For example, Ada specifies that multi-dimensional arrays are represented in memory in row-major order. In contrast, the Fortran standard specifies column-major order. If we want to define a type in Ada that can be used for passing parameters to Fortran routines, we need to specify that convention for the type. For example:

```
type Matrix is array (Rows, Columns) of Float
  with Convention => Fortran;
```

(Rows and Columns are user-defined discrete subtypes.)

As a result when we declare Matrix objects the Ada compiler will use the column-major layout. That makes it possible to pass objects of the type to imported Fortran subprograms because the formal parameter will also be of type Matrix. The imported Fortran routine will then see the parameter in memory as it expects to see it. So although you wouldn't need to import or export a type itself, you might very well import or export an object of the type, or pass it as a argument.

When Convention is applied to subprograms, a natural mistake is to think that we are specifying the programming language used to implement the subprogram. In reality, the convention indicates the subprogram calling convention, not the implementation language. The calling convention specifies how parameters are passed to and from subprogram calls, how result values for functions are returned, the order that parameters are pushed on the call stack, how dynamically-sized parameters are passed, and so on. Ordinarily these are matters you don't need to consider because you're working within a single convention automatically, in other words the one used by the Ada compiler you're using.

To illustrate that the convention is not the implementation language, consider a subprogram that we intend to import and call from Ada. This imported routine is implemented in assembly language, but, in addition, let's say it is written to use the same calling convention as the Ada compiler we are using for Ada code. Therefore, the calling convention would be Ada even though the implementation is in assembler.

```
procedure P (X : Integer) with
   ...
   Convention => Ada,
   ...
```

In the example above, Ada is known as a convention identifier, as is Fortran in the earlier example. Convention identifiers are defined by the Ada language standard, but also by Ada vendors.

The Ada standard defines two convention identifiers: Ada (the default), and Intrinsic. In addition, Annex B defines convention identifiers C, COBOL, and Fortran. Support for these Annex B conventions is optional.

GNAT supports the standard and Annex B conventions, as well as the following: Assembler, "C_PLUS_PLUS" (or CPP), Stdcall, WIN32, and a few others. C_PLUS_PLUS is the convention identifier required by the standard when C++ is supported. (Convention identifiers are actual identifiers, not strings, so they must obey the syntax rules for identifiers. "C++" would not be a valid identifier.) See the GNAT User Guide for those other GNAT-specific conventions.

Stdcall and WIN32 actually do specify a particular calling convention, but for those convention identifiers that are language names, how do we get from the name to a calling convention?

The ultimate requirement for any calling convention is compatibility with the Ada compiler we are using. Specifically, the Ada compiler must recognize what the calling convention specifies, and support importing and exporting subprograms with that convention applied.

For the Ada convention that's simple. There is no standard calling convention for Ada. Convention Ada simply means the calling convention applied by the Ada compiler we happen to be using. (We'll talk about Intrinsic shortly.)

So far, so good. But how to we get from those other language names to corresponding calling conventions? There is no standard calling convention for, say, C, any more than there is a standard calling convention for Ada.

In fact we don't get to the calling convention, at least not directly. What the language name in the convention identifier actually tells us is that, when that convention is supported, there is a compiler for that foreign language that uses a calling convention known to, and supported by, the Ada compiler we are using. The Ada compiler vendor defines which languages it supports, after all. For example, when supported, convention C means that there is a compatible C compiler known to the Ada compiler vendor. For GNAT you can guess which C compiler that might be.

It's actually pretty straightforward once you have the big picture. If the convention is supported, the Ada compiler in use knows of a compiler for that language with which it can work. Annex B just defines some convention identifiers for the sake of portability.

But suppose a given Ada compiler supports more than one vendor for a given programming language? In that case the Ada compiler would define and support multiple convention identifiers for the same programming language. Presumably these identifiers would be differentiated by the compiler vendors' names. Thus we might have available conventions `GNU_Fortran` and `Intel_Fortran` if both were supported. The `Fortran` convention identifier would then indicate the default vendor's compiler.

The `Intrinsic` calling convention represents subprograms that are "built in" to the compiler. When such a subprogram is called the compiler doesn't actually generate the code for an out-of-line call. Instead, the compiler emits the assembly code — often just a single instruction — corresponding to the intrinsic subprogram's name. There will be a separate declaration for the subprogram, but no actual subprogram body containing a sequence of statements. The compiler just knows what to emit in place of the call.

For example:

```
function Shift_Left
  (Value  : Unsigned_16;
   Amount : Natural)
  return Unsigned_16
    with ..., Convention => Intrinsic;
```

The effect is much like a subprogram call that is always in-lined, except that there's no body for the subprogram. In this example the compiler simply issues a shift-left instruction in assembly language.

You'll see the `Intrinsic` convention applied to many language-defined subprograms. For example:

```
generic
   type Source(<>) is limited private;
   type Target(<>) is limited private;
function Ada.Unchecked_Conversion(S : Source) return Target
   with ..., Convention => Intrinsic;
```

Thus when we call an instantiation of `Ada.Unchecked_Conversion` there is no actual call made to some subprogram. The compiler just treats the bits of S as a value of type `Target`.

Intrinsic subprograms are a good way to access interesting capabilities of the target hardware, without having to write the assembly language yourself (although we will show how to do that, later, directly in Ada). For example, some targets provide an instruction that atomically compares and swaps a value in memory. Ada 2022 just added a standard package for this, but before that we could use the following to access a gcc built-in:

```
-- Perform an atomic compare and swap: if the current value of
-- Destination.all is Comparand, then write New_Value into Destination.all.
```

(continues on next page)

(continued from previous page)

```
-- Returns an indication of whether the swap took place.

function Sync_Val_Compare_And_Swap_Bool_8
  (Destination : access Unsigned_8;
   Comparand   : Unsigned_8;
   New_Value   : Unsigned_8)
   return Boolean
with Convention => Intrinsic,
     ...
```

We would specify additional aspects beyond that of `Convention` but these have not yet been discussed. That's what the ellipses indicate in the various examples above.

36.1.2 Aspect/Pragma Import and Export

You've already seen these aspects in the Ada Introduction course, but for completeness: `Import` brings a foreign entity into Ada code, and `Export` makes an Ada entity available to foreign code. In practice, these entities consist of objects and subprograms, but the language doesn't impose many restrictions. It is up to the vendor to decide what makes sense for their specific target.

The aspects `Import` and `Export` are so-called Boolean aspects because their value is either **`True`** or **`False`**. For example:

```
Obj : Matrix with
   Export => True,
   ...
```

For any Boolean-valued aspect the default is **`True`** so you only need to give the value explicitly if that value is **`False`**. There would be no point in doing that in these two cases, of course. Hence we just give the aspect name:

```
Obj : Matrix with
   Export,
   ...
```

Recall that objects of some types are initialized automatically during the objects' elaboration, unless they are explicitly initialized as part of their declarations. Access types are like that, for example. Objects of these types are default initialized to **`null`** as part of ensuring that their values are always meaningful (absent unchecked conversion).

```
type Reference is access Integer;

Obj : Reference;
```

In the above the value of `Obj` is **`null`**, just as if we had explicitly set it that way.

But that initialization is a problem if we are importing an object of an access type. Presumably the value is set by the foreign code, so automatic initialization to null would overwrite the incoming value. Therefore, the language guarantees that implicit initialization won't be applied to imported objects.

```
type Reference is access Integer;

Obj : Reference with Import;
```

Now the value of `Obj` is whatever the foreign code sets it to, and is not, in other words, overwritten during elaboration of the declaration.

36.1.3 Aspect/Pragma External_Name and Link_Name

For an entity with a `True` `Import` or `Export` aspect, we can also specify a so-called external name or link name. These names are specified via aspects `External_Name` and `Link_Name` respectively.

An external name is a string value indicating the name for some entity as known by foreign language code. For an entity that Ada code imports, this is the name that the foreign code declares it to be. For an entity that Ada code exports, this is the name that the foreign code is told to use. This string value is exactly the name to be used, so if you misspell the name the link will fail. For example:

```
function Sync_Val_Compare_And_Swap_Bool_8
  (Destination : access Unsigned_8;
   Comparand   : Unsigned_8;
   New_Value   : Unsigned_8)
  return Boolean
with
  Import,
  Convention    => Intrinsic,
  External_Name => "__sync_bool_compare_and_swap_1";
```

The `External_Name` and `Link_Name` values are strings because the foreign unit names don't necessary follow the Ada rules for identifiers (the leading underscores in this case). Note that the ending digit in the name above is different from the declared Ada name.

Usually, the name of the imported or exported entity is precisely known and hence exactly specified by `External_Name`. Sometimes, however, a compilation system may have a linker "preprocessor" that augments the name actually used by the linkage step. For example, an implementation might always prepend "_" and then pass the result to the system linker. In that case we don't want to specify the exact name. Instead, we want to provide the "starting point" for the name modification. That's the purpose of the aspect `Link_Name`.

If you don't specify either `External_Name` or `Link_Name` the compilation system will choose one in some implementation-defined manner. Typically this would be the entity's defining name in the Ada declaration, or some simple transformation thereof. But usually we know the name exactly and so we use `External_Name` to give it.

As you can see, it really wouldn't make sense to specify both `External_Name` and `Link_Name` since the semantics of the two conflict. But if both are specified for some reason, the `External_Name` value is ignored.

Note that `Link_Name` cannot be specified for `Intrinsic` subprograms because there is no actual unit being linked into the executable, because intrinsics are built-in. In this case you must specify the `External_Name`.

Finally, because you will see a lot the pragma usage we should go into enough detail so that you know what you're looking at when you see them.

Pragma `Import` and pragma `Export` work almost like a subprogram call. Parameters cannot be omitted unless named notation is used. Reordering the parameters is not permitted, however, unlike subprogram calls.

The BNF syntax is as follows. We show Import, but Export has identical parameters:

```
pragma Import(
    [Convention =>] convention_identifier,
    [Entity =>] local_name
 [, [External_Name =>] external_name_string_expression]
 [, [Link_Name =>] link_name_string_expression]);
```

As you can see, the parameters correspond to the individual aspects `Convention`, `External_Name`, and `Link_Name`. When using aspects you don't need to say which Ada entity

you're applying the aspects to, because the aspects are part of the entity declaration syntax. In contrast, the pragma is distinct from the declaration so we must specify what's being imported or exported via the `Entity` parameter. That's the declared Ada name, in other words. Note that both the `External_Name` and `Link_Name` parameters are optional.

Here's that same built-in function, using the pragma to import it:

```
-- Perform an atomic compare and swap: if the current value of
-- Destination.all is Comparand, then write New_Value into Destination.all.
-- Returns an indication of whether the swap took place.

function Sync_Val_Compare_And_Swap_Bool_8
  (Destination : access Unsigned_8;
   Comparand   : Unsigned_8;
   New_Value   : Unsigned_8)
   return Boolean;

pragma Import (Intrinsic,
               Sync_Val_Compare_And_Swap_Bool_8,
               "__sync_bool_compare_and_swap_1");
```

The first pragma parameter is for the convention. The next parameter, the `Entity`, is the Ada unit's declared name. The last parameter is the external name. The compiler either knows what we are referencing by that external name or it will reject the pragma. As we mentioned before, the string value for the name is not required to match the Ada unit name.

You will see later that there are other convention identifiers as well, but we will wait for the *Specific Interfacing section* (page 1161) to introduce those.

36.1.4 Package Interfaces

Package `Interfaces` must be provided by all Ada implementations. The package is intended to provide types that reflect the actual numeric types provided by the target hardware. Of course, the standard has no way to know what hardware is involved, therefore the actual content is implementation-defined. But even so, it is possible to standardize the names for these types, and that is what the language standard does.

Specifically, the standard defines the format for the names for the hardware's signed and modular (unsigned) integer types, and for the floating-point types.

The signed integers have names of the form `Integer_n`, where *n* is the number of bits used by the machine-supported type. The type for an eight-bit signed integer would be named `Integer_8`, for example, and then `Integer_16` and so on for the larger types, for as many as the target machine supports.

Likewise, for the unsigned integers, the names are of the form `Unsigned_n`, with the same meaning for *n*. The colloquial eight-bit "byte" would be named `Unsigned_8`, with `Unsigned_16` for the 16-bit version, and so on, again for as many as the machine supports.

For floating-point types it is harder to talk about a format that is sufficiently common to standardize. The IEEE floating-point standard is well known and widely used, however, so if the machine does support the IEEE format that name can be used. Such types would be named `IEEE_Float_n`, again with the same meaning for *n*. Thus we might see declarations for types `IEEE_Float_32` and `IEEE_Float_64` and so on, for all the machine supported floating-point types.

In addition to these type declarations, for the unsigned integers only, there will be declarations for shift and rotate operations provided as intrinsic functions.

The resulting package declaration might look something like this:

```
package Interfaces is

   type Integer_8  is range -2 ** 7 .. 2 ** 7 - 1;

   type Integer_16 is range -2 ** 15 .. 2 ** 15 - 1;

   type Integer_32 is range -2 ** 31 .. 2 ** 31 - 1;

   ...

   type Unsigned_8 is mod 2 ** 8;

   function Shift_Left   (Value : Unsigned_8;  Amount : Natural) return Unsigned_8;
   function Shift_Right  (Value : Unsigned_8;  Amount : Natural) return Unsigned_8;
   function Rotate_Left  (Value : Unsigned_8;  Amount : Natural) return Unsigned_8;
   function Rotate_Right (Value : Unsigned_8;  Amount : Natural) return Unsigned_8;
   function Shift_Right_Arithmetic (Value : Unsigned_8;  Amount : Natural)
     return Unsigned_8;

   type Unsigned_16 is mod 2 ** 16;

   function Shift_Left  (Value : Unsigned_16;  Amount : Natural)
     return Unsigned_16;
   function Shift_Right (Value : Unsigned_16;  Amount : Natural)
     return Unsigned_16;
   ...

   type Unsigned_32 is mod 2 ** 32;

   function Shift_Left  (Value : Unsigned_32;  Amount : Natural)
     return Unsigned_32;
   function Shift_Right (Value : Unsigned_32;  Amount : Natural)
     return Unsigned_32;
   ...

   type IEEE_Float_32 is digits 6;
   type IEEE_Float_64 is digits 15;
   ...

end Interfaces;
```

As you can see, when you need to write code in terms of the hardware's numeric types, this package is a great resource. There's no need to declare your own `UInt32` type, for example, although of course you could, trivially:

```
type UInt32 is mod 2 ** 32;
```

But if you do, realize that you won't get the shift and rotate operations for your type. Those are only defined for the types in package `Interfaces`. If you do need to declare such a type, and you do want the additional shift/rotate operations, use inheritance:

```
type UInt32 is new Interfaces.Unsigned_32;
```

GNAT also defines a pragma, as an alternative to inheritance:

```
type UInt32 is mod 2 ** 32;
pragma Provide_Shift_Operators (UInt32);
```

The approach using inheritance is preferable because it is portable, all other things being equal.

One reason to make up your own unsigned type is that you need one that does not in fact

reflect the target hardware's numeric types. For example, a hardware device register might have gaps of bits that are currently not used by the device. Those gaps are frequently not the size of a type declared in package `Interfaces`. We might need an `Unsigned_3` type, for example. That's a reasonable thing to do.

36.2 Language-Specific Interfacing

In addition to the aspects and pragmas for importing and exporting entities that work with any language, Ada also defines standard language-specific facilities for interfacing with a set of foreign languages. The standard defines which languages, but vendors can (and do) expand the set.

Specifically, the "language-specific" interfacing facilities are collections of Ada declarations that provide Ada analogues for specific foreign language types and subprograms. Package `Interfaces` is the root package for a hierarchy of packages that organize these declarations by language, with one or more child packages per language.

Note that the declarations within package `Interfaces` are, by definition, compile-time visible to any child package in the subsystem. Thus whenever one of the language-specific packages needs to mention the machine types they are automatically available.

The standard defines specific support for foreign languages C, COBOL, and Fortran. Thus there are one or more child packages rooted at `Interfaces` that have those language names as their child package names: `Interfaces.C`, `Interfaces.COBOL`, and `Interfaces.Fortran`.

The material below will focus on C and, to a lesser extent, Fortran, ignoring altogether the support for COBOL. That's not because COBOL is unimportant. There is a lot of COBOL business software out there in use. Rather, we skip COBOL because it is not relevant to embedded systems. Similarly, although Fortran is extensively used, especially in high-performance computing, it is not used extensively in embedded systems. We will provide some information about the Fortran support but will not dwell on it.

Even though we do not consider C to be appropriate for large development projects, neither technically not economically, it has its place in small, low-criticality embedded systems. Ada developers can profit from existing device drivers and mature libraries coded in C, for example. Hence interfacing to it is important.

What about C++? Interfacing to C++ is tricky compared to C, because of the vendor-defined name-mangling, automatic invocations of constructors and destructors, exceptions, and so on. Generally, interfacing with C++ code can be facilitated by preventing much of those difficulties using the `extern "C" {... }` linkage-specification. Doing so then makes the bracketed C++ code look like C, so the C interfacing facilities then can be used.

36.2.1 Package Interfaces.C

The child package `Interfaces.C` supports interfacing with units written in the C programming language. Support is in the form of Ada constants and types, and some subprograms. The constants correspond to C's `limits.h` header file, and the Ada types correspond to types for C's `int`, `short`, `unsigned_short`, `unsigned_long`, `unsigned_char`, `size_t`, and so on. There is also support for converting Ada's type **`String`** to/from `char_array`, and similarly for type **`Wide_String`**, etc.

It's a large package so we will elide parts. The idea is to give you a feel for what's there. If you want the details, see either the Ada reference manual or bring up the source code in GNAT Studio.

```
package Interfaces.C is

   --  Declaration's based on C's <limits.h>

   CHAR_BIT  : constant := 8;
   SCHAR_MIN : constant := -128;
   SCHAR_MAX : constant := 127;
   UCHAR_MAX : constant := 255;

   --  Signed and Unsigned Integers. Note that in GNAT, we have ensured that
   --  the standard predefined Ada types correspond to the standard C types

   type int   is new Integer;
   type short is new Short_Integer;
   type long  is range -(2 ** (System.Parameters.long_bits - Integer'(1)))
     .. +(2 ** (System.Parameters.long_bits - Integer'(1))) - 1;
   type long_long is new Long_Long_Integer;

   type signed_char is range SCHAR_MIN .. SCHAR_MAX;
   for signed_char'Size use CHAR_BIT;

   type unsigned           is mod 2 ** int'Size;
   type unsigned_short     is mod 2 ** short'Size;
   type unsigned_long      is mod 2 ** long'Size;
   type unsigned_long_long is mod 2 ** long_long'Size;

   ...

   --  Floating-Point

   type C_float     is new Float;
   type double      is new Standard.Long_Float;
   type long_double is new Standard.Long_Long_Float;

   ----------------------------
   -- Characters and Strings --
   ----------------------------

   type char is new Character;

   nul : constant char := char'First;

   function To_C   (Item : Character) return char;
   function To_Ada (Item : char)      return Character;

   type char_array is array (size_t range <>) of aliased char;
   for char_array'Component_Size use CHAR_BIT;

   ...

end Interfaces.C;
```

The primary purpose of these types is for use in the formal parameters of Ada subprograms imported from C or exported to C. The various conversion functions can be called from within Ada to manipulate the actual parameters.

When writing the Ada subprogram declaration corresponding to a C function, an Ada procedure directly corresponds to a void function. An Ada procedure also corresponds to a C function if the return value is always to be ignored. Otherwise, the Ada declaration should be a function.

As we said, the types declared in this package can be used as the formal parameter types. That is the intended and recommended approach. However, some Ada types naturally

correspond to C types, and you might see them used instead of those from `Interfaces.C`. Type `int` is the C native integer type for the target, for example, as is type **`Integer`** in Ada. Likewise, C's type **`float`** and type Ada's **`Float`** are likely compatible. GNAT goes to some lengths to maintain compatibility with C, since the two gcc compilers share so much internal technology. Other vendors might not do so. Best practice is use the types in `Interfaces.C` for your parameters.

Of course, the types in `Interfaces.C` are not sufficient for all uses. You will often need to use user-defined types for the formal parameters, such as enumeration types and record types.

Ada enumeration types are compatible with C's enums but note that C requires enum values to be the size of an `int`, whereas Ada does not. The Ada compiler uses whatever sized machine type will support the specified number of enumeral values. It might therefore be smaller than an `int` but it might also be larger. (Declaring more enumeration values than would fit in an integer is unlikely except in tool-generated code, but it is possible.) For example:

```
type Small_Enum is (A, B, C);
```

If we printed the object size for `Small_Enum` we'd get 8 (on a typical machine with GNAT). Therefore, applying the aspect `Convention` to the Ada enumeration type declaration is a good idea:

```
type Small_Enum is (A, B, C) with Convention => C;
```

Now the object size will be 32, the same as `int`.

Speaking of enumeration types, note that Ada 2022 added a boolean type to `Interfaces.C` named `C_Bool` to match that of C99, so you should use it instead of Ada's **`Boolean`** type for formal parameters.

A simple Ada record type is compatible with a C struct, but remember that the Ada compiler is allowed to reorder the record components. The compiler would do that if it saw that the layout was inefficient, but the point here is that the compiler could do it silently. As a result, you should specify the record layout explicitly using a record representation clause, matching the layout of the C struct in question. Then there will be no question of the layouts matching. Once your record types get more complicated, for example with discriminants or tagged record extensions, things get tricky. Your best bet it to stick with the simple cases when interfacing to C.

Some types that you might think would correspond do not, at least not necessarily. For example, an Ada access type's value might be represented as a simple address, but it might not. In GNAT, an access value designating a value of some unconstrained array type (e.g., **`String`**) is comprised of two addresses, by default. One designates the characters and the other designates the bounds. You can override that with a pragma, but you must know to do so. For example, if we run the following program, we will see that the object size for the access type `Name` is twice the object size of `System.`**`Address`**:

```
with Ada.Text_IO;  use Ada.Text_IO;
with System;       use System;

procedure Demo is

   type Name is access String;

begin
   Put_Line (Address'Object_Size'Image);
   Put_Line (Name'Object_Size'Image);
end Demo;
```

Some Ada types simply have no corresponding type in C, such as record extensions, task

types, and protected types. You'll have to pass those as an "opaque" type, usually as an address. It isn't clear that a C function would know what to do with values of these types, but the general notion of passing an opaque type as an address is useful and not uncommon. Of course, that approach forgoes all type safety, so avoid it when possible.

In addition to the types for the formal parameters, you'll also need to know how parameters are passed to and from C functions. That affects the parameter profiles on both sides, Ada and C. The text in Annex B for `Interfaces.C` specifies how parameters are to be passed back and forth between Ada and C so that your subprogram declarations can be portable. That's the approach for each supported programming language, i.e., in the discussion of the corresponding child package under `Interfaces`.

The rules are expressed in terms of scalar types, "elementary" types, array types, and record types. Remember that scalar types are composed of the discrete types and the real types, so we're talking about the signed and modular integers, enumerations, floating-point, and the two kinds of fixed-point types. The "elementary" types consist of the scalars and access types. The rules are fairly intuitive, but throw in Ada's access parameters and parameter modes and some subtleties arise. We won't cover all the various rules but will explore some of the subtleties.

First, the easy cases: mode **in** scalar parameters, such as `int`, as simply passed by copy. Scalar parameters are passed by copy anyway in Ada so the mechanism aligns with C in a straightforward manner. A record type T is passed by reference, so on the C side we'd see `t*` where `t` is a C struct corresponding to T. A constrained array type in Ada with a component type T would correspond to a C formal parameter `t*` where `t` corresponds to T. An Ada access parameter **access** T corresponds on the C side to `t*` where `t` corresponds to T. And finally, a private type is passed according to the full definition of the type; the fact that it is private is just a matter of controlling the client view, being private doesn't affect how it is passed. There are other simple cases, such as access-to-subprogram types, but we can leave that to the Annex.

