facilities not covered elsewhere, but we assume you're familiar with it.

The Ada foreign language interfacing facilities include both "general" and "language-specific" capabilities. The "general" facilities are known as such because they are not tied to any specific language. These pragmas and aspects work with any of the supported foreign languages. In contrast, the "language-specific" interfacing facilities are collections of Ada declarations that provide Ada analogues for specific foreign language types and subprograms. For example, as you saw in that "Interfacing" section, there is a package with a number of declarations for C types, such as **`int`**, **`float`**, and **`double`**, as well as C "strings", with subprograms to convert back and forth between them and Ada's string type. Other languages are also supported, both by the Ada Standard and by vendor additions. You will frequently use both the "general" and the "language-specific" facilities together.

All these interfacing capabilities are defined in Annex B of the language standard. Note that Annex B is not a "Specialized Needs" annex, unlike some of the other annexes. The Specialized Needs annexes are wholly optional, whereas all Ada implementations must implement Annex B. However, some parts of Annex B are optional, so more precisely we should say that every implementation must support all the required features of Annex B. That comes down mainly to the package `Interfaces` (more on that package in a moment). However, if an implementation does implement any optional part of Annex B, it must be implemented as described by the standard, or with less functionality. An implementation cannot use the same name for some facility (aspect, etc.) but with different semantics. That's true of the Specialized Needs annexes too: not every part need be implemented, but any part that is implemented must conform to the standard. In practice, for Annex B, all implementations provide the required parts, but not all provide support for all the "language-specific" foreign

languages' interfaces. The vendors make a business decision for the optional parts, just as they do regarding the Specialized Needs annexes.

36.1 General Interfacing

In the "Interfacing" section of the Ada introductory course you saw that Ada defines aspects and pragmas for working with foreign languages. These aspects and pragmas are functionally interchangeable, and we will use whichever one of the two that is most convenient in our discussion. The pragmas are officially "obsolescent," but that merely means that a newer approach is available, in this case the corresponding aspects. You can use either one without concern for future support because language constructs that are obsolescent are not removed from the language. Any compiler that supports such constructs will almost certainly support them forever, for the sake of not invalidating existing customers' code. The pragmas have been in the language since Ada 95 so there's a lot of existing code using them. Changing the compiler isn't cost-free, after all, so why spend the money to potentially lose a customer? Likewise, a brand new compiler will also probably support them, for the sake of potentially gaining a customer.

The general interfacing facility consists of these aspects and pragmas, specifically `Import`, `Export`, and `Convention`. As you saw in the Ada Introduction course, `Import` brings a foreign entity into Ada code, `Export` does the opposite, and `Convention` supplies additional information and directives to the compiler. We will go into the details of each.

Regardless of whether the Ada code is importing or exporting some entity, there will be an Ada declaration for that entity. That declaration tells the compiler how the entity can be used, as usual. The interfacing aspects and pragmas are then applied to these Ada declarations.

If we are exporting, then the entity is implemented in Ada. For a subprogram that means there will also be a subprogram body matching the declaration, and the compiler will enforce that requirement as usual. In contrast, if we are importing a subprogram, then it is not implemented in Ada, and therefore there will be no corresponding subprogram body for the Ada declaration. The compiler would not allow it if we tried. In that case the `Import` is the subprogram's completion.

Subprograms often have a separate declaration. Sometimes that's required, for example when we want to include a subprogram as part of a package's API, but at other times it is optional. Remember that a subprogram body acts as a corresponding declaration when there is no separate declaration defined. Thus, either way, we have a subprogram declaration available for the interfacing aspects and/or pragmas.

For data that are imported or exported, we'll have the declaration of the object in Ada to which we can apply the necessary interfacing aspects/pragmas. But we will also have the types for these objects, and as you will see, the types can be part of interfacing too.

36.1.1 Aspect/Pragma Convention

As you saw in the *"Interfacing" section of the Ada introductory course* (page 175), when importing and exporting you'll also specify the "convention" for the entity in question. The pragmas for importing and exporting include a parameter for this purpose. When using the aspects, you'll specify the `Convention` aspect too.

For types, though, you will specify the `Convention` aspect/pragma alone, without `Import` or `Export`. In this case the convention specifies the layout for objects of that type, presumably a layout different than the Ada compiler would normally use. You would need to specify this other layout either because you're going to later declare and export an object of the type, or because you are going to declare an object of the type and pass it as a argument to an imported subprogram.