Now to the more complicated cases. First, some C ABIs (application binary interfaces) pass small structs by copy instead of by reference. That can make sense, in particular when the struct is small, say the size of an address or smaller. In that case there's no performance benefit to be had by passing a reference. When that situation applies, there is another convention we have not yet mentioned: `C_Pass_By_Copy`. As a result the record parameter will be passed by copy instead of the default, by reference (i.e., T rather than *T), as long as the mode is **in**. For example:

```
type R2 is record
   V : int;
end record
with Convention => C_Pass_By_Copy;

procedure F2 (P : R2) with
   Import,
   Convention => C,
   External_Name => "f2";
```

```
struct R2 {
   int V;
};

void f2 (R2 p);
```

On the C side we expect that p is passed by copy and indeed that is how we find it. That said, passing record values to structs by reference is the more common programmer choice. Like arrays, records are typically larger than an address. The point here is that the Ada code can be configured easily to match the C code.

Next, consider passing array values, both to and from C. When passing an array value to C, remember that Ada array types have bounds. Those bounds are either specified at compile

time when they are declared, or, for unconstrained array types, specified elsewhere, at run-time.

Array types are not first-class types in C, and C has no notion of unconstrained array types, or even of upper bounds. Therefore, passing an unconstrained array type value is interesting. One approach is to avoid them. Instead, declare a sufficiently large constrained array as a subtype of the unconstrained array type, and then just pass the actual upper bound you want, along with the array object itself.

```
type List is array (Integer range <>) of Interfaces.C.int;

subtype Constrained_List is List (1 .. 100);

procedure P (V : Constrained_List;  Size : Interfaces.C.int);
pragma Import (C, P, "p");

Obj : Constrained_List := (others => 42);  -- arbitrary values
```

With that, we can just pass the value by reference as usual on the C side:

```
void p (int* v, int size) {
  // whatever
}
```

But that's assuming we know how many array components are sufficient from the C code's point of view. In the example above we'll pass a value up to 100 to the `Size` parameter and hope that is sufficient.

Really, it would work to use the unconstrained array type as the formal parameter type instead:

```
type List is array (Integer range <>) of Interfaces.C.int;

procedure P (V : List;  Size : Interfaces.C.int);
pragma Import (C, P, "p");
```

The C function parameter profile wouldn't change. But why does this work? With values of unconstrained array types, the bounds are stored with the value. Typically they are stored just ahead of the first component, but it is implementation-defined. So why doesn't the above accidentally pass the bounds instead of the first array component itself? It works because we are guaranteed by the Ada language that passing an array will pass (the address of) the components, not the bounds, even for Ada unconstrained array types.

Now for the other direction: passing an array from C to Ada. Here the lack of bounds information on the C side really makes a difference. We can't just pass the array by itself because that would not include the bounds, unlike an Ada call to an Ada routine. In this case the approach is the similar to the first alternative described above, in which we declare a very large array and then pass the bounds explicitly:

```
type List is array (Natural) of int;
--  DO NOT DECLARE AN OBJECT OF THIS TYPE

procedure P (V : List; Size : Interfaces.C.int);
pragma Export (C, P, "p");

procedure P (V : List; Size : Interfaces.C.int) is
begin
   for J in 0 .. Size - 1 loop
      -- whatever
   end loop;
end P;
```

```
extern void p (int* v, int size);

int x [100];

p (x, 100);  // call to Ada routine, passing x
```

The fundamental idea is to declare an Ada type big enough to handle anything conceivably needed on the C side. Subtype **Natural** means `0 .. Integer'Last` so `List` is quite large indeed. Just be sure never to declare an object of that type. You'll probably run out of storage on an embedded target.

Earlier we said that it is the Ada type that determines how parameters are passed, and that scalars and elementary types are always passed by copy. For mode **in** that's simple, the copy to the C formal parameter is done and that's all there is to it. But suppose the mode is instead **out** or **in out**? In that case the presumably updated value must be returned to the caller, but C doesn't do that by copy. Here the compiler will come to the rescue and make it work, transparently. Specifically, we just declare the Ada subprogram's formal parameter type as usual, but on the C formal we use a reference. We're talking about scalar and elementary types so let's use `int` arbitrarily. We make the mode **in out** but **out** would also serve:

```
procedure P (Formal : in out int);
```

```
void function p (int* formal);
```

Now the compiler does its magic: it generates code to make a copy of the actual parameter, but it makes that copy into a hidden temporary object. Then, when calling the C routine, it passes the address of the hidden object, which corresponds to the reference expected on the C side. The C code updates the value of the temporary object via the reference, and then, on return, the compiler copies the value back from the temporary to the actual parameter. Problem solved, if a bit circuitous.

There are other aspects to interfacing with C, such as variadic functions that take a varying number of arguments, but you can find these elsewhere in the learn courses.

Next, we examine the child packages under `Interfaces.C`. These packages are not used as much as the parent `Interfaces.C` package so we will provide an overview. You can look up the contents within GNAT Studio or the Ada language standard.

36.2.2 Package Interfaces.C.Strings

Package `Interfaces.C` declares types and subprograms allowing an Ada program to allocate, reference, update, and free C-style strings. In particular, the private type `chars_ptr` corresponds to a common use of `char *` in C programs, and an object of this type can be passed to imported subprograms for which `char *` is the type of the argument of the C function. A subset of the package content is as follows:

```
package Interfaces.C.Strings is

   type chars_ptr is private;
   ...

   function New_Char_Array (Chars : in char_array) return chars_ptr;

   function New_String (Str : in String) return chars_ptr;

   procedure Free (Item : in out chars_ptr);
```

(continues on next page)

(continued from previous page)

```
   ...

   function Value (Item : in chars_ptr) return char_array;
   function Value (Item : in chars_ptr) return String;
   ...

   function Strlen (Item : in chars_ptr) return size_t;

   procedure Update (Item   : in chars_ptr;
                     Offset : in size_t;
                     Chars  : in char_array;
                     Check  : in Boolean := True);

   ...

end Interfaces.C.Strings;
```

Note that allocation might be via malloc, or via Ada's allocator **new**. In either case, the returned value is guaranteed to be compatible with char*. Deallocation must be via the supplied procedure Free.

An amusing point is that you can overwrite the end of the char array just like you can in C, via procedure Update. The Check parameter indicates whether overwriting past the end is checked. The default is **True**, unlike in C, but you could pass an explicit **False** if you felt the need to do something questionable.

36.2.3 Package Interfaces.C.Pointers

The generic package Interfaces.C.Pointers allows us to perform C-style operations on pointers. It includes an access type named Pointer, various Value functions that dereference a Pointer value and deliver the designated array, several pointer arithmetic operations, and "copy" procedures that copy the contents of a source pointer into the array designated by a destination pointer.

We won't go into the details further. See the Ada RM for more.

36.2.4 Package Interfaces.Fortran

Like Interfaces.C, package Interfaces.Fortran defines Ada types to be used when working with subprograms using the Fortran calling convention. These types have representations that are identical to the default representations of the Fortran intrinsic types *Integer*, *Real*, *Double Precision*, *Complex*, *Logical*, and *Character* in some supported Fortran implementation. And like the C package, the ways that parameters of various types are passed are also specified.

We leave the details to you to look up in the language standard, if you find them needed in an embedded application.

36.2.5 Machine Code Insertions (MCI)

When working close to the hardware, especially when interacting with a device, it is not uncommon for the hardware to require a very specific set of assembly language instructions to be generated. There are two ways to achieve this: the right way and the wrong way.

The wrong way is to experiment with the source code and compiler switches until you get the exact assembly code you need generated (assuming it is possible at all). But what happens when the next compiler release arrives with a new optimization? And abandon all hope if you go to a new compiler vendor. This approach is both labor-intensive and very brittle.

The right way is to express the precise assembly code sequence explicitly within the Ada source code. (That's true to any high level language, not just Ada.) Or you can call an intrinsic function, if there is one that does exactly what you need. We will focus on inserting it directly, in what is known as "machine code insertion", or "inline assembler."

As an example of the need for this capability, consider the GPIO (General Purpose I/O) port on an STM32 Arm microcontroller. Each port contains 16 individual I/O pins, each of which can be configured as an independent discrete input or output, or as a control line for a device, with pull-up or pull-down registers, with different clock speeds, and so on. Different on-chip devices use various collections of pins in ways specific to the devices, and require exclusive assignment of the pins. However, any given pin can be used by several different devices. For example, pin 11 on port A ("PA11") can be used by USART #1 as the clear-to-send ("CTS") line, or the CAN #1 bus Rx line, or Channel 4 of Timer 1, among others. Therefore, one of the responsibilities of the system designer is to allocate pins to devices, ensuring that they are allocated uniquely. It is difficult to debug the case in which a pin is accidentally configured for one device and then reconfigured for use with another device (assuming the first device remains in use). To help ensure exclusive allocations, every GPIO port on this Arm implementation has a way of locking the configuration of each I/O pin. That way, some other part of the software can't successfully change the configuration accidentally, for use with some other device. Even if the same configuration was to be used for another device, the lock prevents the accidental update so we find out about the unintentional sharing.

To lock a pin on a port requires a special sequence of reads and writes to a GPIO register for that port. A specific bit pattern is required during the reads and writes. The sequence and bit pattern is such that accidentally locking the pin is highly unlikely.

Once we see how to express assembly language sequences in general we will see how to get the necessary sequence to lock a port/pin pair. Unfortunately, although you can express exactly the code sequence required, such a sequence of assembly language instructions is clearly target hardware-specific. That means portability is inherently limited. Moreover, the syntax for expressing it varies with the vendor, even for the same target hardware. Being able to insert it at the Ada source level doesn't help with either portability issue. You should understand that the use-case for machine code insertion is for small, short sequences. Otherwise you would write the code in assembly language directly, in a separate file. That might obtain a degree of vendor independence, at least for the given target, but not necessarily. The use of inline assembler is intended for cases in which a separate file containing assembly language is not simpler.

With those caveats in place, let's first examine how to do it in general and then how to express it with GNAT specifically.

The right way to express an arbitrary sequence of one or more assembly language statements is to use so-called "code statements." A code statement is an Ada statement, but it is also a qualified expression of a type defined in package `System.Machine_Code`. The content of that package, and the details of code statements, are implementation-defined. Although that affects portability there really is no alternative because we are talking about machine instruction sets, which vary considerably and cannot be standardized at this level.

Package `System.Machine_Code` contains types whose values provide a way of expressing

assembly instructions. For example, let's say that there is a "HLT" instruction that halts the processor for some target. There is no other parameter required, just that op-code. Let's also say that one of the types in System.Machine_Code is for these "short" instructions consisting only of an op-code. The syntax for the type declaration would then allow the following code statement:

```
Short_Instruction'(Command => HLT);
```

Each of Short_Instruction, Command, and HLT are defined by the vendor in this hypothetical version of package System.Machine_Code. You can see why we say that it is both a statement (note the semicolon) and a qualified expression (note the apostrophe).

Code statements must appear in a subprogram body, after the **begin**. Only code statements are allowed in such a body, only use-clauses can be in the declarative part, and no exception handlers are allowed. The complete example would be as follows:

```
procedure Halt -- stops processor
   with Inline;

with System.Machine_Code; use System.Machine_Code;
procedure Halt is
begin
   Short_Instruction'(Command => HLT);
end Halt;
```

With that, to halt the processor the Ada code can simply call procedure Halt. When the optimizer is enabled there will be no code emitted to make the call, we'd simply see the halt instruction emitted directly in-line.

Package System.Machine_Code provides access to machine instructions but as we mentioned, the content is vendor-defined. In addition, the package itself is optional, but is required if Annex C, the Systems Programming Annex, is implemented by the vendor. In practice most all vendors provide this annex.

In GNAT, the content of System.Machine_Code looks something like this:

```
type Asm_Input_Operand  is ...
type Asm_Output_Operand is ...
type Asm_Input_Operand_List  is array (Integer range <>) of Asm_Input_Operand;
type Asm_Output_Operand_List is array (Integer range <>) of Asm_Output_Operand;

type Asm_Insn is private;

...

function Asm
   (Template : String;
    Outputs  : Asm_Output_Operand := No_Output_Operands;
    Inputs   : Asm_Input_Operand  := No_Input_Operands;
    Clobber  : String  := "";
    Volatile : Boolean := False) return Asm_Insn;
```

With this package content, the expression in a code statement is of type Asm_Insn, short for "assembly instruction." Multiple overloaded functions named Asm return values of that type.

The Template parameter in a string containing one or more assembly language instructions. These instructions are specific to the target machine. The parameter Outputs provides mappings from registers to source-level entities that are updated by the assembly statement(s). Inputs provides mappings from source-level entities to registers for inputs. Volatile, when True, tells the compiler not to optimize the call away, and Clobber tells the compiler which registers, or memory, if any, are altered by the instructions in Template.

("Clobber" is colloquial English for "destroy.") That last is important because the compiler was likely already using some of those registers so the compiler will need to restore them after the call.

We could say, for example, the following, taking all the defaults except for `Volatile`:

```
Asm ("nop", Volatile => True);
```

As you can imagine the full details are extensive, beyond the scope of this introduction. See the GNAT User Guide ("Inline Assembler") for all the gory details.

Now, back to our GPIO port/bin locking example. The port type is declared as follows:

```
type GPIO_Port is limited record
   ...
   LCKR : Word with Atomic;  -- lock register
   ...
end record with ...
```

We've elided all but the LCKR component representing the "lock register" within each port. We'd have a record representation clause to ensure the required layout but that's not important here. `Word` is an unsigned (modular) 32-bit integer type. One of the hardware requirements for accessing the lock register is that the entire register has to be read or written whenever any bits within it are accessed. The compiler must not, for example, write one of the bytes within the register in order to set or clear a bit within that part of the register. Therefore we mark the register as Atomic. If the compiler cannot honor that aspect the compilation will fail, so we would know there is a problem.

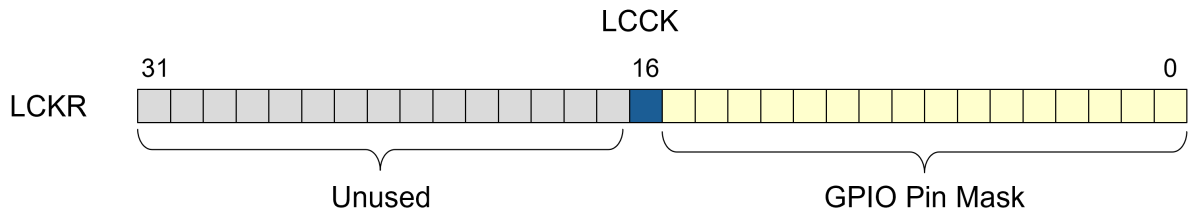
Per the ST Micro Reference Manual, the lock control bit is referred to as LCKK and is bit #16, i.e., the first in the upper half of the LCKR register word.

```
LCCK : constant Word := 16#0001_0000#;  -- the "lock control bit"
```

That bit is also known as the "Lock Key" (hence the abbreviation) because it is used to control the locking of port/pin configurations.

There are 16 GPIO pins per port, represented by the lower 16 bits of the register. Each one of these 16 bits corresponds to one of the 16 GPIO pins on a port. If any given bit reads as a 1 then the corresponding pin is locked.

Graphically that looks like this:



Therefore, the Ada types are:

```
type GPIO_Pin is
   (Pin_0, Pin_1, Pin_2,  Pin_3,  Pin_4,  Pin_5,  Pin_6,  Pin_7,
    Pin_8, Pin_9, Pin_10, Pin_11, Pin_12, Pin_13, Pin_14, Pin_15);

for GPIO_Pin use (Pin_0  => 16#0001#,
                  Pin_1  => 16#0002#,
                  Pin_2  => 16#0004#,
                  ...
                  Pin_15 => 16#8000#);
```

Note that we had to override the default enumeration representation so that each pin — each enumeral value — would occupy a single dedicated bit in the bit-mask.

With that in place, let's lock a pin. A specific sequence is required to set a pin's lock bit. The sequence writes and reads values from the port's LCKR register. Remember that this 32-bit register has 16 bits for the pin mask (0 .. 15), with bit #16 used as the "lock control bit".

1. write a 1 to the lock control bit with a 1 in the pin bit mask for the pin to be locked
2. write a 0 to the lock control bit with a 1 in the pin bit mask for the pin to be locked
3. do step 1 again
4. read the entire LCKR register
5. read the entire LCKR register again (optional)

Throughout the sequence the same value for the lower 16 bits of the word must be maintained (i.e., the pin mask), including when clearing the LCCK bit in the upper half.

If we wrote this in Ada it would look like this:

```
procedure Lock (Port : in out GPIO_Port;  Pin : GPIO_Pin) is
   Temp : Word with Volatile;
begin
   --  set the lock control bit and the pin bit, clear the others
   Temp := LCCK or Pin'Enum_Rep;
   --  write the lock and pin bits
   Port.LCKR := Temp;
   --  clear the lock bit in the upper half
   Port.LCKR := Pin'Enum_Rep;
   --  write the lock bit again
   Port.LCKR := Temp;
   --  read the lock bit
   Temp := Port.LCKR;
   --  read the lock bit again
   Temp := Port.LCKR;
end Lock;
```

`Pin'Enum_Rep` gives us the underlying value for the enumeration value. We cannot use `'Pos` because that attribute provides the logical position number within the enumerated values, and as such always increases consecutively. We need the underlying representation value that we specified explicitly.

The Ada procedure works, but only if the optimizer is enabled (which also precludes debugging). But even so, there is no guarantee that the required assembly language instruction sequence would be generated, especially one that maintains that required bit mask value on each access. A machine-code insertion is appropriate for all the reasons presented earlier:

```
procedure Lock (Port : in out GPIO_Port;
                Pin  :        GPIO_Pin) is
   use System.Machine_Code, ASCII, System;
begin
   Asm ("orr  r3, %1, #65536" & LF & HT &  -- 0) Temp := LCCK or Pin'Enum_Rep
        "str  r3, [%0, #28]"  & LF & HT &  -- 1) Port.LCKR := Temp
        "str  %1, [%0, #28]"  & LF & HT &  -- 2) Port.LCKR := Pin'Enum_Rep
        "str  r3, [%0, #28]"  & LF & HT &  -- 3) Port.LCKR := Temp
        "ldr  r3, [%0, #28]"  & LF & HT &  -- 4) Temp := Port.LCKR
        "ldr  r3, [%0, #28]"  & LF & HT,   -- 5) Temp := Port.LCKR
        Inputs => (Address'Asm_Input ("r", This'Address), -- %0
                   (GPIO_Pin'Asm_Input ("r", Pin))),       -- %1
        Volatile => True,
```

(continues on next page)

(continued from previous page)

```
        Clobber  => ("r3"));
end Lock;
```

We've combined the instructions into one `Asm` expression. As a result, we can use ASCII line-feed and horizontal tab characters to format the listing produced by the compiler so that each instruction is on a separate line and aligned with the previous instruction, as if we had written the sequence in assembly language directly. That enhances readability later, during examination of the compiler output to verify the required sequence was emitted.

In the above, `"%0"` is the first input, containing the address of the `Port` parameter. `"%1"` is the other input, the value of the `Pin` parameter. We're using register `r3` explicitly, as the "temporary" variable, so we tell the compiler that it has been "clobbered."

If we examine the assembly language output from compiling the file, we find the body of procedure `Lock` is as hoped:

```
ldr  r2, [r0, #4]
ldrh r1, [r0, #8]
.syntax unified
orr  r3, r1, #65536
str  r3, [r2, #28]
str  r1, [r2, #28]
str  r3, [r2, #28]
ldr  r3, [r2, #28]
ldr  r3, [r2, #28]
```

The first two statements load register 2 (r2) and register 1 (r1) with the subprogram parameters, i.e., the port and pin, respectively. Register 2 gets the starting address of the port record, in particular. (Offset #28 is the location of the LCKR register. The port is passed by reference so that address is actually that of the hardware device.)

We will have separately declared procedure `Lock` with inlining enabled, so whenever we call the procedure we will get the exact assembly language sequence required to lock the indicated pin on the given port, without any additional code for a procedure call.

Note that we get the calling convention right automatically, because the subprogram is not a foreign entity written in some other language (such as assembly language). It's an Ada subprogram with special content so the Ada convention applies as usual.

36.3 When Ada Is Not the Main Language

When multiple programming languages are involved, the main procedure might not be implemented in Ada. Maybe the bulk of the program is written in C, for example, and this C code calls some Ada routines that have been exported (with the C convention).

That means the Ada builder does not create the executable image's entry point. In fact the Ada main procedure is never the entry point for the final executable image, it's just where the application code begins, like the C `main` function. There are setup and initialization steps that must happen before any program can execute on a target, and the entry point code is responsible for this functionality. For example, on a bare machine target, the hardware must be initialized, the trap vectors installed, the segments initialized, and so on. On a target running an operating system, the OS is responsible for that initialization but there will be OS-specific initialization steps too. For example, if command-line arguments are supported these may be gathered. All this initialization code is generated by the builder, regardless of the language, followed by a call to the main routine.

Some of the initialization is specific to Ada programming, and must occur before any calls occur to the exported Ada routines. In particular, the entry point code emitted by the Ada builder initializes the Ada run-time system and calls all the elaboration routines for the

library units in the application code. Only then does the emitted code invoke the Ada main. If the Ada builder is not going to create the executable it has no chance to emit the code to do that prior initialization. A foreign language builder will not emit such code, so we have a problem.

You could learn enough about how the foreign builder works, and how your Ada builder works, to create a work-around. You could learn what the Ada builder would emit, in other words, and ensure those routines are called manually, either directly or by augmenting the builder scripts (assuming that's possible). But the work-around would be labor-intensive and not robust to changes by the tool vendors. It would be an ugly hack, in other words.

That work-around would not be portable either. The Ada standard can't address hardware- or OS-specific initialization, but it can standardize the name for a routine to do the Ada-specific initialization. Specifically, procedure `adainit` initializes the Ada application code and the Ada run-time library. Similarly, one might need to shut down the Ada code when no further calls will be made to the exported Ada routines. Procedure `adafinal` performs this shut-down functionality. Neither procedure has parameters.

The main function in the other language is intended to import these routines and manually call them each exactly once. `adainit` must be called prior to any calls to the Ada code, and `adafinal` is to be called after all the calls to the Ada code.

For example:

```
#include "stdio.h"

extern int checksum (char *input, int count);

extern void adainit (void);
extern void adafinal (void);

int main (int argc, char *argv[]) {
   char * Str = "Hello World!";
   int sum;
   adainit ();
   sum = checksum (Str, strlen (Str));
   adafinal ();
   printf ("checksum for '%s' is %d", Str, sum);
   return 0;
}
```

In the above, we have an Ada routine to compute a checksum, called by a C main function. Therefore, we use "extern" to tell the C compiler that the "checksum" function is defined elsewhere, i.e., in the Ada routine. Likewise, we tell the compiler that functions `adainit` and `adafinal` are defined elsewhere. The call to `adainit` is made before the call to any Ada code, thus all the elaboration code is guaranteed to happen before `checksum` needs it. Once the Ada code is not needed, the call to `adafinal` can be made.

Both `adainit` and `adafinal` have no effect after the first invocation. That means you cannot structure your foreign code to iteratively call the two routines whenever you want to invoke some Ada code. In practice you just call them once in the main and be done with it.

CHAPTER

THIRTYSEVEN

INTERACTING WITH DEVICES

Interacting with hardware devices is one of the more frequent activities in embedded systems programming. It is also one of the most enjoyable because you can make something happen in the physical world. There's a reason that making an LED blink is the "hello world" of embedded programming. Not only is it easy to do, it is surprisingly satisfying. I suspect that even the developers of "Full Authority Digital Engine Controllers" (FADEC) — the computers that are in complete, total control of commercial airline engines — have fond memories of making an LED blink early in their careers. And of course a blinking LED is a good way to indicate application status, especially if off-board I/O is limited, which is often the case.

Working at the device register level can be error prone and relatively slow, in terms of source-lines-of-code (SLOC) produced. That's partly because the hardware is in some cases complicated, and partly because of the way the software is written. Using bit masks for setting and clearing bits is not a readable approach, comparatively speaking. There's just not enough information transmitted to the reader. It might be clear enough when written, but will you see it that way months later? Readability is important because programs are read many more times than they are written. Also, an unreadable program is more difficult to maintain, and maintenance is where most money is spent in long-lived applications. Comments can help, until they are out of date. Then they are an active hindrance.

For example, what do you think the following code does? This is real code, where `temp` and `temp2` are unsigned 32-bit integers:

```
temp = ((uint32_t)(GPIO_AF) <<
          ((uint32_t)((uint32_t)GPIO_PinSource & (uint32_t)0x07) * 4));
GPIOx->AFR[GPIO_PinSource >> 0x03] &= ~((uint32_t)0xF <<
          ((uint32_t)((uint32_t)GPIO_PinSource & (uint32_t)0x07) * 4));
temp_2 = GPIOx->AFR[GPIO_PinSource >> 0x03] | temp;
GPIOx->AFR[GPIO_PinSource >> 0x03] = temp_2;
```

That's unfair to ask, absent any context. The code configures a general purpose I/O (GPIO) pin on an Arm microcontroller for one of the "alternate functions". `GPIOx` is a pointer to a GPIO port, `GPIO_PinSource` is a GPIO pin number, and `GPIO_AF` is the alternate function number. But let's say you knew that. Is the code correct? The longer it takes to know, the less productive you are.

The fact that the code above is in C is beside the point. If we wrote it the same way in Ada it would be equally opaque, if not more so. There are simpler approaches. Judicious use of record and array types is one. We'll say more about that later, but the underlying idea is to let the compiler do as much work for us as possible. For example, the data structures used in the code above require explicit shifting whenever they are accessed. If we can avoid that at the source code level — by having the compiler do it for us — we will have simplified the code considerably. Furthermore, letting the compiler do the work for us makes the code more maintainable (which is where the money is). For example, if the code does the shifting explicitly and the data structures are changed, we'll have to change the number of bits to shift left or right. Constants will help there, but we still have to remember to change them;

the compiler won't complain if we forget. In contrast, if we let the compiler do this shifting for us, the amounts to shift will be changed automatically.

Some devices are very simple. In these cases the application may interact directly with the device without unduly affecting productivity. For example, there was a board that had a user-accessible rotary switch with sixteen distinct positions. Users could set the switch to whatever the application code required, e.g., to indicate some configuration information. The entire software interface to this device consisted of a single read-only 8-bit byte in memory. That's all there was to it: you read the memory and thus got the numeric setting of the switch.

More complex devices, however, usually rely on software abstraction to deal with the complexity. Just as abstraction is a fundamental way to combat complexity in software, abstraction also can be used to combat the complexity of driving sophisticated hardware. The abstraction is presented to users by a software "device driver" that exists as a layer between the application code and the hardware device. The layer hides the gory details of the hardware manipulation behind subprograms, types, and parameters.

We say that the device driver layer is an abstraction because, at the least, the names of the procedures and functions indicate what they do, so at the call site you can tell *what* is being done. That's the point of abstraction: it allows us to focus on what, rather than how. Consider that GPIO pin configuration code block again. Instead of writing that block every time we need to configure the alternate function for a pin, suppose we called a function:

```
GPIO_PinAFConfig(USARTx_TX_GPIO_PORT, USARTx_TX_SOURCE, USARTx_TX_AF);
```

The `GPIO_PinAFConfig` function is part of the GPIO device driver provided by the STM32 Standard Peripherals Library (SPL). Even though that's not the best function name conceivable, calls to the function will be far more readable than the code of the body, and we only have to make sure the function implementation is correct once. And assuming the device drivers' subprograms can be inlined, the subprogram call imposes no performance penalty.

Note the first parameter to the call above: `USARTx_TX_GPIO_PORT`. There are multiple GPIO ports on an Arm implementation; the vendor decides how many. In this case one of them has been connected to a USART (Universal Synchronous Asynchronous Receiver Transmitter), an external device for sending and receiving serial data. When there are multiple devices, good software engineering suggests that the device driver present a given device as one of a type. That's what an "abstract data type" (ADT) provides for software and so the device driver applies the same design. An ADT is essentially a class, in class-oriented languages. In Ada, an ADT is represented as a private type declared in a package, along with subprograms that take the type as a parameter.

The Ada Drivers Library (ADL) provided by AdaCore and the Ada community uses this design to supply Ada drivers for the timers, I2C, A/D and D/A converters, and other devices common to microcontrollers. Multiple devices are presented as instances of abstract data types. A variety of development platforms from various vendors are supported, including the STM32 series boards. The library is available on GitHub for both non-proprietary and commercial use here: https://github.com/AdaCore/Ada_Drivers_Library. We are going to use some of these drivers as illustrations in the following sections.

37.1 Non-Memory-Mapped Devices

Some devices are connected to the processor on a dedicated bus that is separate from the memory bus. The Intel processors, for example, used to have (and may still have) instructions for sending and receiving data on this bus. These are the "in" and "out" instructions, and their data-length specific variants.

The original version of Ada defined a package named `Low_Level_IO` for such architectures, but there were very few implementations (maybe just one, known to support the Intel processors). As a result, the package was actually removed from the language standard. Implementations could still support the package, it just wouldn't be a standard package. That's different from constructs that are marked as "obsolescent" by the standard, e.g., the pragmas replaced by aspects, among other things. Obsolescent constructs are still part of the standard.

If a given target machine has such I/O instructions for the device bus, these can be invoked in Ada via machine-code insertions. For example:

```
procedure Send_Control (Device : Port;  Data : Unsigned_16) is
   pragma Suppress (All_Checks);
begin
   asm ("outw %1, (%0)",
        Inputs  => (Port'Asm_Input("dx",Device),
                    Unsigned_16'Asm_Input("ax",Data)),
        Clobber => "ax, dx");
end Send_Control;

procedure Receive_Control (Device : Port;  Data : out Unsigned_16) is
   pragma Suppress (All_Checks);
begin
   asm ("inw (%1), %0",
        Inputs   => (Port'Asm_Input("dx",Device)),
        Outputs  => (Unsigned_16'Asm_Output("=ax",Data)),
        Clobber  => "ax, dx",
        Volatile => True);
end Receive_Control;
```

Applications could use these subprograms to set the frequency of the Intel PC tone generator, for example, and to turn it on and off. (You can't do that any more in application code because modern operating systems don't give applications direct access to the hardware, at least not by default.)

Although the `Low_Level_IO` package is no longer part of the language, you can write this sort of thing yourself, or vendors can do it. That's possible because the Systems Programming Annex, when implemented, guarantees fully effective use of machine-code inserts. That means you can express anything the compiler could emit. The guarantee is important because otherwise the compiler might "get in the way." For example, absent the guarantee, the compiler would be allowed to insert additional assembly language statements in between yours. That can be a real problem, depending on what your statements do. For instance, if your MCI assembly statements do something and then check a resulting condition code, such as the overflow flag, those interleaved compiler-injected statements might clear that condition code before your code can check it. Fortunately, the annex guarantees that sort of thing cannot happen.

37.2 Memory-Mapped Devices

In *another earlier chapter* (page 1117), we said that we could query the address of some object, and we also showed how to use that result to specify the address of some other object. We used that capability to create an "overlay," in which two objects are used to refer to the same memory locations. As we indicated in that discussion, you would not use the same type for each object — the point, after all, is to provide a view of the shared underlying memory cells that is not already available otherwise. Each distinct type would provide a distinct view of the memory values, that is, a set of operations providing some required functionality.

For example, here's an overlay composed of a 32-bit signed integer object and a 32-bit array object:

```
type Bits32 is array (0 .. 31) of Boolean
   with Component_Size => 1;

X : aliased Integer_32;
Y : Bits32 with Address => X'Address;
```

Because one view is as an integer and the other as an array, we can access that memory using the two different views' operations. Using the view as an array object (Y) we can access individual bits of the memory shared with X. Using the view as an integer (X), we can do arithmetic on the contents of that memory. (We could have used an unsigned integer instead of the signed type, and thereby gained the bit-oriented operations, but that's not the point.)

Very often, though, there is only one Ada object that we place at some specific address. That's because the Ada object is meant to be the software interface to some memory-mapped hardware device. In this scenario we don't have two overlaid Ada objects, we just have one. The other "object" is the hardware device mapped to that starting address. Since they are at the same memory location(s), accessing the Ada object accesses the hardware device.

For a real-world but nonetheless simple example, recall that example of a rotary switch on the front of our embedded computer that we mentioned in the introduction. This switch allows humans to provide some very simple input to the software running on the computer.

```
Rotary_Switch : Unsigned_8 with
  Address => System.Storage_Elements.To_Address (16#FFC0_0801#);
```

We declare the object and also specify the address, but not by querying some entity. We already know the address from the hardware documentation. But we cannot simply use an integer address literal from that documentation because type `System.Address` is almost always a private type. We need a way to compose an `Address` value from an integer value. The package `System.Storage_Elements` defines an integer representation for `Address` values, among other useful things, and a way to convert those integer values to `Address` values. The function `To_Address` does that conversion.

As a result, in the Ada code, reading the value of the variable `Rotary_Switch` reads the number on the actual hardware switch.

Note that if you specify the wrong address, it is hard to say what happens. Likewise, it is an error for an address clause to disobey the object's alignment. The error cannot be detected at compile time, in general, because the address is not necessarily known at compile time. There's no requirement for a run-time check for the sake of efficiency, since efficiency seems paramount here. Consequently, this misuse of address clauses is just like any other misuse of address clauses — execution of the code is erroneous, meaning all bets are off. You need to know what you're doing.

What about writing to the variable? Is that meaningful? In this particular example, no. It

is effectively read-only memory. But for some other device it very well could be meaningful, certainly. It depends on the hardware. But in this case, assigning a value to the `Rotary_Switch` variable would have no effect, which could be confusing to programmers. It looks like a variable, after all. We wouldn't declare it as a constant because the human user could rotate the switch, resulting in a different value read. Therefore, we would hide the Ada variable behind a function, precluding the entire issue. Clients of the function can then use it for whatever purpose they require, e.g., as the unique identifier for a computer in a rack.

Let's talk more about the type we use to represent a memory-mapped device. As we said, that type defines the view we have for the object, and hence the operations we have available for accessing the underlying mapped device.

We choose the type for the representative Ada variable based on the interface of the hardware mapped to the memory. If the interface is a single monolithic register, for example, then an integer (signed or unsigned) of the necessary size will suffice. But suppose the interface is several bytes wide, and some of the bytes have different purposes from the others? In that case, a record type is the obvious solution, with distinct record components dedicated to the different parts of the hardware interface. We could use individual bits too, of course, if that's what the hardware does. Ada is particularly good at this fine-degree of representation because record components of any types can be specified in the layout, down to the bit level, within the record.

In addition, we might want to apply more than one type, at any one time, to a given memory-mapped device. Doing so allows the client code some flexibility, or it might facilitate an internal implementation. For example, the STM32 boards from ST Microelectronics include a 96-bit device unique identifier on each board. The identifier starts at a fixed memory location. In this example we provide two different views — types — for the value. One type provides the identifier as a String containing twelve characters, whereas another type provides the value as an array of three 32-bit unsigned words (i.e., 12 bytes). The two types are applied by two overloaded functions that are distinguished by their return type:

```
package STM32.Device_Id is

   subtype Device_Id_Image is String (1 .. 12);

   function Unique_Id return Device_Id_Image;

   type Device_Id_Tuple is array (1 .. 3) of UInt32
     with Component_Size => 32;

   function Unique_Id return Device_Id_Tuple;

end STM32.Device_Id;
```

The subtype `Device_Id_Image` is the view of the 96-bits as an array of twelve 8-bit characters. (Using type **`String`** here isn't essential. We could have defined an array of bytes instead of **`Character`**.) Similarly, subtype `Device_Id_Tuple` is the view of the 96-bits as an array of three 32-bit unsigned integers. Clients can then choose how they want to view the unique id by choosing which function to call.

In the package body we implement the functions as two ways to access the same shared memory:

```
with System;

package body STM32.Device_Id is

   ID_Address : constant System.Address := System'To_Address (16#1FFF_7A10#);

   function Unique_Id return Device_Id_Image is
```

(continues on next page)

(continued from previous page)

```
      Result : Device_Id_Image with Address => ID_Address, Import;
   begin
      return Result;
   end Unique_Id;

   function Unique_Id return Device_Id_Tuple is
      Result : Device_Id_Tuple with Address => ID_Address, Import;
   begin
      return Result;
   end Unique_Id;

end STM32.Device_Id;
```

The GNAT-defined attribute `System'To_Address` in the declaration of `ID_Address` is the same as the function `System.Storage_Elements.To_Address` except that, if the argument is static, the function result is static. This means that such an expression can be used in contexts (e.g., preelaborable packages) which require a static expression and where the function call could not be used (because the function call is always non-static, even if its argument is static).

The only difference in the bodies is the return type and matching type for the local `Result` variable. Both functions read from the same location in memory.

Earlier we indicated that the bit-pattern implementation of the GPIO function could be expressed differently, resulting in more readable, therefore maintainable, code. The fact that the code is in C is irrelevant; the same approach in Ada would not be any better. Here's the complete code for the function body:

```
void GPIO_PinAFConfig(GPIO_TypeDef *GPIOx,
                      uint16_t      GPIO_PinSource,
                      uint8_t       GPIO_AF)
{
  uint32_t temp = 0x00;
  uint32_t temp_2 = 0x00;

  /* Check the parameters */
  assert_param(IS_GPIO_ALL_PERIPH(GPIOx));
  assert_param(IS_GPIO_PIN_SOURCE(GPIO_PinSource));
  assert_param(IS_GPIO_AF(GPIO_AF));

  temp = ((uint32_t)(GPIO_AF) <<
            ((uint32_t)((uint32_t)GPIO_PinSource & (uint32_t)0x07) * 4));
  GPIOx->AFR[GPIO_PinSource >> 0x03] &= ~((uint32_t)0xF <<
            ((uint32_t)((uint32_t)GPIO_PinSource & (uint32_t)0x07) * 4));
  temp_2 = GPIOx->AFR[GPIO_PinSource >> 0x03] | temp;
  GPIOx->AFR[GPIO_PinSource >> 0x03] = temp_2;
}
```

The problem, other than the magic numbers (some named constants would have helped), is that the code is doing nearly all the work instead of off-loading it to the compiler. Partly that's because in C we cannot declare a numeric type representing a 4-bit quantity, so everything is done in terms of machine units, in this case 32-bit unsigned integers.

Why do we need 4-bit values? At the hardware level, each memory-mapped GPIO port has a sequence of 16 4-bit quantities, one for each of the 16 pins on the port. Those 4-bit quantities specify the "alternate functions" that the pin can take on, if needed. The alternate functions allow a given pin to do more than act as a single discrete I/O pin. For example, a pin could be connected to the incoming lines of a USART. We use the configuration routine to apply the specific 4-bit code representing the alternate function required for our application.

These 16 4-bit alternate function fields are contiguous in the register (hence memory) so we can represent them as an array with a total size of 64-bits (i.e., 16 times 4). In the C

version this array has two components of type **uint32_t** so it must compute where the corresponding 4-bit value for the pin is located within those two words. In contrast, the Ada version of the array has components of the 4-bit type, rather than two 32-bit components, and simply uses the pin number as the index. The resulting Ada procedure body is extremely simple:

```
procedure Configure_Alternate_Function
  (Port : in out GPIO_Port;
   Pin  : GPIO_Pin;
   AF   : GPIO_Alternate_Function_Code)
is
begin
   Port.AFR (Pin) := AF;
end Configure_Alternate_Function;
```

In the Ada version, AFR is a component within the GPIO_Port record type, much like in the C code's struct. However, Ada allows us to declare a much more descriptive set of types, and it is these types that allows the developer to off-load the work to the compiler.

First, in Ada we can declare a 4-bit numeric type:

```
type Bits_4 is mod 2**4 with Size => 4;
```

The Bits_4 type was already globally defined elsewhere so we just derive our 4-bit "alternate function code" type from it. Doing so allows the compiler to enforce simple strong typing so that the two value spaces are not accidentally mixed. This approach also increases understanding for the reader:

```
type GPIO_Alternate_Function_Code is new Bits_4;
--  We cannot use an enumeration type because there are duplicate binary
--  values
```

Hence type GPIO_Alternate_Function_Code is a copy of Bits_4 in terms of operations and values, but is not the same type as Bits_4 so the compiler will keep them separate for us.

We can then use that type as the array component type for the representation of the AFR:

```
type Alternate_Function_Fields is
  array (GPIO_Pin) of GPIO_Alternate_Function_Code
  with Component_Size => 4, Size => 64;  -- both in units of bits
```

Note that we can use the GPIO Pin parameter directly as the index into the array type, obviating any need to massage the Pin value in the procedure. That's possible because the type GPIO_Pin is an enumeration type:

```
type GPIO_Pin is
  (Pin_0, Pin_1, Pin_2,  Pin_3,  Pin_4,  Pin_5,  Pin_6,  Pin_7,
   Pin_8, Pin_9, Pin_10, Pin_11, Pin_12, Pin_13, Pin_14, Pin_15);

for GPIO_Pin use
  (Pin_0  => 16#0001#,
   Pin_1  => 16#0002#,
   Pin_2  => 16#0004#,
   Pin_3  => 16#0008#,
   Pin_4  => 16#0010#,
   Pin_5  => 16#0020#,
   Pin_6  => 16#0040#,
   Pin_7  => 16#0080#,
   Pin_8  => 16#0100#,
   Pin_9  => 16#0200#,
   Pin_10 => 16#0400#,
```

(continues on next page)

(continued from previous page)

```
   Pin_11 => 16#0800#,
   Pin_12 => 16#1000#,
   Pin_13 => 16#2000#,
   Pin_14 => 16#4000#,
   Pin_15 => 16#8000#);
```

In the hardware, the GPIO_Pin values don't start at zero and monotonically increase. Instead, the values are bit patterns, where one bit within each value is used. The enumeration representation clause allows us to express that representation.

Type `Alternate_Function_Fields` is then used to declare the AFR record component in the `GPIO_Port` record type:

```
type GPIO_Port is limited record
   MODER      : Pin_Modes_Register;
   OTYPER     : Output_Types_Register;
   Reserved_1 : Half_Word;
   OSPEEDR    : Output_Speeds_Register;
   PUPDR      : Resistors_Register;
   IDR        : Half_Word;       --  input data register
   Reserved_2 : Half_Word;
   ODR        : Half_Word;       --  output data register
   Reserved_3 : Half_Word;
   BSRR_Set   : Half_Word;       --  bit set register
   BSRR_Reset : Half_Word;       --  bit reset register
   LCKR       : Word with Atomic;
   AFR        : Alternate_Function_Fields;
   Unused     : Unaccessed_Gap;
end record with
  Size => 16#400# * 8;

for GPIO_Port use record
   MODER      at 0  range 0 .. 31;
   OTYPER     at 4  range 0 .. 15;
   Reserved_1 at 6  range 0 .. 15;
   OSPEEDR    at 8  range 0 .. 31;
   PUPDR      at 12 range 0 .. 31;
   IDR        at 16 range 0 .. 15;
   Reserved_2 at 18 range 0 .. 15;
   ODR        at 20 range 0 .. 15;
   Reserved_3 at 22 range 0 .. 15;
   BSRR_Set   at 24 range 0 .. 15;
   BSRR_Reset at 26 range 0 .. 15;
   LCKR       at 28 range 0 .. 31;
   AFR        at 32 range 0 .. 63;
   Unused     at 40 range 0 .. 7871;
end record;
```

These declarations define a record type that matches the content and layout of the STM32 GPIO Port memory-mapped device.

Let's compare the two procedure implementations again. Here they are, for convenience:

```
void GPIO_PinAFConfig(GPIO_TypeDef *GPIOx,
                      uint16_t      GPIO_PinSource,
                      uint8_t       GPIO_AF)
{
  uint32_t temp = 0x00;
  uint32_t temp_2 = 0x00;

  /* Check the parameters */
```

(continues on next page)

(continued from previous page)

```
  assert_param(IS_GPIO_ALL_PERIPH(GPIOx));
  assert_param(IS_GPIO_PIN_SOURCE(GPIO_PinSource));
  assert_param(IS_GPIO_AF(GPIO_AF));

  temp = ((uint32_t)(GPIO_AF) <<
            ((uint32_t)((uint32_t)GPIO_PinSource & (uint32_t)0x07) * 4));
  GPIOx->AFR[GPIO_PinSource >> 0x03] &= ~((uint32_t)0xF <<
            ((uint32_t)((uint32_t)GPIO_PinSource & (uint32_t)0x07) * 4));
  temp_2 = GPIOx->AFR[GPIO_PinSource >> 0x03] | temp;
  GPIOx->AFR[GPIO_PinSource >> 0x03] = temp_2;
}
```

```
procedure Configure_Alternate_Function
  (Port : in out GPIO_Port;
   Pin  : GPIO_Pin;
   AF   : GPIO_Alternate_Function_Code)
is
begin
   Port.AFR (Pin) := AF;
end Configure_Alternate_Function;
```

Which one is correct? Both. But clearly, the Ada version is far simpler, so much so that it is immediately obvious that it is correct. Not so for the coding approach used in the C version, comparatively speaking. It is true that the Ada version required a couple more type declarations, but those make the procedure body far simpler. That resulting simplicity is a reflection of the balance between data structures and executable statements that we should always try to achieve. Ada just makes that easier to achieve than in some other languages.

Of course, the underlying hardware likely has no machine-supported 4-bit unsigned type so larger hardware numeric types are used in the generated code. Hence there are shifts and masking being done in the Ada version as well, but they do not appear in the source code. The developer has let the compiler do that work. An additional benefit of this approach is that the compiler will change the shifting and masking code for us if we change the explicit type declarations.

Why is simplicity so important? Simplicity directly increases understandability, which directly affects correctness and maintainability, which greatly affects the economic cost of the software. In large, long-lived projects, maintenance is by far the largest economic cost driver. In high-integrity applications, correctness is essential. Therefore, doing anything reasonable to keep the code as simple as possible is usually worth the effort. In some projects the non-functional requirements, especially performance, can dictate less simple code, but that won't apply to all of the code. Where possible, simplicity rules.

One more point about the GPIO ports. There are as many of these ports as the Arm microcontroller vendor decides to implement. And as we said, they are memory-mapped, at addresses specified by the vendor. If the memory used by all the ports is contiguous, we can conveniently use an array of the `GPIO_Port` record type to represent all the ports implemented. We would just set the array object's address at the address specified for the first port object in memory. Then, normal array indexing will provide access to any given port in the memory-mapped hardware.

This array approach requires each array component — the `GPIO_Port` record type — to be the right size so that all the array components start on addresses corresponding to the start of the next port in hardware.

That starting address correspondence for the array components is obtained automatically as long as the record type includes all the memory used by any individual device. In that case the next array component will indeed start at an address matching the next device in hardware. Note that this assumes the first array component matches the address of the first hardware device in memory. The first array component is at the same address as the

whole array object itself (a fact that is guaranteed by the language), so the array address must be set to whatever the vendor documentation specified for the first port.

However, in some cases the vendor will leave gaps of unused memory for complicated memory-mapped objects like these ports. They do so for the sake of future expansion of the implementation, e.g., to add new features or capacity. The gaps are thus between consecutive hardware devices.

These gaps are presumably (hopefully!) included in the memory layout documented for the device, but it won't be highlighted particularly. You should check, therefore, that the documented starting addresses of the second and subsequent array components are what you will get with a simple array object having components of that record type.

For example, the datasheet for the STM32F407 Arm implementation indicates that the GPIO ports start at address 16#4002_0000#. That's where GPIO_A begins. The next port, GPIO_B, starts at address 16#4002_0400#, or a byte offset of 1024 in decimal. In the STM32F4 Reference Manual, however, the GPIO port register layout indicates a size for any one port that is much less than 1024 bytes. As you saw earlier in the corresponding record type declaration, on the STM32F4 each port only requires 40 (decimal) bytes. Hence there's a gap of unused memory between the ports, including after the last port, of 984 bytes (7872 bits).

To represent the gap, an "extra", unused record component was added, with the necessary location and size specified within the record type, so that the unused memory is included in the representation. As a result, each array component will start at the right address (again, as long as the first one does). Telling the compiler, and future maintainers, that this extra component is not meant to be referenced by the software would not hurt. You can use the pragma or aspect `Unreferenced` for that purpose. Here's the code again, for convenience:

```
type GPIO_Port is limited record
   MODER      : Pin_Modes_Register;
   OTYPER     : Output_Types_Register;
   Reserved_1 : Half_Word;
   OSPEEDR    : Output_Speeds_Register;
   PUPDR      : Resistors_Register;
   IDR        : Half_Word;       --  input data register
   Reserved_2 : Half_Word;
   ODR        : Half_Word;       --  output data register
   Reserved_3 : Half_Word;
   BSRR_Set   : Half_Word;       --  bit set register
   BSRR_Reset : Half_Word;       --  bit reset register
   LCKR       : Word with Atomic;
   AFR        : Alternate_Function_Fields;
   Unused     : Unaccessed_Gap with Unreferenced;
end record with
   Size => 16#400# * 8;

for GPIO_Port use record
   MODER      at 0  range 0 .. 31;
   OTYPER     at 4  range 0 .. 15;
   Reserved_1 at 6  range 0 .. 15;
   OSPEEDR    at 8  range 0 .. 31;
   PUPDR      at 12 range 0 .. 31;
   IDR        at 16 range 0 .. 15;
   Reserved_2 at 18 range 0 .. 15;
   ODR        at 20 range 0 .. 15;
   Reserved_3 at 22 range 0 .. 15;
   BSRR_Set   at 24 range 0 .. 15;
   BSRR_Reset at 26 range 0 .. 15;
   LCKR       at 28 range 0 .. 31;
   AFR        at 32 range 0 .. 63;
   Unused     at 40 range 0 .. 7871;
end record;
```

The type for the gap, Unaccessed_Gap, must represent 984 bytes so we declared an array like so:

```
Gap_Size : constant := 984;  -- bytes
--  There is a gap of unused, reserved memory after the end of the
--  bytes used by any given memory-mapped GPIO port. The size of the
--  gap is indicated in the STM32F405xx etc. Reference Manual, RM 0090.
--  Specifically, Table 1 shows the starting and ending addresses mapped
--  to the GPIO ports, for an allocated size of 16#400#, or 1024 (decimal)
--  bytes per port. However, in the same document, the register map for
--  these ports shows only 40 bytes currently in use. Presumably this gap is
--  for future expansion when additional functionality or capacity is added,
--  such as more pins per port.

type Unaccessed_Gap is array (1 .. Gap_Size) of Unsigned_8 with
   Component_Size => Unsigned_8'Size,
   Size           => Gap_Size * Unsigned_8'Size;
--  This type is used to represent the necessary gaps between GPIO
--  ports in memory. We explicitly allocate a record component of
--  this type at the end of the record type for that purpose.
```

We also set the size of the entire record type to 16#400# bytes since that is the total of the required bytes plus the gap, as per the documentation. As such, this is a "confirming" size clause because the reserved gap component increases the required size to that value (which is the point). We don't really need to do both, i.e., declare the reserved gap component and also set the record type size to the larger value. We could have done either one alone. One could argue that setting the size alone would have been simpler, in that it would obviate the type declaration and corresponding record component declaration. Being doubly explicit seemed a good idea at the time.

37.3 Dynamic Address Conversion

In the overlay example there were two distinct Ada objects, of two different types, sharing one (starting) address. The overlay provides two views of the memory at that address because there are two types involved. In this idiom the address is known when the code is written, either because it is a literal value specified in some hardware spec, or it is simply the address of the other object (in which case the actual address value is neither known nor relevant).

When there are several views required, declaring multiple overlaid variables at the same address absolutely can work, but can be less convenient than an alternative idiom. The alternative is to convert an address value to a value of an access type. Dereferencing the resulting access value provides a view of the memory corresponding to the designated type, starting at the converted address value.

For example, perhaps a networking component is given a buffer — an array of bytes — representing a received message. A subprogram is called with the buffer as a parameter, or the parameter can be the address of the buffer. If the subprogram must interpret this array via different views, this alternative approach works well. We could have an access type designating a message preamble, for example, and convert the first byte's address into such an access value. Dereferencing the conversion gives the preamble value. Likewise, the subprogram might need to compute a checksum over some of the bytes, so a different view, one of an array of a certain set size, could be used. Again, we could do that with overlaid objects but the alternative can be more convenient.

Here's a simple concrete example to illustrate the approach. Suppose we want to have a utility to swap the two bytes at any arbitrary address. Here's the declaration:

```
procedure Swap2 (Location : System.Address);
```

Callers pass the address of an object intended to have its (first) two bytes swapped:

```
Swap2 (Z'Address);
```

In the call, Z is of type Interfaces.Integer_16, for example, or Unsigned_16, or even something bigger as long as you only care about swapping the first two bytes.

The incomplete implementation using the conversion idiom could be like so:

```
procedure Swap2 (Location : System.Address) is
   X : Word renames To_Pointer (Location).all;
begin
   X :=  Shift_Left (X, 8) or Shift_Right (X, 8);
end Swap2;
```

The declaration of X is the pertinent part.

In the declaration, X is of type Word, a type (not yet shown) derived from Interfaces.Unsigned_16. Hence X can have the inherited shift and logical **or** operations applied.

The To_Pointer (Location) part of the declaration is a function call. The function returns the conversion of the incoming address value in Location into an access value designating Word values. We'll explain how to do that momentarily. The **.all** explicitly dereferences the access value resulting from the function call.

Finally, X renames the Word designated by the converted access value. The benefit of the renaming, in addition to the simpler name, is that the function is only called once, and the access value deference is only evaluated once.

Now for the rest of the implementation not shown earlier.

```
type Word is new Interfaces.Unsigned_16;

package Word_Ops is new System.Address_To_Access_Conversions (Word);
use Word_Ops;
```

System.Address_To_Access_Conversions is a language-defined generic package that provides just two functions: one to convert an address value to an access type, and one to convert in the opposite direction:

```
generic
   type Object (<>) is limited private;
package System.Address_To_Access_Conversions is

   type Object_Pointer is access all Object;

   function To_Pointer (Value : Address) return Object_Pointer;
   function To_Address (Value : Object_Pointer) return Address;

   pragma Convention (Intrinsic, To_Pointer);
   pragma Convention (Intrinsic, To_Address);

end System.Address_To_Access_Conversions;
```

Object is the generic formal type parameter, i.e., the type we want our converted addresses to designate via the type Object_Pointer. In the byte-swapping example, the type Word was passed to Object in the instantiation.

The access type used by the functions is Object_Pointer, declared along with the functions. Object_Pointer designates values of the type used for the generic actual parameter, in this case Word.

Note the pragma Convention applied to each function, indicating that there is no actual function call involved; the compiler emits the code directly, if any code is actually required. Otherwise the compiler just treats the incoming **Address** bits as a value of type Object_Pointer.

The instantiation specifies type Word as the generic actual type parameter, so now we have a set of functions for that type, in particular To_Pointer.

Let's look at the code again, this time with the additional declarations:

```
type Word is new Interfaces.Unsigned_16;

package Word_Ops is new System.Address_To_Access_Conversions (Word);
use Word_Ops;

procedure Swap2 (Location : System.Address) is
   X : Word renames To_Pointer(Location).all;
begin
   X :=  Shift_Left (X, 8) or Shift_Right (X, 8);
end Swap2;
```

Word_Ops is the generic instance, followed immediately by a **use** clause so that we can refer to the visible content of the package instance conveniently.

In the renaming expression, To_Pointer (Location) converts the incoming address in Location to a pointer designating the Word at that address. The **.all** dereferences the resulting access value to get the designated Word value. Hence X refers to that two-byte value in memory.

We could almost certainly achieve the same affect by replacing the call to the function in To_Pointer with a call to an instance of Ada.Unchecked_Conversion. The conversion would still be between an access type and a value of type System.**Address**, but the access type would require declaration by the user. In both cases there would be an instantiation of a language-defined facility, so there's not much saving in lines of source code, other than the access type declaration. Because System.Address_To_Access_Conversions is explicitly intended for this purpose, good style suggests its use in preference to unchecked conversion, but both approaches are common in production code.

In either case, the conversion is not required to work, although in practice it will, most of the time. Representing an access value as an address value is quite common because it matches the typical underlying hardware's memory model. But even so, a single address is not necessarily sufficient to represent an access value for any given designated type. In that case problems arise, and they are difficult to debug.

For example, in GNAT, access values designating values of unconstrained array types, such as **String**, are represented as two addresses, known as "fat pointers". One address points to the bounds for the specific array object, since they can vary. The other address designates the characters. Therefore, conversions of a single address to an access value requiring fat pointers will not work using unchecked conversions. (There is a way, however, to tell GNAT to use a single address value, but it is an explicit step in the code. Once done, though, unchecked conversions would then work correctly.)

You can alternatively use generic package System.Address_To_Access_Conversions. That generic is defined for the purpose of converting addresses to access values, and vice versa. But note that the implementation of the generic's routines must account for the representation their compiler uses for unbounded types like **String**.

37.4 Address Arithmetic

Part of "letting the compiler do the work for you" is not doing address arithmetic in the source code if you can avoid it. Instead, for instance, use the normal "dot notation" to reference components, and let the compiler compute the offsets to those components. The approach to implementing procedure `Configure_Alternate_Function` for a `GPIO_Port` is a good example.

That said, sometimes address arithmetic is the most direct expression of what you're trying to implement. For example, when implementing your own memory allocator, you'll need to do address arithmetic.

Earlier in this section we mentioned the package `System.Storage_Elements`, for the sake of the function that converts integer values to address values. The package also defines functions that provide address arithmetic. These functions work in terms of type `System.Address` and the package-defined type `Storage_Offset`. The type `Storage_Offset` is an integer type with an implementation-defined range. As a result you can have positive and negative offsets, as needed. Addition and subtraction of offsets to/from addresses is supported, as well as the **mod** operator.

Combined with package `System` (for type `System.Address`), the functions and types in this package provide the kinds of address arithmetic other languages provide. Nevertheless, you should prefer having the compiler do these computations for you, if possible.

Here's an example illustrating the facilities. The procedure defines an array of record values, then traverses the array, printing the array components as it goes. (This is not the way to really implement such code. It's just an illustration for address arithmetic.)

```
with Ada.Text_IO;                use Ada.Text_IO;
with System.Storage_Elements;    use System.Storage_Elements;
with System.Address_To_Access_Conversions;

procedure Demo_Address_Arithmetic is

   type R is record
      X : Integer;
      Y : Integer;
   end record;

   R_Size : constant Storage_Offset := R'Object_Size / System.Storage_Unit;

   Objects : aliased array (1 .. 10) of aliased R;     --  arbitrary bounds

   Objects_Base : constant System.Address := Objects'Address;

   Offset : Storage_Offset;

   --  display the object of type R at the address specified by Location
   procedure Display_R (Location : in System.Address) is

      package R_Pointers is new System.Address_To_Access_Conversions (R);
      use R_Pointers;

       Value : R renames To_Pointer (Location).all;
      --  The above converts the address to a pointer designating an R value
      --  and dereferences it, using the name Value to refer to the
      --  dereferenced R value.
   begin
      Put (Integer'Image (Value.X));
      Put (", ");
      Put (Integer'Image (Value.Y));
```

(continues on next page)

(continued from previous page)

```
      New_Line;
   end Display_R;

begin
   Objects := ((0,0), (1,1), (2,2), (3,3), (4,4),
               (5,5), (6,6), (7,7), (8,8), (9,9));

   Offset := 0;

   --  walk the array of R objects, displaying each one individually by
   --  adding the offset to the base address of the array
   for K in Objects'Range loop
      Display_R (Objects_Base + Offset);
      Offset := Offset + R_Size;
   end loop;
end Demo_Address_Arithmetic;
```

Seriously, this is just for the purpose of illustration. It would be much better to just index into the array directly.

CHAPTER

THIRTYEIGHT

GENERAL-PURPOSE CODE GENERATORS

In *another chapter* (page 1153), we mentioned that the best way to get a specific set of machine instructions emitted from the compiler is to write them ourselves, in the Ada source code, using machine-code insertions (MCI). The rationale was that the code generator will make reasonable assumptions, including the assumption that performance is of uppermost importance, but that these assumptions can conflict with device requirements.

For example, the code generator might not issue the specific sequence of machine code instructions required by the hardware. The GPIO pin "lock" sequence in that referenced chapter is a good example. Similarly, the optimizer might remove what would otherwise be "redundant" read/writes to a memory-mapped variable.

The code generator might issue instructions to read a small field in a memory-mapped record object using byte-sized accesses, when instead the device requires whole-word or half-word access instructions.

The code generator might decide to load a variable from memory into a register, accessing the register when the value is required. Typically that approach will yield far better performance than going to memory every time the value is read or updated. But suppose the variable is for a memory-mapped device? In that case we really need the generated code to go to memory every time.

As you can see, there are times when we cannot let the code generator make the usual assumptions. Therefore, Ada provides aspects and pragmas that developers can use to inform the compiler of facts that affect code generation in this regard.

These facilities are defined in the Systems Programming Annex, C.6, specifically. The title of that sub-clause is "Shared Variables" because the objects (memory) can be shared between tasks as well as between hardware devices and the host computer. We ignore the context of variables shared between tasks, focusing instead of shared memory-mapped devices, as this course is about embedded systems.

When describing these facilities we will use aspects, but remember that the corresponding pragmas are defined as well, except for one. (We'll mention it later.) For the other aspects, the pragmas existed first and, although obsolescent, remain part of the language and supported. There's no need to change your existing source code using the pragmas to use the aspects instead, unless you need to change it for some other reason.

As this is an introduction, we will not go into absolutely all the details, but will instead give a sense of what the language provides, and why.

38.1 Aspect Independent

To interface with a memory-mapped device, there will be an Ada object of an appropriate type that is mapped to one or more bytes of memory. The software interacts with the device by reading and/or writing to the memory locations mapped to the device, using the operations defined by the type in terms of normal Ada semantics.

Some memory-mapped devices can be directly represented by a single scalar value, usually of some signed or unsigned numeric type. More sophisticated devices almost always involve several distinct input and output fields. Therefore, representation in the software as a record object is very common. Ada record types have such extensive and flexible support for controlling their representation, down to the individual bit level, that using a record type makes sense. (And as mentioned, using normal record component access via the "dot notation" offloads to the compiler the address arithmetic needed to access individual memory locations mapped to the device.) And of course the components of the mapped record type can themselves be of scalar and composite types too, so an extensive descriptive capability exists with Ada.

Let's say that one of these record components is smaller than the size of the smallest addressable memory unit on the machine, which is to say, smaller than the machine instructions can read/write memory individually. A Boolean record component is a good example, and very common. The machine cannot usually read/write single bits in memory, so the generated code will almost certainly read or write a byte to get the enclosed single-bit Boolean component. It might use a larger sized access too, a half-word or word. Then the generated code masks off the bits that are not of interest and does some shifts to get the desired component.

Reading and writing the bytes surrounding the component accessed in the source code can cause a problem. In particular, some devices react to being read or written by doing something physical in the hardware. That's the device designer's intent for the software. But we don't want that to happen accidentally due to surrounding bytes being accessed.

Therefore, to prevent these "extra" bytes from being accessed, we need a way to tell the compiler that we need the read or write accesses for the given object to be independent of the surrounding memory. If the compiler cannot do so, we'll get an error and the compilation will fail. That beats debugging, every time.

Therefore, the aspect `Independent` specifies that the code generated by the compiler must be able to load and store the memory for the specified object without also accessing surrounding memory. More completely, it declares that a type, object, or component must be independently addressable by the hardware. If applied to a type, it applies to all objects of the type.

Likewise, aspect `Independent_Components` declares that the individual components of an array or record type must be independently addressable.

With either aspect the compiler will reject the declaration if independent access is not possible for the type/object in question.

For example, if we try to mark each Boolean component of a record type as `Independent` we can do so, either individually or via `Indepndent_Components`, but doing so will require that each component is a byte in size (or whatever the smallest addressable unit happens to be on this machine). We cannot make each Boolean component occupy one bit within a given byte if we want them to be independently accessed.

```
package P is

   type R is record
      B0 : Boolean;
      B1 : Boolean;
      B2 : Boolean;
```

(continues on next page)

(continued from previous page)

```
      B3 : Boolean;
      B4 : Boolean;
      B5 : Boolean;
   end record with
     Size => 8,
     Independent_Components;

   for R use record
      B0 at 0 range 0 .. 0;
      B1 at 0 range 1 .. 1;
      B2 at 0 range 2 .. 2;
      B3 at 0 range 3 .. 3;
      B4 at 0 range 4 .. 4;
      B5 at 0 range 5 .. 5;
   end record;

end P;
```

For a typical target machine the compiler will reject that code, complaining that the `Size` for R' must be at least 48 bits, i.e., 8 bits per component. That's because the smallest quantity this machine can independently address is an 8-bit byte.

But if we don't really need the individual bits to be independently accessed — and let's hope no hardware designer would define such a device — then we have more flexibility. We could, for example, require that objects of the entire record type be independently accessible:

```
package Q is

   type R is record
      B0 : Boolean;
      B1 : Boolean;
      B2 : Boolean;
      B3 : Boolean;
      B4 : Boolean;
      B5 : Boolean;
   end record with
     Size => 8,
     Independent;

   for R use record
      B0 at 0 range 0 .. 0;
      B1 at 0 range 1 .. 1;
      B2 at 0 range 2 .. 2;
      B3 at 0 range 3 .. 3;
      B4 at 0 range 4 .. 4;
      B5 at 0 range 5 .. 5;
   end record;

end Q;
```

This the compiler should accept, assuming a machine that can access bytes in memory individually, without having to read some number of other bytes.

But for another twist, suppose we need one of the components to be aliased, so that we can construct access values designating it via the **`Access`** attribute? For example, given the record type R above, and some object `Foo` of that type, suppose we want to say `Foo.B0'Access`? We'd need to mark the component as **`aliased`**:

```
package QQ is

   type R is record
```

(continues on next page)

(continued from previous page)

```
      B0 : aliased Boolean;
      B1 : Boolean;
      B2 : Boolean;
      B3 : Boolean;
      B4 : Boolean;
      B5 : Boolean;
   end record with
     Size => 8,
     Independent;

   for R use record
      B0 at 0 range 0 .. 0;
      B1 at 0 range 1 .. 1;
      B2 at 0 range 2 .. 2;
      B3 at 0 range 3 .. 3;
      B4 at 0 range 4 .. 4;
      B5 at 0 range 5 .. 5;
   end record;

end QQ;
```

The compiler will once again reject the code, complaining that the size of B0 must be a multiple of a `Storage_Unit`, in other words, the size of something independently accessible in memory on this machine.

Why? The issue here is that aliased objects, including components of composite types, must be represented in such a way that creating the designating access ("pointer") value is possible. The component B0, if allocated only one bit, would not allow an access value to be created due to the usual machine accessibility limitation we've been discussing.

Similarly, a record component that is of some by-reference type, such as any tagged type, introduces the same issues as an aliased component. That's because the underlying implementation of by-reference parameter passing is much like a `'Access` attribute reference.

As important as the effect of this aspect is, you probably won't see it specified. There are other aspects that are more typically required. However, the semantics of `Independent` are part of the semantics of some of these other aspects. Applying them applies `Independent` too, in effect. So even though you don't typically apply it directly, you need to understand the independent access semantics. We discuss these other, more commonly applied aspects next.

These representation aspects may be specified for an object declaration, a component declaration, a full type declaration, or a generic formal (complete) type declaration. If any of these aspects are specified True for a type, then the corresponding aspect is True for all objects of the type.

38.2 Aspect `Volatile`

Earlier we said that the compiler (specifically the optimizer) might decide to load a variable from memory into a register, accessing the register when the value is required or updated. Similarly, the compiler might reorder instructions, and remove instructions corresponding to redundant assignments in the source code. Ordinarily we'd want those optimizations, but in the context of embedded memory-mapped devices they can be problematic.

The hardware might indeed require the source code to read or write to the device in a way that the optimizer would consider redundant, and in order to interact with the device we need every read and write to go to the actual memory for the mapped device, rather than a register. As developers we have knowledge about the context that the compiler lacks.

The compiler is aware of the fact that the Ada object is memory-mapped because of the address clause placing the object at a specific address. But the compiler does not know we are interacting with an external hardware device. Perhaps, instead, the object is mapped to a specific location because some software written in another language expects to access it there. In that case redundant reads or writes of the same object really would be redundant. The fact that we are interacting with a hardware device makes a difference.

In terms of the language rules, we need reading from, and writing to, such devices to be part of what the language refers to as the "external effects" of the software. These effects are what the code must actually produce. Anything else — the internal effects — could be removed by the optimizer.

For example, suppose you have a program that writes a value to some variable and also writes the string literal "42" to a file. That's is absolutely all that the program contains.

```
with Ada.Text_IO;  use Ada.Text_IO;

procedure Demo is
   Output : File_Type;
   Silly  : Integer;
begin
   Silly := 0;
   Create (Output, Out_File, "output.txt");
   Put (Output, "42");
   Close (Output);
end Demo;
```

The value of the variable `Silly` is not used in any way so there is no point in even declaring the variable, much less generating code to implement the assignment. The update to the variable has only an internal effect. With warnings enabled we'll receive notice from the compiler, but they're just warnings.

However, writing to the file is an external effect because the file persists beyond the end of the program's execution. The optimizer (when enabled) would be free to remove any access to the variable `Silly`, but not the write to the file.

We can make the compiler recognize that a software object is part of an external effect by applying the aspect `Volatile`. (Aspect `Atomic` is pertinent too. More in a moment.) As a result, the compiler will generate memory load or store instructions for every read or update to the object that occurs in the source code. Furthermore, it cannot generate any additional loads or stores to that variable, and it cannot reorder loads or stores from their order in the source code. "What You See Is What You Get" in other words.

```
with Ada.Text_IO;  use Ada.Text_IO;

procedure Demo is
   Output : File_Type;
   Silly  : Integer with Volatile;
begin
   Silly := 0;
   Create (Output, Out_File, "output.txt");
   Put (Output, "42");
   Close (Output);
end Demo;
```

If we compile the above, we won't get the warning we got earlier because the compiler is now required to generate the assignment for `Silly`.

The variable `Silly` is not even a memory-mapped object, but remember that we said these aspects are important to the tasking context too, for shared variables. We're ignoring that context in this course.

There is another reason to mark a variable as `Volatile`. Sometimes you want to have

exactly the load and store instructions generated that match those of the Ada code, even though the volatile object is not a memory-mapped object. For example, *elsewhere* (page 1153) we said that the best way to achieve exact assembly instruction sequences is the use of machine-code inserts (MCI). That's true, but for the moment let's say we want to write it in Ada without the MCIs. Our earlier example was the memory-mapped GPIO ports on Arm microcontrollers produced by ST Microelectronics. Specifically, these ports have a "lock" per GPIO pin that allows the developer to configure the pin and then lock it so that no other configuration can accidentally change the configuration of that pin. Doing so requires an exact sequence of loads and stores. If we wrote this in Ada it would look like this:

```
procedure Lock
  (Port : in out GPIO_Port;
   Pin  : GPIO_Pin)
is
   Temp : Word with Volatile;
begin
   --  set the lock control bit and the pin
   --  bit, clear the others
   Temp := LCCK or Pin'Enum_Rep;

   --  write the lock and pin bits
   Port.LCKR := Temp;

   --  clear the lock bit in the upper half
   Port.LCKR := Pin'Enum_Rep;

   --  write the lock bit again
   Port.LCKR := Temp;

   --  read the lock bit
   Temp := Port.LCKR;

   --  read the lock bit again
   Temp := Port.LCKR;
end Lock;
```

`Temp` is marked volatile for the sake of getting exactly the load and stores that we express in the source code, corresponding to the hardware locking protocol. It's true that `Port` is a memory-mapped object, so it too would be volatile, but we also need `Temp` to be volatile.

This high-level coding approach will work, and is simple enough that MCIs might not be needed. However, what really argues against it is that the correct sequence of emitted code requires the optimizer to remove all the other cruft that the code generator would otherwise include. (The gcc code generator used by the GNAT compiler generates initially poor code, by design, relying on the optimizer to clean it up.) In other words, we've told the optimizer not to change or add loads and stores for `Temp`, but without the optimizer enabled the code generator generates other code that gets in the way. That's OK in itself, as far as procedure `Lock` is concerned, but if the optimizer is sufficiently enabled we cannot debug the rest of the code. Using MCIs avoids these issues. The point, though, is that not all volatile objects are memory mapped.

So far we've been illustrating volatility with scalar objects, such as `Lock.Temp` above. What about objects of array and record types? (There are other "composite" types in Ada but they are not pertinent here.)

When aspect `Volatile` is applied to a record type or an object of such a type, all the record components are automatically volatile too.

For an array type (but not a record type), a related aspect `Volatile_Components` declares that the components of the array type — but not the array type itself — are volatile. However, if the `Volatile` aspect is specified, then the `Volatile_Components` aspect is automatically applied too, and vice versa. Thus components of array types are covered auto-

matically.

If an object (of an array type or record type) is marked volatile then so are all of its sub-components, even if the type itself is not marked volatile.

Therefore aspects `Volatile` and `Volatile_Components` are nearly equivalent. In fact, `Volatile_Components` is superfluous. The language provides the `Volatile_Components` aspect only to give symmetry with the `Atomic_Components` and `Independent_Components` aspects. You can simply apply `Volatile` and be done with it.

Finally, note that applying aspect `Volatile` does not implicitly apply `Independent`, although you can specify it explicitly if need be.

38.3 Aspect `Atomic`

Consider the GPIO pin configuration lock we've mentioned a few times now, that freezes the configuration of a given pin on a given GPIO port. The register, named LCKR for "lock register", occupies 32-bits, but only uses 17 total bits (currently). The low-order 16 bits, [0:15], represent the 16 GPIO pins on the given port. Bit #16 is the lock bit. That bit is the first bit in the upper half of the entire word. To freeze the configuration of a given pin in [0:15], the lock bit must be set at the same time as the bit to be frozen. In other words, the lower half and the upper half of the 32-bit word representing the register must be written together, at the same time. That way, accidental (un)freezing is unlikely to occur, because the most efficient, hence typical way for the generated code to access individual bits is for the compiler to load or store just the single byte that contains the bit or bits in question.

This indivisibility effect can be specified via aspect `Atomic`. As a result, all reads and updates of such an object as a whole are indivisible. In practice that means that the entire object is accessed with one load or store instruction. For a 16-bit object, all 16-bits are loaded and stored at once. For a 32-bit object, all 32-bits at once, and so on. The upper limit is the size of the largest machine scalar that the processor can manipulate with one instruction, as defined by the target processor. The typical lower bound is 8, for a byte-addressable machine.

Therefore, within the record type representing a GPIO port, we include the lock register component and apply the aspect `Atomic`:

```
type GPIO_Port is limited record
   ...
   LCKR : UInt32 with Atomic;
   ...
end record with
  ...
  Size => 16#400# * 8;
```

Hence loads and stores to the LCKR component will be done atomically, otherwise the compiler will let us know that it is impossible. That's all we need to do for the lock register to be read and updated atomically.

You should understand that only accesses to the whole, entire object are atomic. In the case of the lock register, the entire object is a record component, but that causes no problems here.

There is, however, something we must keep in mind when manipulating the values of atomic objects. For the lock register we're using a scalar type to represent the register, an unsigned 32-bit integer. There are no sub-components because scalar types don't have components, by definition. We simply use the bit-level operations to set and clear the individual bits. But we cannot set the bits — the lock bit and the bit for the I/O pin to freeze — one at a time because the locking protocol requires all the bits to be written at the same time, and only the entire 32-bit load and stores are atomic. Likewise, if instead of a scalar we used

a record type or an array type to represent the bits in the lock register, we could not write individual record or array components one at a time, for the same reason we could not write individual bits using the unsigned scalar. The `Atomic` aspect only applies to loads and stores of the entire register.

Therefore, to update or read individual parts of an atomic object we must use a coding idiom in which we explicitly read or write the entire object to get to the parts. For example, to read an individual record component, we'd first read the entire record object into a temporary variable, and then access the component of that temporary variable. Likewise, to update one or more individual components, we'd first read the record object into a temporary variable, update the component or components within that temporary, and then write the temporary back to the mapped device object. This is known as the "read-modify-write" idiom. You'll see this idiom often, regardless of the programming language, because the hardware requirement is not unusual. Fortunately Ada defines another aspect that makes the compiler do this for us. We'll describe it in the next section.

Finally, there are issues to consider regarding the other aspects described in this section.

If you think about atomic behavior in the context of machine instructions, loading and storing from/to memory atomically can only be performed for quantities that are independently addressable. Consequently, all atomic objects are considered to be specified as independently addressable too. Aspect specifications and representation items cannot change that fact. You can expect the compiler to reject any aspect or representation choice that would prevent this from being true.

Likewise, atomic accesses only make sense on actual memory locations, not registers. Therefore all atomic objects are volatile objects too, automatically.

However, unlike volatile objects, the components of an atomic object are not automatically atomic themselves. You'd have to mark these types or objects explicitly, using aspect `Atomic_Components`. Unlike `Volatile_Components`, aspect `Atomic_Components` is thus useful.

As is usual with Ada programming, you can rely on the compiler to inform you of problems. The compiler will reject an attempt to specify `Atomic` or `Atomic_Components` for an object or type if the implementation cannot support the indivisible and independent reads and updates required.

38.4 Aspect `Full_Access_Only`

Many devices have single-bit flags in the hardware that are not allocated to distinct bytes. They're packed into bytes and words shared with other flags. It isn't just individual bits either. Multi-bit fields that are smaller than a byte, e.g., two 4-bit quantities packed into a byte, are common. We saw that with the GPIO alternate functions codes earlier.

Ordinarily in Ada we represent such composite hardware interfaces using a record type. (Sometimes an array type makes more sense. That doesn't change anything here.) Compared to using bit-patterns, and the resulting bit shifting and masking in the source code, a record type representation and the resulting "dot notation" for accessing components is far more readable. It is also more robust because the compiler does all the work of retrieving these individual bits and bit-fields for us, doing any shifting and masking required in the generated code. The loads and stores are done by the compiler in whatever manner the compiler thinks most efficient.

When the hardware device requires atomic accesses to the memory mapped to such flags, we cannot let the compiler generate whatever width load and store accesses it thinks best. If full-word access is required, for example, then only loads and stores for full words can work. Yet aspect `Atomic` only guarantees that the entire object, in this case the record object, is loaded and stored indivisibly, via one instruction. The aspect doesn't apply to reads and updates to individual record components.

In the section on Atomic above, we mentioned that proper access to individual components of atomic types/objects can be achieved by a "read-modify-write" idiom. In this idiom, to read a component you first read into a temporary the entire enclosing atomic object. Then you read the individual component from that temporary variable. Likewise, to update an individual component, you start with the same approach but then update the component(s) within the temporary, then store the entire temporary back into the mapped atomic object. Applying aspect Atomic to the enclosing object ensures that reading and writing the temporary will be atomic, as required.

Using bit masks and bit patterns to access logical components as an alternative to a record type doesn't change the requirement for the idiom.

Consider the STM32F4 DMA device. The device contains a 32-bit stream configuration register that requires 32-bit reads and writes. We can map that register to an Ada record type like so:

```
type Stream_Config_Register is record
   --  ...
   Direction         : DMA_Data_Transfer_Direction;
   P_Flow_Controller : Boolean;
   TCI_Enabled       : Boolean;  -- transfer complete
   HTI_Enabled       : Boolean;  -- half-transfer complete
   TEI_Enabled       : Boolean;  -- transfer error
   DMEI_Enabled      : Boolean;  -- direct mode error
   Stream_Enabled    : Boolean;
end record
   with Atomic, Size => 32;
```

The "confirming" size clause ensures we have declared the type correctly such that it will fit into 32-bits. There will also be a record representation clause to ensure the record components are located internally as required by the hardware. We don't show that part.

The aspect Atomic is applied to the entire record type, ensuring that the memory mapped to the hardware register is loaded and stored only as 32-bit quantities. In this example it isn't that we want the loads and stores to be indivisible. Rather, we want the generated machine instructions that load and store the object to use 32-bit word instructions, even if we are only reading or updating a component of the object. That's what the hardware requires for all accesses.

Next we'd use that type declaration to declare one of the components of an enclosing record type representing one entire DMA "stream":

```
type DMA_Stream is record
   CR   : Stream_Config_Register;
   NDTR : Word;    -- upper half must remain at reset value
   PAR  : Address; -- peripheral address register
   M0AR : Address; -- memory 0 address register
   M1AR : Address; -- memory 1 address register
   FCR  : FIFO_Control_Register;
end record
   with Volatile, Size => 192;  -- 24 bytes
```

Hence any individual DMA stream record object has a component named CR that represents the corresponding configuration register.

The DMA controllers have multiple streams per unit so we'd declare an array of DMA_Stream components. This array would then be part of another record type representing a DMA controller. Objects of the DMA_Controller type would be mapped to memory, thus mapping the stream configuration registers to memory.

Now, given all that, suppose we want to enable a stream on a given DMA controller. Using the read-modify-write idiom we would do it like so:

```
procedure Enable
   (Unit   : in out DMA_Controller;
    Stream : DMA_Stream_Selector)
is
   Temp : Stream_Config_Register;
   --  these registers require 32-bit accesses, hence the temporary
begin
   Temp := Unit.Streams (Stream).CR;  --  read entire CR register
   Temp.Stream_Enabled := True;
   Unit.Streams (Stream).CR := Temp;  --  write entire CR register
end Enable;
```

That works, and of course the procedural interface presented to clients hides the details, as it should.

To be fair, the bit-pattern approach can express the idiom concisely, as long as you're careful. Here's the C code to enable and disable a selected stream:

```
#define DMA_SxCR_EN    ((uint32_t)0x00000001)

/* Enable the selected DMAy Streamx by setting EN bit */
DMAy_Streamx->CR  |=  DMA_SxCR_EN;

/* Disable the selected DMAy Streamx by clearing EN bit */
DMAy_Streamx->CR  &=  ~DMA_SxCR_EN;
```

The code reads and writes the entire CR register each time it is referenced so the requirement is met.

Nevertheless, the idiom is error-prone. We might forget to use it at all, or we might get it wrong in one of the very many places where we need to access individual components.

Fortunately, Ada provides a way to have the compiler implement the idiom for us, in the generated code. Aspect `Full_Access_Only` specifies that all reads of, or writes to, a component are performed by reading and/or writing all of the nearest enclosing full access object. Hence we add this aspect to the declaration of `Stream_Config_Register` like so:

```
type Stream_Config_Register is record
   --  ...
   Direction         : DMA_Data_Transfer_Direction;
   P_Flow_Controller : Boolean;
   TCI_Enabled       : Boolean;  -- transfer complete interrupt
   HTI_Enabled       : Boolean;  -- half-transfer complete
   TEI_Enabled       : Boolean;  -- transfer error interrupt
   DMEI_Enabled      : Boolean;  -- direct mode error interrupt
   Stream_Enabled    : Boolean;
end record
   with Atomic, Full_Access_Only, Size => 32;
```

Everything else in the declaration remains unchanged.

Note that `Full_Access_Only` can only be applied to `Volatile` types or objects. `Atomic` types are automatically `Volatile` too, so either one is allowed. You'd need one of those aspects anyway because `Full_Access_Only` just specifies the accessing instruction requirements for the generated code when accessing components.

The big benefit comes in the source code accessing the components. Procedure `Enable` is now merely:

```
procedure Enable
   (Unit   : in out DMA_Controller;
    Stream : DMA_Stream_Selector)
is
```

(continues on next page)

(continued from previous page)

```
begin
   Unit.Streams (Stream).CR.Stream_Enabled := True;
end Enable;
```

This code works because the compiler implements the read-modify-write idiom for us in the generated code.

The aspect `Full_Access_Only` is new in Ada 2022, and is based on an implementation-defined aspect that GNAT first defined named `Volatile_Full_Access`. You'll see that GNAT aspect throughout the Arm device drivers in the Ada Drivers Library, available here: https://github.com/AdaCore/Ada_Drivers_Library. Those drivers were the motivation for the GNAT aspect.

Unlike the other aspects above, there is no pragma corresponding to the aspect `Full_Access_Only` defined by Ada 2022. (There is such a pragma for the GNAT-specific version named `Volatile_Full_Access`, as well as an aspect.)

CHAPTER

THIRTYNINE

HANDLING INTERRUPTS

39.1 Background

Embedded systems developers offload functionality from the application processor onto external devices whenever possible. These external devices may be on the same "chip" as the central processor (e.g., within a System-on-Chip) or they may just be on the same board, but the point here is that they are not the processor executing the application. Offloading work to these other devices enables us to get more functionality implemented in a target platform that is usually very limited in resources. If the processor has to implement everything we might miss deadlines or perhaps not fit into the available code space. And, of course, some specialized functionality may simply require an external device, such as a sensor.

For a simple example, a motor encoder is a device attached to a motor shaft that can be used to count the number of full or partial rotations that the shaft has completed. When the shaft is rotating quickly, the application would need to interact with the encoder frequently to get an up-to-date count, representing a non-trivial load on the application processor. There are ways to reduce that load, which we discuss shortly, but by far the simplest and most efficient approach is to do it all in hardware: use a timer device driven directly by the encoder. The timer is connected to the encoder such that the encoder signals act like an external clock driving the timer's internal counter. All the application processor must do to get the encoder count is query the timer's counter. The timer is almost certainly memory-mapped, so querying the timer amounts to a memory access.

In some cases, we even offload communication with these external devices onto other external devices. For example, the I2C[273] (Inter-Integrated Circuit) protocol is a popular two-wire serial protocol for communicating between low-level hardware devices. Individual bits of the data are sent by driving the data line high and low in time with the clock signal on the other line. The protocol has been around for a long time and many embedded devices use it to communicate. We could have the application drive the data line for each individual bit in the protocol. Known as "bit-banging," that would be a significant load on the processor when the overall traffic volume is non-trivial. Fortunately, there are dedicated devices — I2C transceivers — that will implement the protocol for us. To send application data to another device using the I2C protocol, we just give the transceiver the data and destination address. The rest is done in the transceiver hardware. Receiving data is of course also possible. I2C transceivers are ubiquitous because the protocol is so common among device implementations. A USART[274] / UART[275] is a similar example.

Having offloaded some of the work, the application must have some way to interact with the device in order to know what is happening. Maybe the application has requested the external device perform some service — an analog-to-digital conversion, say — and must know when that function has completed. Maybe a communications device is receiving

[273] https://en.wikipedia.org/wiki/I%C2%B2C
[274] https://en.wikipedia.org/wiki/Universal_synchronous_and_asynchronous_receiver-transmitter
[275] https://en.wikipedia.org/wiki/Universal_asynchronous_receiver-transmitter

incoming data for the application to process. Or maybe that communications device has completed sending outgoing data and is ready for more to send.

Ultimately, interaction with the external device will be either synchronous or asynchronous, and has system-level design implications.

For synchronous interaction, the application periodically queries the device, typically a status flag or function on the device. Known as "polling," this approach is simple to implement but wastes cycles when the external device has not yet completed the request. After all, the point of offloading the work is to allow the application processor to execute other functionality. Polling negates that benefit. On the other hand, if the expected time to completion is extremely short, polling can be sufficiently efficient to make sense.

Usually, there's enough time involved so that polling is undesirable. The external environment takes time to respond and change state. Maybe a sensor has been designed to wait passively for something to happen in the external world, and only on the infrequent occurrence of that event should the application be notified. Perhaps a switch is to be toggled in certain circumstances, or an intruder detected. In this case, nothing happens for extended intervals.

As a consequence of all this, there's a very good chance that the internal processor should not poll these external devices.

Before we discuss the asynchronous alternative, there's another issue to consider. However the notification from the external device is implemented, a very quick response from the internal processor may be required. Think back to that serial port with a USART again. The USART is responsible for composing the arriving characters (or bytes) from their individual incoming bits on the receiving line. When all the bits for a single character have arrived, what happens next depends on the software design. In the simplest case, the internal processor copies the single character from the USART to an internal buffer and then goes back to doing something else while the next full character arrives in the USART. The response to the USART must be fairly quick because the next incoming character's bits are arriving. The internal processor must get the current character before it is overwritten by the next arriving character, otherwise we'll lose data. So we can say that the response to the notification from the external device must often be very quick.

Now, ideally in the USART case, we would further offload the work from the internal processor. Instead of having the processor copy each arriving character from the USART into an application buffer, we would have another external hardware device — a direct memory access (DMA)[276] device — copy each arriving character from the USART to the buffer. A DMA device copies data from one location to another, in this case from the address of the USART's one-character memory-mapped register to the address of the application buffer in memory. The copy is performed by the DMA hardware so it is extremely fast and costs the main processor no cycles. But even with this approach, we need to notify the application that a complete message is ready for processing. We might need to do that quickly so that enough time remains for the application to process the message content prior to the arrival of the next message.

Therefore, the general requirement is for an external device to be able to asynchronously notify the internal processor, and for the notification to be implemented in such a way that the beginning of the response can be sufficiently and predictably quick.

Fortunately, computers already have such a mechanism: interrupts. The details vary considerably with the hardware architecture, but the overall idea is independent of the ISA[277]: an external event can trigger a response from the processor by becoming "active." The current state of the application is temporarily stored, and then an interrupt response routine, known as an "interrupt handler" is executed. Upon completion of the handler, the original state of the application is restored and the application continues execution. The time between the interrupt becoming active and the start of the responding handler execution is known as the "interrupt latency."

[276] https://en.wikipedia.org/wiki/Direct_memory_access
[277] https://en.wikipedia.org/wiki/Instruction_set_architecture

Hardware interrupts typically have priorities assigned, depending on the hardware. These priorities are applied when multiple interrupts are triggered at the same time, to define the order in which the interrupts are presented and the handlers invoked. The canonical model is that only higher-priority interrupts can preempt handlers executing in response to interrupts with lower or equal priority.

Ada defines a model for hardware interrupts and interrupt handling that closely adheres to the conceptual model described above. If you have experience with interrupt handling, you will recognize them in the Ada model. One very important point to make about the Ada facilities is that they are highly portable, so they don't require extensive changes when moving to an new target computer. Part of that portability is due to the language-defined model.

Before we go into the Ada facility details, there's a final point. Sometimes we *do* want the application to wait for the external device. When would that be the case? To answer that, we need to introduce another term. The act of saving and restoring the state of the interrupted application software is known as "interrupt context switching." If the time for the device to complete the application request is approximately that of the context switching, the application might as well wait for the device after issuing the request.

Another reason to consider polling is that the architectural complexity of interrupt handling is greater than that of polling. If your system has some number of devices to control and polling them would be fast enough for the application to meet requirements, it is simpler to do so. But that will likely only work for a few devices, or at least a few that have short response time requirements.

The application code can wait for the device by simply entering a loop, exiting only when some external device status flag indicates completion of the function. The loop itself, in its simplest form, would contain only the test for exiting. As mentioned earlier, polling in a tight loop like this only makes sense for very fast device interactions. That's not the usual situation though, so polling should not be your default design assumption. Besides, active polling consumes power. On an embedded platform, conserving power is often important.

That loop polling the device will never exit if the device can fail to signal completion. Or maybe it might take too long in some odd case. If you don't want to be potentially stuck in the loop indefinitely, chewing up cycles and power, you can add an upper bound on the number of attempts, i.e., loop iterations. For example:

```
procedure Await_Data_Ready (This : in out Three_Axis_Gyroscope) is
   Max_Status_Attempts : constant := 10_000;
   --  This upper bound is arbitrary but must be sufficient for the
   --  slower gyro data rate options and higher clock rates.  It need
   --  not be as small as possible, the point is not to hang forever.
begin
   Polling: for K in 1 .. Max_Status_Attempts loop
      if Data_Status (This).ZYX_Available then
         return;
      end if;
   end loop Polling;
   raise Gyro_Failure;
end Await_Data_Ready;
```

In the above, `Data_Status` is a function that returns a record object containing Boolean flags. The if-statement queries one of those flags. Thus the loop either detects the desired device status or raises an exception after the maximum number of attempts have been made. In this version, the maximum is a known upper bound so a local constant will suffice. The maximum could be passed as a parameter instead, or declared in a global "configuration" package containing such constants.

Presumably, the upper bound on the attempts is either specified by the device documentation or empirically determined. Sometimes, however, the documentation will instead specify a maximum possible response time, for instance 30 milliseconds. Any time beyond

that maximum indicates a device failure.

In the code above, the number of iterations indirectly defines the amount of elapsed time the caller waits. That time varies with the target's system clock and the generated instructions' required clock cycles, hence the approach is not portable. Alternatively, we can work in terms of actual time, which will be portable across all targets with a sufficiently precise clock.

You can use the facilities in package `Ada.Real_Time` to work with time values. That package defines a type `Time_Span` representing time intervals, useful for expressing relative values such as elapsed time. There is also type `Time` representing an absolute value on the timeline. A function `Clock` returns a value of type `Time` representing "now," along with overloaded addition and subtraction operators taking `Time` and `Time_Span` parameters. The package also provides operators for comparing `Time` values. (The value returned by `Clock` is monotonically increasing so you don't need to handle time zone jumps and other such things, unlike the function provided by `Ada.Calendar`.)

If the timeout is not context-specific then we'd use a constant as we did above, otherwise we'd allow the caller to specify the timeout. For example, here's a polling routine included with the DMA device driver we've mentioned a few times now. Some device-specific parts have been removed to keep the example simple. The appropriate timeout varies, so it is a parameter to the call:

```
procedure Poll_For_Completion
  (This    : in out DMA_Controller;
   Stream  : DMA_Stream_Selector;
   Timeout : Time_Span;
   Result  : out DMA_Error_Code)
is
   Deadline : constant Time := Clock + Timeout;
begin
   Result := DMA_No_Error;  -- initially
   Polling : loop
      exit Polling when Status (This, Stream, Transfer_Complete_Indicated);
      if Clock >= Deadline then
         Result := DMA_Timeout_Error;
         return;
      end if;
   end loop Polling;
   Clear_Status (This, Stream, Transfer_Complete_Indicated);
end Poll_For_Completion;
```

In this approach, we compute the deadline as a point on the timeline by adding the value returned from the `Clock` function (i.e., "now") to the time interval specified by the parameter. Then, within the loop, we compare the value of the `Clock` to that deadline.

Finally, with another design approach we can reduce the processor cycles "wasted" when the polled device is not yet ready. Specifically, in the polling loop, when the device has not yet completed the requested function, we can temporarily relinquish the processor so that other tasks within the application can execute. That isn't perfect because we're still checking the device status even though we cannot exit the loop. And it requires other tasks to exist in your design, although that's probably a good idea for other reasons (e.g., logical threads having different, non-harmonic periods). This approach would look like this (an incomplete example):

```
procedure Poll_With_Delay is
   Next_Release : Time;
   Period       : constant Time_Span := Milliseconds (30); -- let's say
begin
   Next_Release := Clock;
   loop
      exit when Status (...);
```

(continues on next page)

(continued from previous page)

```
      Next_Release := Next_Release + Period;
      delay until Next_Release;
   end loop;
end Poll_With_Delay;
```

The code above will check the status of some device every 30 milliseconds (an arbitrary period just for illustration) until the `Status` function result allows the loop to exit. If the device "hangs" the loop is never exited, but as you saw there are ways to address that possibility. When the code does not exit the loop, the next point on the timeline is computed and the task executing the code then suspends, allowing the other tasks in the application to execute. Eventually, the next release point is reached and so the task becomes ready to execute again (and will, subject to priorities).

But how long should the polling task suspend when awaiting the device? We need to suspend long enough for the other tasks to get something done, but not so long that the device isn't handled fast enough. Finding the right balance is often not simple, and is further complicated by the "task switching" time. That's the time it takes to switch the execution context from one task to another, in this case in response to the "delay until" statement suspending the polling task. And it must be considered in both directions: when the delay expires we'll eventually switch back to the polling task.

As you can see, polling is easily expressed but has potentially significant drawbacks and architectural ramifications so it should be avoided as a default approach.

Now let's explore the Ada interrupt facilities.

39.2 Language-Defined Interrupt Model

The Ada language standard defines a model for hardware interrupts, as well as language-defined mechanisms for handling interrupts consistent with that model. The model is defined in Annex C, the "Systems Programming" annex, section 3 "Interrupt Support." The following is the text of that section with only a few simplifications and elisions.

- Interrupts are said to occur. An occurrence of an interrupt is separable into generation and delivery.
  - Generation of an interrupt is the event in the underlying hardware or system that makes the interrupt available to the program.
  - Delivery is the action that invokes part of the program as response to the interrupt occurrence.
- Between generation and delivery, the interrupt occurrence is pending.
- Some or all interrupts may be blocked. When an interrupt is blocked, all occurrences of that interrupt are prevented from being delivered.
- Certain interrupts are reserved. A reserved interrupt is either an interrupt for which user-defined handlers are not supported, or one which already has an attached handler by some other RTL-defined means. The set of reserved interrupts is determined by the hardware and run-time library (RTL).
- Program units can be connected to non-reserved interrupts. While connected, the program unit is said to be attached to that interrupt. The execution of that program unit, the interrupt handler, is invoked upon delivery of the interrupt occurrence.
- While a handler is attached to an interrupt, it is called once for each delivered occurrence of that interrupt.
- The corresponding interrupt is blocked while the handler executes. While an interrupt is blocked, all occurrences of that interrupt are prevented from being delivered.

Whether such occurrences remain pending or are lost is determined by the hardware and the RTL.

- Each interrupt has a default treatment which determines the system's response to an occurrence of that interrupt when no user-defined handler is attached. The set of possible default treatments is defined by the RTL.
- An exception propagated from a handler that is invoked by an interrupt has no effect. In particular, it is not propagated out of the handler, in the same way that exceptions do not propagate outside of task bodies.
- If the `Ceiling_Locking` policy is in effect, the interrupt handler executes with the active priority that is the ceiling priority of the corresponding protected object. ("Protected object" is abbreviated as "PO" for convenience).
- If the hardware or the underlying system holds pending interrupt occurrences, the RTL must provide for later delivery of these occurrences to the program.

(The above is not everything in the model but we can ignore the rest in this introduction.)

Because interrupt occurrences are generated by the hardware and delivered by the underlying system software (run-time library or real-time operating system), the application code is mainly responsible for responding to occurrences. Of course, the application must first configure the relevant external devices so that they generate the expected interrupts.

The actual response is application-specific but is also hardware-specific. The latter often (but not always) requires clearing the interrupt status within the generating device so that the same occurrence is not delivered again.

Furthermore, the standard model requires the underlying software to block further occurrences while the handler executes, and only allow preemption by higher-priory interrupt occurrences (if any). The application handlers are not responsible for these semantics either. As you will see, the choice of program unit used for expressing handlers makes this all very convenient for the developer.

As a consequence, in terms of the response, the application developer must write the specific handlers and attach those handlers to the corresponding interrupts. Attaching the handlers is implemented in the underlying system software, and it is this same underlying software that delivers the occurrences.

We will now explore the Ada facilities in detail. At the end of this chapter we will explore some common idioms using these mechanisms, especially with regard to the handlers' interaction with the rest of the application.

39.3 Interrupt Handlers

Interrupt handling is, by definition, asynchronous: some event occurs that causes the processor to suspend the application, respond to the event, and then resume application execution.

Because these events are asynchronous, the actions performed by the interrupt handler and the application are subject to the same sorts of race conditions as multiple tasks acting on shared data.

For example, a "reader" task may be in the act of reading (copying) the value of some shared variable, only to be preempted by a "writer" task that updates the value of the variable. In that case, when the "reader" task resumes execution, it will finish the read operation but will, as a result, have a value that is partly from the old value and partly from the new value. The effect is unpredictable. An interrupt handler can have the same effect on shared data as the preempting "writer" task that interrupts the "reader" task. This problem is possible for shared data of any type that is not atomically read or written. You can think of large record objects if that helps, but it even applies to some scalars.

That scenario applies even if no explicit tasks are declared in the application. That's because an implicit "environment task" is executing the main subprogram. In that case, the main subprogram is the entire application, but more typically some non-null application code is actively executing in one or more tasks.

But it's not just a matter of tasks. We said that interrupts usually have priorities. Typically that means a higher-priority interrupt will preempt the execution of the handler for a lower-priority interrupt. It's the same issue.

Furthermore, the fact that an interrupt has occurred needs to be communicated to the application, for example to say that updated data are available, perhaps a sensor reading or characters from a serial port. As we said above, we usually don't want to poll for that fact, so the application must be able to suspend until the event has occurred. Often we'll have a dedicated task within the application that suspends, rather than the entire application, but that's an application detail.

Ada's protected objects address all these asynchronous issues. Shared data declared within a protected object can be accessed only via protected procedures or protected entries, both of which execute with mutually exclusive access. Hence no race conditions are possible.

Here is an extremely simple, but realistic, example of a PO. This is not an interrupt handler example — we'll get to that — but it does show a shared variable and a protected procedure that executes with mutually exclusive access no matter how many tasks concurrently call it. The PO provides unique serial numbers.

```
protected Serial_Number is
   procedure Get_Next (Number : out Positive);
private
   Value : Positive := 1;
end Serial_Number;

protected body Serial_Number is

   procedure Get_Next (Number : out Positive) is
   begin
      Number := Value;
      Value := Value + 1;
   end Get_Next;

end Serial_Number;
```

Imagine there are multiple assembly lines creating devices of various sorts. Each device gets a unique serial number. These assembly lines run concurrently, so the calls to `Get_Next` occur concurrently. Without mutually exclusive access to the `Value` variable, multiple devices could get the same serial number.

Protected entries can suspend a caller until some condition is true; in this case, the fact that an interrupt has occurred and been handled. (As we will see, a protected entry is not the only way to synchronize with an accessing task, but it is the most robust and general.)

Here's an example of a PO with a protected entry:

```
protected type Persistent_Signal is
   entry Wait;
   procedure Send;
private
   Signal_Arrived : Boolean := False;
end Persistent_Signal;

protected body Persistent_Signal is
```

(continues on next page)

(continued from previous page)

```
   entry Wait when Signal_Arrived is
   begin
      Signal_Arrived := False;
   end Wait;

   procedure Send is
   begin
      Signal_Arrived := True;
   end Send;

end Persistent_Signal;
```

This is a PO providing a "Persistent Signal" abstraction. It allows a task to wait for a "signal" from another task. The signal is not lost if the receiving task is not already waiting, hence the term "persistent." Specifically, if `Signal_Arrived` is **`False`**, a caller to `Wait` will be suspended until `Signal_Arrived` becomes **`True`**. A caller to Send sets `Signal_Arrived` to **`True`**. If a caller to `Wait` was already present, suspended, it will be allowed to continue execution. If no caller was waiting, eventually some caller will arrive, find `Signal_Arrived` **`True`**, and will be allowed to continue. In either case, the `Signal_Arrived` flag will be set back to **`False`** before the `Wait` caller is released. Protected objects can have a priority assigned, similar to tasks, so they are integrated into the global priority semantics including interrupt priorities.

Therefore, in Ada an interrupt handler is a protected procedure declared within some protected object (PO). A given PO may handle more than one interrupt, and if so, may use one or more protected procedures to do so.

Interrupts can be attached to a protected procedure handler using a mechanism we'll discuss shortly. When the corresponding interrupt occurs, the attached handler is invoked. Any exceptions propagated by the handler's execution are ignored and do not go past the procedure.

While the protected procedure handler executes, the corresponding interrupt is blocked. As a consequence, another occurrence of that same interrupt will not preempt the handler's execution. However, if the hardware does not allow interrupts to be blocked, no blocking occurs and a subsequent occurrence would preempt the current execution of the handler. In that case, your handlers must be written with that possibility in mind. Most targets do block interrupts so we will assume that behavior in the following descriptions.

The standard mutually exclusive access provided to the execution of protected procedures and entries is enforced whether the "call" originates in hardware, via an interrupt, or in the application software, via some task. While any protected action in the PO executes, the corresponding interrupt is blocked, such that another occurrence will not preempt the execution of that actions' procedure or entry body execution in the PO.

On some processors blocked interrupts are lost, they do not persist. However, if the hardware can deliver an interrupt that had been blocked, the Systems Programming Annex requires the handler to be invoked again later, subject to the PO semantics described above.

The default treatment for a given interrupt depends on the RTL implementation. The default may be to jump immediately to system-defined handler that merely loops forever, thereby "hanging" the system and preventing any further execution of the application. On a bare-board target that would be a very common approach. Alternatively the default could be to ignore the interrupt entirely.

As mentioned earlier, some interrupts may be reserved, meaning that the application cannot install a replacement handler. For instance, most bare-board systems include a clock that is driven by a dedicated interrupt. The application cannot (or at least should not) override the interrupt handler for that interrupt. The determination of which interrupts are reserved is RTL-defined. Attempting to attach a user-defined handler for a reserved interrupt raises `Program_Error`, and the existing treatment is unchanged.

39.4 Interrupt Management

Ada defines a standard package that provides a primary type for identifying individual interrupts, as well as subprograms that take a parameter of that type in order to manage the system's interrupts and handlers. The package is named `Ada.Interrupts`, appropriately.

The primary type in that package is named `Interrupt_Id` and is an compiler-defined discrete type, meaning that it is either an integer type (signed or not) or an enumeration type. That representation is guaranteed so you can be sure that `Interrupt_Id` can be used, for example, as the index for an array type.

Package `Ada.Interrupts` provides functions to query whether a given interrupt is reserved, or if an interrupt has a handler attached. Procedures are defined to allow the application to attach and detach handlers, among other things. These procedures allow the application to dynamically manage interrupts. For example, when a new external device is added, perhaps as a "hot spare" replacing a damaged device, or when a new external device is simply connected to the target, the application can arrange to handle the new interrupts without having to recompile the application or restart application execution.

However, typically you will not use these procedures or functions to manage interrupts. In part that's because the architecture is usually static, i.e., the handlers are set up once and then never changed. In that case you won't need to query whether a given exception is reserved at run-time, or to check whether a handler is attached. You'd know that already, as part of the system architecture choices. For the same reasons, another mechanism for attaching handlers is more commonly used, and will be explained in that section. The package's type `Interrupt_Id`, however, will be used extensively.

A child package `Ada.Interrupts.Names` defines a target-dependent set of constants providing meaningful names for the `Interrupt_Id` values the target supports. Both the number of constants and their names are defined by the compiler, reflecting the variations in hardware available. This package and the enclosed constants are used all the time. For the sake of illustration, here is part of the package declaration for a Cortex M4F microcontroller supported by GNAT:

```
package Ada.Interrupts.Names is
   Sys_Tick_Interrupt     : constant Interrupt_ID := 1;
   ...
   EXTI0_Interrupt        : constant Interrupt_ID := 8;
   ....
   DMA1_Stream0_Interrupt : constant Interrupt_ID := 13;
   ...
   HASH_RNG_Interrupt     : constant Interrupt_ID := 80;
   ...
end Ada.Interrupts.Names;
```

Notice `HASH_RNG_Interrupt`, the name for `Interrupt_Id` value 80 on this target. That is the interrupt that the on-chip random number generator hardware uses to signal that a new value is available. We will use this interrupt in an example at the end of this chapter.

The representation chosen by the compiler for `Interrupt_Id` is very likely an integer, as in the above package, so the child package provides readable names for the numeric values. If `Interrupt_Id` is represented as an enumeration type the enumeral values are probably sufficiently readable, but the child package must be provided by the vendor nonetheless.

39.5 Associating Handlers With Interrupts

As we mentioned above, the Ada standard provides two ways to attach handlers to interrupts. One is procedural, described earlier. The other mechanism is automatic, achieved during elaboration of the protected object enclosing the handler procedure. The behavior is not unlike the activation of tasks: declared tasks are activated automatically as a result of their elaboration, whereas dynamically allocated tasks are activated as a result of their allocations.

We will focus exclusively on the automatic, elaboration-driven attachment model because that is the more common usage, and as a result, that is what GNAT supports on bare-board targets. It is also the mechanism that the standard Ravenscar and Jorvik profiles require. Our examples are consistent with those targets.

In the elaboration-based attachment model, we specify the interrupt to be attached to a given protected procedure within a protected object. This interrupt specification occurs within the enclosing protected object declaration. (Details in a moment.) When the enclosing PO is elaborated, the run-time library installs that procedure as the handler for that interrupt. A given PO may contain one or more interrupt handler procedures, as well as any other protected subprograms and entries.

In particular, we can associate an interrupt with a protected procedure by applying the aspect `Attach_Handler` to that procedure as part of its declaration, with the `Interrupt_Id` value as the aspect parameter. The association can also be achieved via a pragma with the same name as the aspect. Strictly speaking, the pragma `Attach_Handler` is obsolescent, but that just means that there is a newer way to make the association (i.e., the aspect). The pragma is not illegal and will remain supported. Because the pragma existed in a version of Ada prior to aspects you will see a lot of existing code using the pragma. You should become familiar with it. There's no language-driven reason to change the source code to use the aspect. New code should arguably use the aspect, but there's no technical reason to prefer one over the other.

Here is an example of a protected object with one protected procedure interrupt handler. It uses the `Attach_Handler` aspect to tie a random number generator interrupt to the `RNG_Controller.Interrupt_Handler` procedure:

```
protected RNG_Controller is
   ...
   entry Get_Random (Value : out UInt32);
private

   Last_Sample    : UInt32 := 0;
   Buffer         : Ring_Buffer;
   Data_Available : Boolean := False;

   procedure Interrupt_Handler with
      Attach_Handler => Ada.Interrupts.Names.HASH_RNG_Interrupt;

end RNG_Controller;
```

That's all that the developer must do to install the handler. The compiler and run-time library do the rest, automatically.

The local variables are declared in the private part, as required by the language, because they are shared data meant to be protected from race conditions. Therefore, the only compile-time access possible is via visible subprograms and entries declare in the visible part. Those subprograms and entries execute with mutually exclusive access so no race conditions are possible, as guaranteed by the language.

Note that procedure `Interrupt_Handler` is declared in the private part of `RNG_Controller`, rather than the visible part. That location is purely a matter of choice (unlike the variables),

but there is a good reason to hide it: application software can call an interrupt handler procedure too. If you don't ever intend for that to happen, have the compiler enforce your intent. An alert code reader will then recognize that clients cannot call that procedure. If, on the other hand, the handler is declared in the visible part, the reader must examine more of the code to determine whether there are any callers in the application code. Granted, a software call to an interrupt handler is rare, but not illegal, so you should state your intent in the code in an enforceable manner.

Be aware that the Ada compiler is allowed to place restrictions on protected procedure handlers. The compiler can restrict the content of the procedure body, for example, or it might forbid calls to the handler from the application software. The rationale is to allow direct invocation by the hardware, to minimize interrupt latency to the extent possible.

For completeness, here's the same `RNG_Controller` protected object using the pragma instead of the aspect to attach the interrupt to the handler procedure:

```
protected RNG_Controller is
   ...
   entry Get_Random (Value : out UInt32);
private

   Last_Sample    : UInt32 := 0;
   Buffer         : Ring_Buffer;
   Data_Available : Boolean := False;

   procedure Interrupt_Handler;
   pragma Attach_Handler (Interrupt_Handler,
                          Ada.Interrupts.Names.HASH_RNG_Interrupt;

end RNG_Controller;
```

As you can see, there isn't much difference. The aspect is somewhat more succinct. (The choice of where to declare the procedure remains the same.)

In this attachment model, protected declarations containing interrupt handlers must be declared at the library level. That means they must be declared in library packages. (Protected objects cannot be library units themselves, just as tasks cannot. They must be declared within some other unit.) Here is the full declaration for the `RNG_Controller` PO declared within a package — in this case within a package body:

```
with Ada.Interrupts.Names;
with Bounded_Ring_Buffers;

package body STM32.RNG.Interrupts is

   package UInt32_Buffers is new Bounded_Ring_Buffers (Content => UInt32);
   use UInt32_Buffers;

   protected RNG_Controller is
      ...
      entry Get_Random (Value : out UInt32);
   private

      Last_Sample    : UInt32 := 0;
      Samples        : Ring_Buffer (Upper_Bound => 9);  -- arbitrary
      Data_Available : Boolean := False;

      procedure Interrupt_Handler with
        Attach_Handler => Ada.Interrupts.Names.HASH_RNG_Interrupt;

   end RNG_Controller;
```

(continues on next page)

(continued from previous page)

```
   ...

end STM32.RNG.Interrupts;
```

But note that we're talking about protected declarations, a technical term that encompasses not only protected types but also anonymously-typed protected objects. In the `RNG_Controller` example, the PO does not have an explicit type declared; it is anonymously-typed. (Task objects can also be anonymously-typed.) You don't have to use a two-step process of first declaring the type and then an object of the type. If you only need one, no explicit type is required.

Although interrupt handler protected types must be declared at library level, the Ada model allows you to have an object of the type declared elsewhere, not necessarily at library level. However, note that the Ravenscar and Jorvik profiles require protected interrupt handler objects — anonymously-typed or not — to be declared at the library level too, for the sake of analysis. The profiles also require the elaboration-based attachment mechanism we have shown. For the sake of the widest applicability, and because with GNAT the most likely use-case involves either Ravenscar or Jorvik, we are following those restrictions in our examples.

39.6 Interrupt Priorities

Many (but not all) processors assign priorities to interrupts, with blocking and preemption among priorities of different levels, much like preemptive priority-based task semantics. Consequently, the priority semantics for interrupt handlers are as if a hardware "task," executing at an interrupt level priority, calls the protected procedure handler.

Interrupt handlers in Ada are protected procedures, which do not have priorities individually, but the enclosing protected object can be assigned a priority that will apply to the handler(s) when executing.

Therefore, protected objects can have priorities assigned using values of subtype `System.Interrupt_Priority`, which are high enough to require the blocking of one or more interrupts. The specific values among the priority subtypes are not standardized but the intent is that interrupt priorities are higher (more urgent) than non-interrupt priorities, as if they are declared like so in package `System`:

```
subtype Any_Priority is Integer range compiler-defined;

subtype Priority is Any_Priority
   range Any_Priority'First .. compiler-defined;

subtype Interrupt_Priority is Any_Priority
   range Priority'Last + 1 .. Any_Priority'Last;
```

For example, here are the subtype declarations in the GNAT compiler for an Arm Cortex M4 target:

```
subtype Any_Priority       is Integer      range 0 .. 255;
subtype Priority           is Any_Priority range Any_Priority'First .. 240;
subtype Interrupt_Priority is Any_Priority range
   Priority'Last + 1  .. Any_Priority'Last;
```

Although the ranges are compiler-defined, when the Systems Programming Annex is implemented the range of `System.Interrupt_Priority` must include at least one value. Vendors are not required to have a distinct priority value in `Interrupt_Priority` for each

hardware interrupt possible on a given target. On a bare-metal target, they probably will have a one-to-one correspondence, but might not in a target with an RTOS or host OS.

A PO containing an interrupt handler procedure must be given a priority within the `Interrupt_Priority` subtype's range. To do so, we apply the aspect `Interrupt_Priority` to the PO. Perhaps confusingly, the aspect and the value's required subtype have the same name.

```
with Ada.Interrupts.Names;  use Ada.Interrupts.Names;
with System;                use System;

package Gyro_Interrupts is

   protected Handler with
      Interrupt_Priority => Interrupt_Priority'Last
   is
   private
      procedure IRQ_Handler;
      pragma Attach_Handler (IRQ_Handler, EXTI2_Interrupt);
   end Handler;

end Gyro_Interrupts;
```

The code above uses the highest (most urgent) interrupt priority value but some other value could be used instead, as long as it is in the `Interrupt_Priority` subtype's range. `Constraint_Error` is raised otherwise.

There is also an alternative pragma, now obsolescent, with the same name as the aspect and subtype. Here is an example:

```
with Ada.Interrupts.Names;  use Ada.Interrupts.Names;

package Gyro_Interrupts is

   protected Handler is
      pragma Interrupt_Priority (245);
   private
      procedure IRQ_Handler;
      pragma Attach_Handler (IRQ_Handler, EXTI2_Interrupt);
   end Handler;

end Gyro_Interrupts;
```

In the above we set the interrupt priority to 245, presumably a value conformant with this specific target. You should be familiar with this pragma too, because there is some much existing code using it. New code should use the aspect, ideally.

If we don't specify the priority for some protected object containing an interrupt handler (using either the pragma or the aspect), the initial priority of protected objects of that type is compiler-defined, but within the range of the subtype `Interrupt_Priority`. Generally speaking, you should specify the priorities per those of the interrupts handled, assuming they have distinct values, so that you can reason concretely about the relative blocking behavior at run-time.

Note that the parameter specifying the priority is optional for the `Interrupt_Priority` pragma. When none is given, the effect is as if the value `Interrupt_Priority'Last` was specified.

```
with Ada.Interrupts.Names;  use Ada.Interrupts.Names;

package Gyro_Interrupts is
```

(continues on next page)

(continued from previous page)

```
   protected Handler is
      pragma Interrupt_Priority;
   private
      ...
   end Handler;

end Gyro_Interrupts;
```

No pragma parameter is given in the above, therefore `Gyro_Interrupts.Handler` executes at `Interrupt_Priority'Last` when invoked.

While an interrupt handler is executing, the corresponding interrupt is blocked. Therefore, the same interrupt will not be delivered again while the handler is executing. Plus, the protected object semantics mean that no software caller is also concurrently executing within the protected object. So no data race conditions are possible. If the system does not support blocking, however, the interrupt is not blocked when the handler executes.

In addition, when interrupt priorities are involved, hardware blocking typically extends to interrupts of equal or lower priority.

You should understand that a higher-priority interrupt could preempt the execution of a lower-priority interrupt's handler. Handlers do not define "critical sections" in which the processor cannot be preempted at all (other than the case of the highest priority interrupt).

Preemption does not cause data races, usually, because the typical case is to have a given protected object handle only one interrupt. It follows that only that one interrupt handler has visibility to the protected data in any given protected object, therefore only that one handler can update it. Any preempting handler would be in a different protected object, hence the preempting handler could not possibly update the data in the preempted handler's PO. No data race condition is possible.

However, protected objects can contain handlers for more than one interrupt. In that case, depending on the priorities, the execution of a higher-priority handler could preempt the execution of a lower priority handler in that same PO. Because each handler in the PO can update the local protected data, these data are effectively shared among asynchronous writers. Data race conditions are, as a result, possible.

The solution to the case of multiple handlers in a single PO is to assign the PO a priority not less than the highest of the interrupt priorities for which it contains handlers. That's known as the "ceiling priority" and works the same as when applying the ceiling for the priorities of caller tasks in the software. Then, whenever any interrupt handled by that PO is delivered, the handler executes at the ceiling priority, not necessarily the priority of the specific interrupt handled. All interrupts at a priority equal or lower than the PO priority are blocked, so no preemption by another handler within that same PO is possible. As a result, a handler for a higher priority interrupt must be in a different PO. If that higher priority handler is invoked, it can indeed preempt the execution of the handler for the lower priority interrupt in another PO. But because these two handlers will not be in the same PO, they will not share the data, so again no race condition is possible.

Note also that software callers will execute at the PO priority as well, so their priority may be increased during that execution. As you can see, the Ceiling Priority Protocol integrates application-level priorities, for tasks and protected objects, with interrupt-level priorities for interrupt handlers.

The Ceiling Locking Protocol is requested by specifying the `Ceiling_Locking` policy (see ARM D.3) to the pragma `Locking_Policy`. Both Ravenscar and Jorvik do so, automatically.

39.7 Common Design Idioms

In this section we explore some of the common idioms used when writing interrupt handlers in Ada.

39.7.1 Parameterizing Handlers

Suppose we have more than one instance of a kind of device. For example, multiple DMA controllers are often available on a System-on-Chip such as an Arm microcontroller. We can simplify our code by defining a device driver **type**, with one object of the type per supported hardware device. This is the same abstract data type (ADT) approach we'd take for software objects in application code, and in general for device drivers when multiple hardware instances are available.

We can also apply the ADT approach to interrupt handlers when we have multiple devices of a given kind that can generate interrupts. In this case, the type will be fully implemented as a protected type containing at least one interrupt handling procedure, with or without additional protected procedures or entries.

As is the case with abstract data types in general, we can tailor each object with discriminants defined with the type, in order to "parameterize" the type and thus allow distinct objects to have different characteristics. For example, we might define a bounded buffer ADT with a discriminant specifying the upper bound, so that distinct objects of the single type could have different bounds. In the case of hardware device instances, one of these parameters will often specify the device being driven, but we can also specify other device-specific characteristics. In particular, for interrupt handler types both the interrupt to handle and the interrupt priority can be discriminants. That's possible because the aspects/pragmas do not require their values to be specified via literals, unlike what was done in the `RNG_Controller` example above.

For example, here is the declaration for an interrupt handler ADT named `DMA_Interrupt_Controller`. This type manages the interrupts for a given DMA device, known as a `DMA_Controller`. Type `DMA_Controller` is itself an abstract data type, declared elsewhere.

```
protected type DMA_Interrupt_Controller
  (Controller   : not null access DMA_Controller;
   Stream       : DMA_Stream_Selector;
   IRQ          : Ada.Interrupts.Interrupt_Id;
   IRQ_Priority : System.Interrupt_Priority)
with
   Interrupt_Priority => IRQ_Priority
is

   procedure Start_Transfer
     (Source      : Address;
      Destination : Address;
      Data_Count  : UInt16);

   procedure Abort_Transfer (Result : out DMA_Error_Code);

   procedure Clear_Transfer_State;

   function Buffer_Error return Boolean;

   entry Wait_For_Completion (Status : out DMA_Error_Code);

private
```

(continues on next page)

(continued from previous page)

```
   procedure Interrupt_Handler with Attach_Handler => IRQ;

   No_Transfer_In_Progess : Boolean := True;
   Last_Status            : DMA_Error_Code := DMA_No_Error;
   Had_Buffer_Error       : Boolean := False;

end DMA_Interrupt_Controller;
```

In the above, the `Controller` discriminant provides an access value designating the specific `DMA_Controller` device instance to be managed. Each DMA device supports multiple independent conversion "streams" so the `Stream` discriminant specifies that characteristic. The `IRQ` and `IRQ_Priority` discriminants specify the handler values for that specific device and stream. These discriminant values are then used in the `Interrupt_Priority` pragma and the `Attach_Handler` aspect in the private part. ("IRQ" is a command handler name across programming languages, and is an abbreviation for "interrupt request.")

Here then are the declarations for two instances of the interrupt handler type:

```
DMA2_Stream0 : DMA_Interrupt_Controller
   (Controller   => DMA_2'Access,
    Stream       => Stream_0,
    IRQ          => DMA2_Stream0_Interrupt,
    IRQ_Priority => Interrupt_Priority'Last);

DMA2_Stream5 : DMA_Interrupt_Controller
   (Controller   => DMA_2'Access,
    Stream       => Stream_5,
    IRQ          => DMA2_Stream5_Interrupt,
    IRQ_Priority => Interrupt_Priority'Last);
```

In the above, both objects `DMA2_Stream0` and `DMA2_Stream5` are associated with the same object named `DMA2`, an instance of the `DMA_Controller` type. The difference in the objects is the stream that generates the interrupts they handle. One object handles `Stream_0` interrupts and the other handles those from `Stream_5`. Package `Ada.Interrupts.Names` for this target (for GNAT) declares distinct names for the streams and devices generating the interrupts, hence `DMA2_Stream0_Interrupt` and `DMA2_Stream5_Interrupt`.

On both objects the priority is the highest interrupt priority (and hence the highest overall), `Interrupt_Priority'Last`. That will work, but of course all interrupts will be blocked during the execution of the handler, as well as the execution of any other subprogram or entry in the same PO. That means that the clock interrupt is blocked for that interval, for example. We use that interrupt value in our demonstrations for expedience, but in a real application you'd almost certainly use a lower value specific to the interrupt handled.

We could reduce the number of discriminants, and also make the code more robust, by taking advantage of the requirement that type `Interrupt_Id` be a discrete type. As such, it can be used as the index type into arrays. Here is a driver example with only the `Interrupt_Id` discriminant required:

```
Device_Priority : constant array (Interrupt_Id) of Interrupt_Priority := ( ... );

protected type Device_Interface
  (IRQ : Interrupt_Id)
with
   Interrupt_Priority => Device_Priority (IRQ)
is
   procedure Handler with Attach_Handler => IRQ;
   ...
end Device_Interface;
```

Now we use the one IRQ discriminant both to assign the priorities for distinct objects and

to attach their handler procedures.

39.7.2 Multi-Level Handlers

Interrupt handlers are intended to be very brief, in part because they prevent lower priority interrupts and application tasks from executing.

However, complete interrupt processing may require more than just the short protected procedure handler's activity. Therefore, two levels of handling are common: the protected procedure interrupt handler and a task. The handler does the least possible and then signals the task to do the rest.

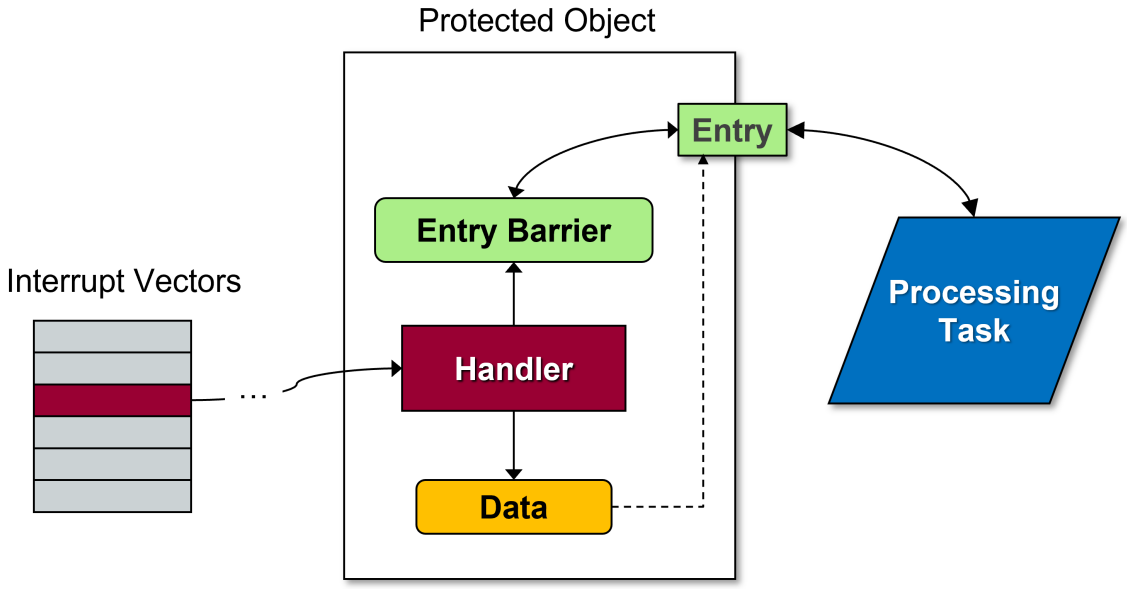
Of course, sometimes the handler does everything required and just needs to signal the application. In that case, the awakened task does no further "interrupt processing" but simply uses the result.

Regardless, the same issues apply: 1) How do application tasks synchronize with the handlers? Assuming the task is not polling the event, at some point the task must stop what it was doing and suspend, waiting for the handler to signal it. 2) Once synchronized, how can the handlers pass data to the tasks?

Using protected objects for interrupt handling provides an efficient mechanism that elegantly addresses both issues. In addition, when data communication is not required, another standard language mechanism is available. These give rise to two design idioms. We will explore both.

In the first idiom, the protected object contains a protected entry as well as the interrupt handler procedure. The task suspends on the entry when ready for the handler results, controlled by the barrier condition as usual. The protected handler procedure responds to interrupts, managing data (if any) as required. When ready, based on what the handler does, the handler sets the entry barrier to `True`. That allows the suspended task to execute the entry body. The entry body can do whatever is required, possibly just copying the local protected data to the entry parameters. Of course, the entry may be used purely for synchronizing with the handler, i.e., suspending and resuming the task, in which case there would be no parameters passed.

The image below depicts this design.



The DMA_Interrupt_Controller described earlier actually uses this design.

```
protected type DMA_Interrupt_Controller
  (Controller   : not null access DMA_Controller;
   Stream       : DMA_Stream_Selector;
   IRQ          : Ada.Interrupts.Interrupt_Id;
   IRQ_Priority : System.Interrupt_Priority)
with
   Interrupt_Priority => IRQ_Priority
is

   procedure Start_Transfer
     (Source      : Address;
      Destination : Address;
      Data_Count  : UInt16);

   procedure Abort_Transfer (Result : out DMA_Error_Code);

   procedure Clear_Transfer_State;

   function Buffer_Error return Boolean;

   entry Wait_For_Completion (Status : out DMA_Error_Code);

private

   procedure Interrupt_Handler with Attach_Handler => IRQ;

   No_Transfer_In_Progess : Boolean := True;
   Last_Status            : DMA_Error_Code := DMA_No_Error;
   Had_Buffer_Error       : Boolean := False;

end DMA_Interrupt_Controller;
```

The client application code (task) calls procedure Start_Transfer to initiate the DMA transaction, then presumably goes off to accomplish something else, and eventually calls the Wait_For_Completion entry. That call blocks the task if the device has not yet completed the DMA transfer. The interrupt handler procedure, cleverly named Interrupt_Handler,

handles the interrupts, one of which indicates that the transfer has completed. Device errors also generate interrupts so the handler detects them and acts accordingly. Eventually, the handler sets the barrier to **True** and the task can get the status via the entry parameter.

```
procedure Start_Transfer
   (Source      : Address;
    Destination : Address;
    Data_Count  : UInt16)
is
begin
   No_Transfer_In_Progess := False;
   Had_Buffer_Error := False;
   Clear_All_Status (Controller.all, Stream);
   Start_Transfer_with_Interrupts
     (Controller.all,
      Stream,
      Source,
      ...,
      Enabled_Interrupts =>
        (Half_Transfer_Complete_Interrupt => False,
         others  => True));
end Start_Transfer;

entry Wait_For_Completion
   (Status : out DMA_Error_Code)
when
   No_Transfer_In_Progress
is
begin
   Status := Last_Status;
end Wait_For_Completion;
```

In the above, the entry barrier consists of the Boolean variable `No_Transfer_In_Progress`. Procedure `Start_Transfer` first sets that variable to **False** so that a caller to `Wait_For_Completion` will suspend until the transaction completes one way or the other. Eventually, the handler sets `No_Transfer_In_Progress` to **True**.

```
procedure Interrupt_Handler is
   subtype Checked_Status_Flag is DMA_Status_Flag with
      Static_Predicate => Checked_Status_Flag /= Half_Transfer_Complete_Indicated;
begin
   for Flag in Checked_Status_Flag loop
      if Status (Controller.all, Stream, Flag) then
         case Flag is
            when FIFO_Error_Indicated =>
               Last_Status := DMA_FIFO_Error;
               Had_Buffer_Error := True;
               No_Transfer_In_Progess := not Enabled (Controller.all, Stream);
            when Direct_Mode_Error_Indicated =>
               Last_Status := DMA_Direct_Mode_Error;
               No_Transfer_In_Progess := not Enabled (Controller.all, Stream);
            when Transfer_Error_Indicated =>
               Last_Status := DMA_Transfer_Error;
               No_Transfer_In_Progess := True;
            when Transfer_Complete_Indicated =>
               Last_Status := DMA_No_Error;
               No_Transfer_In_Progess := True;
         end case;
         Clear_Status (Controller.all, Stream, Flag);
      end if;
   end loop;
```

(continues on next page)

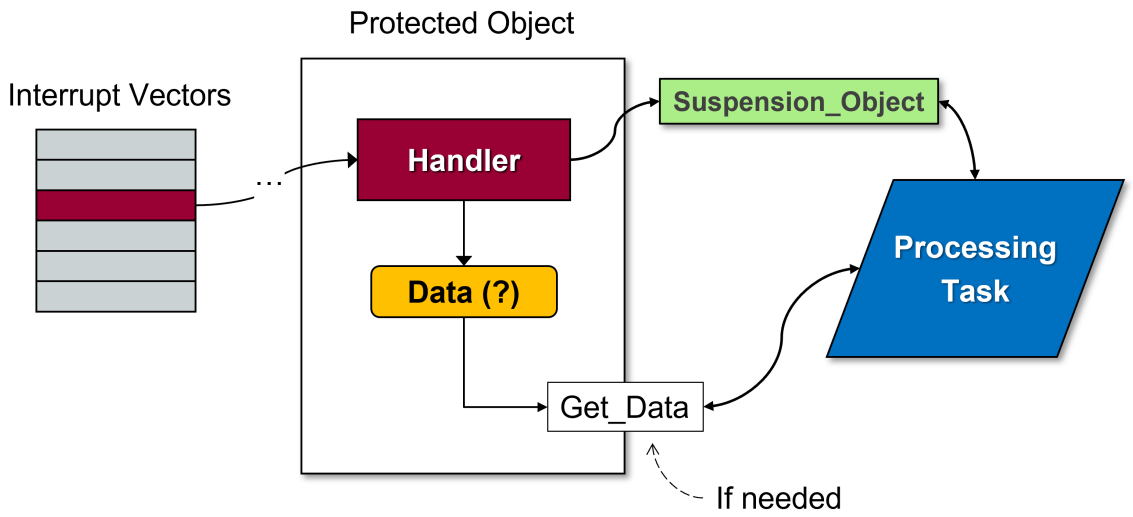
(continued from previous page)

```
end Interrupt_Handler;
```

This device driver doesn't bother with interrupts indicating that transfers are half-way complete so that specific status flag is ignored. In response to an interrupt, the handler checks each status flag to determine what happened. Note the resulting assignments for both the protected variables `Last_Status` and `No_Transfer_In_Progess`. The variable `No_Transfer_In_Progess` controls the entry, and `Last_Status` is passed to the caller via the entry formal parameter. When the interrupt handler exits, the resulting protected action allows the now-enabled entry call to execute.

In the second design idiom, the handler again synchronizes with the application task, but not using a protected entry.

The image below depicts this design.



In this approach, the task synchronizes with the handler using a `Suspension_Object` variable. The type `Suspension_Object` is defined in the language standard package `Ada.Synchronous_Task_Control`. Essentially, the type provides a thread-safe Boolean flag. Callers can suspend themselves (hence the package name) until another task resumes them by setting the flag to **`True`**. Here's the package declaration, somewhat elided:

```
package Ada.Synchronous_Task_Control is

   type Suspension_Object is limited private;

   procedure Set_True (S : in out Suspension_Object);

   procedure Set_False (S : in out Suspension_Object);

   function Current_State (S : Suspension_Object) return Boolean;

   procedure Suspend_Until_True (S : in out Suspension_Object);

private
   ...
end Ada.Synchronous_Task_Control;
```

Tasks call `Suspend_Until_True` to suspend themselves on some object of the type passed

as the parameter. The call suspends the caller until that object becomes **True**. If it is already **True**, the caller continues immediately. Objects of type Suspension_Object are automatically set to **False** initially, and become **True** via a call to Set_True. As part of the return from a call to Suspend_Until_True, the flag is set back to **False**. As a result, you probably only need those two subprograms.

The interrupt handler procedure responds to interrupts, eventually setting some visible Suspension_Object to **True** so that the caller will be signaled and resume. Here's an example showing both the protected object, with handler, and a Suspension_Object declaration:

```
with Ada.Interrupts.Names;          use Ada.Interrupts.Names;
with Ada.Synchronous_Task_Control;  use Ada.Synchronous_Task_Control;

package Gyro_Interrupts is

   Data_Available : Suspension_Object;

   protected Handler is
      pragma Interrupt_Priority;
   private
      procedure IRQ_Handler
        with Attach_Handler => EXTI2_Interrupt;
   end Handler;

end Gyro_Interrupts;
```

In the code above, Gyro_Interrupts.Data_Available is the Suspension_Object variable visible both to the interrupt handler PO and the client task.

EXTI2_Interrupt is "external interrupt number 2" on this particular microcontroller. It is connected to an external device, not on the SoC itself. Specifically, it is connected to a L3GD20 MEMS motion sensor[278], a three-axis digital output gyroscope. This gyroscope can be either polled or generate interrupts when ever data are available. The handler is very simple:

```
with STM32.EXTI;  use STM32.EXTI;

package body Gyro_Interrupts is

   protected body Handler is

      procedure IRQ_Handler is
      begin
         if External_Interrupt_Pending (EXTI_Line_2) then
            Clear_External_Interrupt (EXTI_Line_2);
            Set_True (Data_Available);
         end if;
      end IRQ_Handler;

   end Handler;

end Gyro_Interrupts;
```

The handler simply clears the interrupt and resumes the caller task via a call to Set_True on the variable declared in the package spec.

The lack of an entry means that no data can be passed to the task via entry parameters. It is possible to pass data to the task but doing so would require an additional protected procedure or function.

[278] https://www.st.com/en/mems-and-sensors/l3gd20.html

The gyroscope hardware device interface is in package L3GD20. Here are the pertinent parts:

```
package L3GD20 is

   type Three_Axis_Gyroscope is tagged limited private;

   procedure Initialize
      (This        : in out Three_Axis_Gyroscope;
       Port        : Any_SPI_Port;
       Chip_Select : Any_GPIO_Point);

   ...

   procedure Enable_Data_Ready_Interrupt  (This : in out Three_Axis_Gyroscope);

   ...

   type Angle_Rate is new Integer_16;

   type Angle_Rates is record
      X : Angle_Rate;  -- pitch, per Figure 2, pg 7 of the Datasheet
      Y : Angle_Rate;  -- roll
      Z : Angle_Rate;  -- yaw
   end record with Size => 3 * 16;

   ...

   procedure Get_Raw_Angle_Rates
      (This  : Three_Axis_Gyroscope;
       Rates : out Angle_Rates);

   ...

end L3GD20;
```

With those packages available, we can write a simple main program to use the gyro. The real demo displayed the readings on an LCD but we've elided all those irrelevant details:

```
with Gyro_Interrupts;
with Ada.Synchronous_Task_Control;  use Ada.Synchronous_Task_Control;
with L3GD20;                        use L3GD20;
with STM32.Board;
...

procedure Demo_L3GD20 is

   Axes : L3GD20.Angle_Rates;

   ...

   procedure Await_Raw_Angle_Rates (Rates : out L3GD20.Angle_Rates) is
   begin
      Suspend_Until_True (Gyro_Interrupts.Data_Available);
      L3GD20.Get_Raw_Angle_Rates (STM32.Board.Gyro, Rates);
   end Await_Raw_Angle_Rates;

   ...

begin
   Configure_Gyro;
   Configure_Gyro_Interrupt;
```

(continues on next page)

(continued from previous page)

```
   ...
   loop
      Await_Raw_Angle_Rates (Axes);
      ...
   end loop;
end Demo_L3GD20;
```

The demo is a main procedure, even though we've been describing the client application code in terms of tasks. The main procedure is executed by the implicit "environment task" so it all still works. `Await_Raw_Angle_Rates` suspends (if necessary) on `Gyro_Interrupts.Data_Available` and then calls `L3GD20.Get_Raw_Angle_Rates` to get the rate values.

The operations provided by `Suspension_Object` are faster than protected entries, and noticeably so. However, that performance difference is due to the fact that `Suspension_Object` provides so much less capability than entries. In particular, there is no notion of protected actions, nor expressive entry barriers for condition synchronization, nor parameters to pass data while synchronized. Most importantly, there is no caller queue, so at most one caller can be waiting at a time on any given `Suspension_Object` variable. You'll get `Program_Error` if you try. Protected entries should be your first design choice. Note that the Ravenscar restrictions can make use of `Suspension_Object` much more likely.

39.8 Final Points

As you can see, the semantics of protected objects are a good fit for interrupt handling. However, other forms of handlers are allowed to be supported. For example, the compiler and RTL for a specific target may include support for interrupts generated by a device known to be available with that target. For illustration, let's imagine the target always has a serial port backed by a UART. In addition to handlers as protected procedure without parameters, perhaps the compiler and RTL support interrupt handlers with a single parameter of type `Unsigned_8` (or larger) as supported by the UART.

Overall, the interrupt model defined and supported by Ada is quite close to the canonical model presented by most programming languages, in part because it matches the model presented by typical hardware.

CHAPTER

FORTY

CONCLUSION

In the introduction to this course, we defined an "embedded system" as a computer that is part of a larger system, in which the capability to compute is not the larger system's primary function. These computers are said to be "embedded" in the larger system. That, in itself, sets this kind of programming apart from the more typical host-oriented programming. But the context also implies fewer resources are available, especially memory and electrical power, as well as processor power. Add to those limitations a frequent reliability requirement and you have a demanding context for development.

Using Ada can help you in this context, and for less cost than other languages, if you use it well. Many industrial organizations developing critical embedded software use Ada for that reason. Our goal in this course was to get you started in using it well.

To that end, we spent a lot of time talking about how to use Ada to do low level programming, such as how to specify the layout of types, how to map variables of those types to specific addresses, when and how to do unchecked programming (and how not to), and how to determine the validity of incoming data. Ada has a lot of support for this activity so there was much to explore.

Likewise, we examined development using Ada in combination with other languages, a not uncommon approach. Specifically, we saw how to interface with code and data written in other languages, and how (and why) to work with assembly language. Development in just one language is becoming less common over time so these were important aspects to know.

One of the more distinctive activities of embedded programming involves interacting with the outside world via embedded devices, such as A/D converters, timers, actuators, sensors, and so forth. (This can be one of the more entertaining activities as well.) We covered how to interact with these memory-mapped devices using representation specifications, data structures that simplified the functional code, and time-honored aspects of software engineering, including abstract data types.

Finally, we explored how to handle interrupts in Ada, another distinctive part of embedded systems programming. As we saw, Ada has extensive support for handling interrupts, using the same building blocks — protected objects — used in concurrent programming. These constructs provide a way to handle interrupts that is as portable as possible, in what is otherwise a very hardware-specific endeavor.

In the course, we mentioned a library of freely-available device drivers in Ada known as the Ada Driver Library (ADL). The ADL is a good resource for learning how Ada can be used to develop software for embedded systems using real-world devices and processors. Becoming familiar with it would be a good place to go next. Contributing to it would be even better! The ADL is available on GitHub for both non-proprietary and commercial use here: https://github.com/AdaCore/Ada_Drivers_Library.

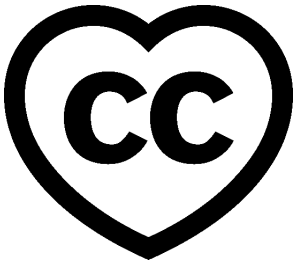
Copyright © 2022, AdaCore

This book is published under a CC BY-SA license, which means that you can copy, redistribute, remix, transform, and build upon the content for any purpose, even commercially, as long as you give appropriate credit, provide a link to the license, and indicate if changes were made. If you remix, transform, or build upon the material, you must distribute your contributions under the same license as the original. You can find license details on this page[279]



This course presents an overview of the new features of the latest Ada 2022 standard.

This document was written by Maxim Reznik and reviewed by Richard Kenner.

Note: The code examples in this course use an 80-column limit, which is a typical limit for Ada code. Note that, on devices with a small screen size, some code examples might be difficult to read.

Note: Each code example from this book has an associated "code block metadata", which contains the name of the "project" and an MD5 hash value. This information is used to identify a single code example.

You can find all code examples in a zip file, which you can download from the learn website[280]. The directory structure in the zip file is based on the code block metadata. For example, if you're searching for a code example with this metadata:

- Project: Courses.Intro_To_Ada.Imperative_Language.Greet
- MD5: cba89a34b87c9dfa71533d982d05e6ab

you will find it in this directory:

```
projects/Courses/Intro_To_Ada/Imperative_Language/Greet/
cba89a34b87c9dfa71533d982d05e6ab/
```

In order to use this code example, just follow these steps:

1. Unpack the zip file;
2. Go to target directory;
3. Start GNAT Studio on this directory;
4. Build (or compile) the project;
5. Run the application (if a main procedure is available in the project).

CHAPTER

FORTYONE

INTRODUCTION

This is a collection of short code examples demonstrating new features of the Ada 2022 Standard[281] as they are implemented in GNAT Ada compiler.

To use some of these features, you may need to use a compiler command line switch or pragma. Compilers starting with GNAT Community Edition 2021[282] or GCC 11[283] use `pragma Ada_2022;` or the `-gnat2022` switch. Older compilers use `pragma Ada_2020;` or `-gnat2020`. To use the square brackets syntax or `'Reduce` expressions, you need `pragma Extensions_Allowed (On);` or the `-gnatX` switch.

CHAPTER

FORTYTWO

'IMAGE ATTRIBUTE FOR ANY TYPE

Note: Attribute 'Image for any type is supported by

- GNAT Community Edition 2020 and latter
- GCC 11

42.1 'Image attribute for a value

Since the publication of the Technical Corrigendum 1[286] in February 2016, the 'Image attribute can now be applied to a value. So instead of My_Type'Image (Value), you can just write Value'Image, as long as the Value is a name[287]. These two statements are equivalent:

```
Ada.Text_IO.Put_Line (Ada.Text_IO.Page_Length'Image);

Ada.Text_IO.Put_Line
  (Ada.Text_IO.Count'Image (Ada.Text_IO.Page_Length));
```

42.2 'Image attribute for any type

In Ada 2022, you can apply the 'Image attribute to any type, including records, arrays, access types, and private types. Let's see how this works. We'll define array, record, and access types and corresponding objects and then convert these objects to strings and print them:

Listing 1: main.adb

```
1  pragma Ada_2022;
2
3  with Ada.Text_IO;
4
5  procedure Main is
6     type Vector is array (Positive range <>) of Integer;
7
8     V1 : aliased Vector := [1, 2, 3];
9
10    type Text_Position is record
11       Line, Column : Positive;
```

(continues on next page)

[286] https://reznikmm.github.io/ada-auth/rm-4-NC/RM-0-1.html
[287] https://reznikmm.github.io/ada-auth/rm-4-NC/RM-4-1.html#S0091

(continued from previous page)

```
12    end record;
13
14    Pos : constant Text_Position := (Line => 10, Column => 3);
15
16    type Vector_Access is access all Vector;
17
18    V1_Ptr : constant Vector_Access := V1'Access;
19
20 begin
21    Ada.Text_IO.Put_Line (V1'Image);
22    Ada.Text_IO.Put_Line (Pos'Image);
23    Ada.Text_IO.New_Line;
24    Ada.Text_IO.Put_Line (V1_Ptr'Image);
25 end Main;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.Image_Attribute
MD5: 47945f0f8a4ba37b838f87b7e5acaa49
```

Runtime output

```
[ 1,  2,  3]

(LINE =>  10,
 COLUMN =>  3)

(access 7ffd7e562358)
```

```
$ gprbuild -q -P main.gpr
  Build completed successfully.
$ ./main
  [ 1,  2,  3]
  (LINE =>  10,
   COLUMN =>  3)
  (access 7fff64b23988)
```

Note the square brackets in the array image output. In Ada 2022, array aggregates could be written *this way* (page 1245)!

CHAPTER

FORTYTHREE

REDEFINING THE 'IMAGE ATTRIBUTE

In Ada 2022, you can redefine 'Image attribute for your type, though the syntax to do this has been changed several times. Let's see how it works in GNAT Community 2021.

Note: Redefining attribute 'Image is supported by

- GNAT Community Edition 2021 (using Text_Buffers)
- GNAT Community Edition 2020 (using Text_Output.Utils)
- GCC 11 (using Text_Output.Utils)

In our example, let's redefine the 'Image attribute for a location in source code. To do this, we provide a new Put_Image aspect for the type:

Listing 1: main.adb

```
1  pragma Ada_2022;
2
3  with Ada.Text_IO;
4  with Ada.Strings.Text_Buffers;
5
6  procedure Main is
7
8     type Source_Location is record
9        Line   : Positive;
10       Column : Positive;
11    end record
12      with Put_Image => My_Put_Image;
13
14    procedure My_Put_Image
15      (Output : in out Ada.Strings.Text_Buffers.Root_Buffer_Type'Class;
16       Value  : Source_Location);
17
18    procedure My_Put_Image
19      (Output : in out Ada.Strings.Text_Buffers.Root_Buffer_Type'Class;
20       Value  : Source_Location)
21    is
22       Line   : constant String := Value.Line'Image;
23       Column : constant String := Value.Column'Image;
24       Result : constant String :=
25         Line (2 .. Line'Last) & ':' & Column (2 .. Column'Last);
26    begin
27        Output.Put (Result);
28    end My_Put_Image;
29
30    Line_10 : constant Source_Location := (Line => 10, Column => 1);
31
32 begin
```

(continues on next page)

(continued from previous page)

```
33    Ada.Text_IO.Put_Line (Line_10'Image);
34 end Main;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.Image_Redefine
MD5: a4a6df87eea66d0a2bcaac9c4cccbe4a
```

Runtime output

```
10:1
```

43.1 What's the Root_Buffer_Type?

Let's see how it's defined in the `Ada.Strings.Text_Buffers` package.

```
type Root_Buffer_Type is abstract tagged limited private;

procedure Put
  (Buffer : in out Root_Buffer_Type;
   Item   : in     String) is abstract;
```

In addition to `Put`, there are also `Wide_Put`, `Wide_Wide_Put`, `Put_UTF_8`, `Wide_Put_UTF_16`. And also `New_Line`, `Increase_Indent`, `Decrease_Indent`.

43.2 Outdated draft implementation

GNAT Community Edition 2020 and GCC 11 both provide a draft implementation that's incompatible with the Ada 2022 specification. For those versions, `My_Put_Image` looks like:

```
procedure My_Put_Image
  (Sink  : in out Ada.Strings.Text_Output.Sink'Class;
   Value : Source_Location)
is
   Line   : constant String := Value.Line'Image;
   Column : constant String := Value.Column'Image;
   Result : constant String :=
     Line (2 .. Line'Last) & ':' & Column (2 .. Column'Last);
begin
    Ada.Strings.Text_Output.Utils.Put_UTF_8 (Sink, Result);
end My_Put_Image;
```

CHAPTER

FORTYFOUR

USER-DEFINED LITERALS

Note: User-defined literals are supported by

- GNAT Community Edition 2020
- GCC 11

In Ada 2022, you can define string, integer, or real literals for your types. The compiler will convert such literals to your type at run time using a function you provide. To do so, specify one or more new aspects:

- `Integer_Literal`
- `Real_Literal`
- `String_Literal`

For our example, let's define all three for a simple type and see how they work. For simplicity, we use a `Wide_Wide_String` component for the internal representation:

Listing 1: main.adb

```
pragma Ada_2022;

with Ada.Wide_Wide_Text_IO;
with Ada.Characters.Conversions;

procedure Main is

   type My_Type (Length : Natural) is record
      Value : Wide_Wide_String (1 .. Length);
   end record
     with String_Literal => From_String,
       Real_Literal      => From_Real,
       Integer_Literal   => From_Integer;

   function From_String (Value : Wide_Wide_String) return My_Type is
      ((Length => Value'Length, Value => Value));

   function From_Real (Value : String) return My_Type is
      ((Length => Value'Length,
        Value  => Ada.Characters.Conversions.To_Wide_Wide_String (Value)));

   function From_Integer (Value : String) return My_Type renames From_Real;

   procedure Print (Self : My_Type) is
   begin
      Ada.Wide_Wide_Text_IO.Put_Line (Self.Value);
   end Print;

```

(continues on next page)

(continued from previous page)

```
begin
   Print ("Test ""string""");
   Print (123);
   Print (16#DEAD_BEEF#);
   Print (2.99_792_458e+8);
end Main;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.User_Defined_Literals
MD5: 3a4a12aa148b6845a1130e818e16c405
```

Runtime output

```
Test "string"
123
16#DEAD_BEEF#
2.99_792_458e+8
```

As you see, real and integer literals are converted to strings while preserving the formatting in the source code, while string literals are decoded: `From_String` is passed the specified string value. In all cases, the compiler translates these literals into function calls.

44.1 Turn Ada into JavaScript

Do you know that *'5'+3* in JavaScript is *53*?

```
> '5'+3
'53'
```

Now we can get the same result in Ada! But before we do, we need to define a custom `+` operator:

Listing 2: main.adb

```
pragma Ada_2022;

with Ada.Wide_Wide_Text_IO;
with Ada.Characters.Conversions;

procedure Main is

   type My_Type (Length : Natural) is record
      Value : Wide_Wide_String (1 .. Length);
   end record
     with String_Literal => From_String,
       Real_Literal      => From_Real,
       Integer_Literal   => From_Integer;

   function "+" (Left, Right : My_Type) return My_Type is
     (Left.Length + Right.Length, Left.Value & Right.Value);

   function From_String (Value : Wide_Wide_String) return My_Type is
      ((Length => Value'Length, Value => Value));

   function From_Real (Value : String) return My_Type is
      ((Length => Value'Length,
        Value  => Ada.Characters.Conversions.To_Wide_Wide_String (Value)));
```

(continues on next page)

(continued from previous page)

```
24
25    function From_Integer (Value : String) return My_Type renames From_Real;
26
27    procedure Print (Self : My_Type) is
28    begin
29       Ada.Wide_Wide_Text_IO.Put_Line (Self.Value);
30    end Print;
31
32 begin
33    Print ("5" + 3);
34 end Main;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.User_Defined_Literals_JS
MD5: 9f41f61b1f4bc03cbe245cd8e0288e4f
```

Runtime output

```
53
```

Jokes aside, this feature is very useful. For example it allows a "native-looking API" for *big integers* (page 1265).

CHAPTER

FORTYFIVE

ADVANCED ARRAY AGGREGATES

Note: These array aggregates are supported by

- GNAT Community Edition 2020
- GCC 11

45.1 Square brackets

In Ada 2022, you can use square brackets in array aggregates. Using square brackets simplifies writing both empty aggregates and single-element aggregates. Consider this:

Listing 1: show_square_brackets.ads

```
pragma Ada_2022;
pragma Extensions_Allowed (On);

package Show_Square_Brackets is

   type Integer_Array is array (Positive range <>) of Integer;

   Old_Style_Empty : Integer_Array := (1 .. 0 => <>);
   New_Style_Empty : Integer_Array := [];

   Old_Style_One_Item : Integer_Array := (1 => 5);
   New_Style_One_Item : Integer_Array := [5];

end Show_Square_Brackets;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.Square_Brackets
MD5: fb4638717d4a12c1dae8e646705ddf17
```

Short summary for parentheses and brackets

- Record aggregates use parentheses
- *Container aggregates* (page 1249) use square brackets
- Array aggregates can use both square brackets and parentheses, but parentheses usage is obsolescent

45.2 Iterated Component Association

There is a new kind of component association:

```
Vector : Integer_Array := [for J in 1 .. 5 => J * 2];
```

This association starts with **for** keyword, just like a quantified expression. It declares an index parameter that you can use in the computation of a component.

Iterated component associations can nest and can be nested in another association (iterated or not). Here we use this to define a square matrix:

```
Matrix : array (1 .. 3, 1 .. 3) of Positive :=
 [for J in 1 .. 3 =>
   [for K in 1 .. 3 => J * 10 + K]];
```

Iterated component associations in this form provide both element indices and values, just like named component associations:

```
Data : Integer_Array (1 .. 5) :=
  [for J in 2 .. 3 => J, 5 => 5, others => 0];
```

Here Data contains (0, 2, 3, 0, 5), not (2, 3, 5, 0, 0).

Another form of iterated component association corresponds to a positional component association and provides just values, but no element indices:

```
Vector_2 : Integer_Array := [for X of Vector => X / 2];
```

You cannot mix these forms in a single aggregate.

It's interesting that such aggregates were originally proposed more than 25 years ago!

Complete code snippet:

Listing 2: show_iterated_component_association.adb

```
pragma Ada_2022;
pragma Extensions_Allowed (On);  --  for square brackets

with Ada.Text_IO;

procedure Show_Iterated_Component_Association is

   type Integer_Array is array (Positive range <>) of Integer;

   Old_Style_Empty : Integer_Array := (1 .. 0 => <>);
   New_Style_Empty : Integer_Array := [];

   Old_Style_One_Item : Integer_Array := (1 => 5);
   New_Style_One_Item : Integer_Array := [5];

   Vector : constant Integer_Array := [for J in 1 .. 5 => J * 2];

   Matrix : constant array (1 .. 3, 1 .. 3) of Positive :=
     [for J in 1 .. 3 =>
       [for K in 1 .. 3 => J * 10 + K]];

   Data : constant Integer_Array (1 .. 5) :=
     [for J in 2 .. 3 => J, 5 => 5, others => 0];

   Vector_2 : constant Integer_Array := [for X of Vector => X / 2];
```

CHAPTER

FORTYSIX

CONTAINER AGGREGATES

Note: Container aggregates are supported by

- GNAT Community Edition 2021
- GCC 11

Ada 2022 introduces container aggregates, which can be used to easily create values for vectors, lists, maps, and other aggregates. For containers such as maps, the aggregate must use named associations to provide keys and values. For other containers it uses positional associations. Only square brackets are allowed. Here's an example:

Listing 1: main.adb

```
pragma Ada_2022;

with Ada.Text_IO;
with Ada.Containers.Vectors;
with Ada.Containers.Ordered_Maps;

procedure Main is

   package Int_Vectors is new Ada.Containers.Vectors
     (Positive, Integer);

   X : constant Int_Vectors.Vector := [1, 2, 3];

   package Float_Maps is new Ada.Containers.Ordered_Maps
     (Integer, Float);

   Y : constant Float_Maps.Map := [-10 => 1.0, 0 => 2.5, 10 => 5.51];
begin
   Ada.Text_IO.Put_Line (X'Image);
   Ada.Text_IO.Put_Line (Y'Image);
end Main;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.Container_Aggregates_1
MD5: dd1dd78890d4bf6c78b79d56abba332d
```

Runtime output

```
[ 1,  2,  3]

[-10 =>  1.00000E+00,  0 =>  2.50000E+00,  10 =>  5.51000E+00]
```

At run time, the compiler creates an empty container and populates it with elements one by one. If you define a new container type, you can specify a new `Aggregate` aspect to enable container aggregates for your container and let the compiler know what subprograms to use to construct the aggregate:

Listing 2: main.adb

```
pragma Ada_2022;

procedure Main is

   package JSON is
      type JSON_Value is private
        with Integer_Literal => To_JSON_Value;

      function To_JSON_Value (Text : String) return JSON_Value;

      type JSON_Array is private
        with Aggregate => (Empty       => New_JSON_Array,
                           Add_Unnamed => Append);

      function New_JSON_Array return JSON_Array;

      procedure Append
        (Self  : in out JSON_Array;
         Value : JSON_Value) is null;

   private
      type JSON_Value is null record;
      type JSON_Array is null record;

      function To_JSON_Value (Text : String) return JSON_Value
        is (null record);

      function New_JSON_Array return JSON_Array is (null record);
   end JSON;

   List : JSON.JSON_Array := [1, 2, 3];
   -------------------------------------
begin
   --  Equivalent old initialization code
   List := JSON.New_JSON_Array;
   JSON.Append (List, 1);
   JSON.Append (List, 2);
   JSON.Append (List, 3);
end Main;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.Container_Aggregates_2
MD5: 9cf1fefa4a725083c50794146d5cbde7
```

The equivalent for maps is:

Listing 3: main.adb

```
pragma Ada_2022;

procedure Main is

   package JSON is
      type JSON_Value is private
```

(continues on next page)

(continued from previous page)

```
        with Integer_Literal => To_JSON_Value;

      function To_JSON_Value (Text : String) return JSON_Value;

      type JSON_Object is private
        with Aggregate => (Empty     => New_JSON_Object,
                           Add_Named => Insert);

      function New_JSON_Object return JSON_Object;

      procedure Insert
        (Self  : in out JSON_Object;
         Key   : Wide_Wide_String;
         Value : JSON_Value) is null;

   private
      type JSON_Value is null record;
      type JSON_Object is null record;

      function To_JSON_Value (Text : String) return JSON_Value
        is (null record);

      function New_JSON_Object return JSON_Object is (null record);
   end JSON;

   Object : JSON.JSON_Object := ["a" => 1, "b" => 2, "c" => 3];
   ------------------------------------------------------------
begin
   --  Equivalent old initialization code
   Object := JSON.New_JSON_Object;
   JSON.Insert (Object, "a", 1);
   JSON.Insert (Object, "b", 2);
   JSON.Insert (Object, "c", 3);
end Main;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.Container_Aggregates_3
MD5: 758ced718aa9a4eefa32325543eb3b1e
```

You can't specify both Add_Named and Add_Unnamed subprograms for the same type. This prevents you from defining JSON_Value with both array and object aggregates present. But we can define conversion functions for array and object and get code almost as dense as the same code in native JSON. For example:

Listing 4: main.adb

```
pragma Ada_2022;

procedure Main is

   package JSON is
      type JSON_Value is private
        with Integer_Literal => To_Value, String_Literal => To_Value;

      function To_Value (Text : String) return JSON_Value;
      function To_Value (Text : Wide_Wide_String) return JSON_Value;

      type JSON_Object is private
        with Aggregate => (Empty     => New_JSON_Object,
                           Add_Named => Insert);
```

(continues on next page)

(continued from previous page)

```
      function New_JSON_Object return JSON_Object;

      procedure Insert
        (Self  : in out JSON_Object;
         Key   : Wide_Wide_String;
         Value : JSON_Value) is null;

      function From_Object (Self : JSON_Object) return JSON_Value;

      type JSON_Array is private
        with Aggregate => (Empty       => New_JSON_Array,
                           Add_Unnamed => Append);

      function New_JSON_Array return JSON_Array;

      procedure Append
        (Self  : in out JSON_Array;
         Value : JSON_Value) is null;

      function From_Array (Self : JSON_Array) return JSON_Value;

   private
      type JSON_Value is null record;
      type JSON_Object is null record;
      type JSON_Array is null record;

      function To_Value (Text : String) return JSON_Value is
        (null record);
      function To_Value (Text : Wide_Wide_String) return JSON_Value is
        (null record);
      function New_JSON_Object return JSON_Object is
        (null record);
      function New_JSON_Array return JSON_Array is
        (null record);
      function From_Object (Self : JSON_Object) return JSON_Value is
        (null record);
      function From_Array (Self : JSON_Array) return JSON_Value is
        (null record);
   end JSON;

   function "+" (X : JSON.JSON_Object) return JSON.JSON_Value
     renames JSON.From_Object;
   function "-" (X : JSON.JSON_Array) return JSON.JSON_Value
     renames JSON.From_Array;

   Offices : JSON.JSON_Array :=
     [+["name"   => "North American Office",
        "phones" => -[1_877_787_4628,
                      1_866_787_4232,
                      1_212_620_7300],
        "email"  => "info@adacore.com"],
      +["name"   => "European Office",
        "phones" => -[33_1_49_70_67_16,
                      33_1_49_70_05_52],
        "email"  => "info@adacore.com"]];
   ------------------------------------------------------------------
begin
   --  Equivalent old initialization code is too long to print it here
   null;
end Main;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.Container_Aggregates_4
MD5: 3e8d96bbcf77e2c63fb87dcf313b98f1
```

The `Offices` variable is supposed to contain this value:

```
[{"name"  : "North American Office",
  "phones": [18777874628,
             18667874232,
             12126207300],
  "email" : "info@adacore.com"},
 {"name"  : "European Office",
  "phones": [33149706716,
             33149700552],
  "email" : "info@adacore.com"}]
```

CHAPTER

FORTYSEVEN

DELTA AGGREGATES

Note: Delta aggregates are supported by

- GNAT Community Edition 2019
- GCC 9

Sometimes you need to create a copy of an object, but with a few modifications. Before Ada 2022, doing this involves a dummy object declaration or an aggregate with associations for each property. The dummy object approach doesn't work in contract aspects or when there are limited components. On the other hand, re-listing properties in an large aggregate can be very tedious and error-prone. So, in Ada 2022, you can use a *delta aggregate* instead.

47.1 Delta aggregate for records

The delta aggregate for a record type looks like this:

```
type Vector is record
   X, Y, Z : Float;
end record;

Point_1 : constant Vector := (X => 1.0, Y => 2.0, Z => 3.0);

Projection_1 : constant Vector := (Point_1 with delta Z => 0.0);
```

The more components you have, the more you will like the delta aggregate.

47.2 Delta aggregate for arrays

You can also use delta aggregates for arrays to change elements, but not bounds. Moreover, it only works for one-dimensional arrays of non-limited components.

```
type Vector_3D is array (1 .. 3) of Float;

Point_2 : constant Vector_3D := [1.0, 2.0, 3.0];
Projection_2 : constant Vector_3D := [Point_2 with delta 3 => 0.0];
```

You can use parentheses for array aggregates, but you can't use square brackets for record aggregates.

Here is the complete code snippet:

Listing 1: main.adb

```
pragma Ada_2022;

with Ada.Text_IO;

procedure Main is

   type Vector is record
      X, Y, Z : Float;
   end record;

   Point_1 : constant Vector := (X => 1.0, Y => 2.0, Z => 3.0);
   Projection_1 : constant Vector := (Point_1 with delta Z => 0.0);

   type Vector_3D is array (1 .. 3) of Float;

   Point_2 : constant Vector_3D := [1.0, 2.0, 3.0];
   Projection_2 : constant Vector_3D := [Point_2 with delta 3 => 0.0];
begin
   Ada.Text_IO.Put (Float'Image (Projection_1.X));
   Ada.Text_IO.Put (Float'Image (Projection_1.Y));
   Ada.Text_IO.Put (Float'Image (Projection_1.Z));
   Ada.Text_IO.New_Line;
   Ada.Text_IO.Put (Float'Image (Projection_2 (1)));
   Ada.Text_IO.Put (Float'Image (Projection_2 (2)));
   Ada.Text_IO.Put (Float'Image (Projection_2 (3)));
   Ada.Text_IO.New_Line;
end Main;
```

CHAPTER

FORTYEIGHT

TARGET NAME SYMBOL (@)

Note: Target name symbol is supported by

- GNAT Community Edition 2019
- GCC 9

Ada 2022 introduces a new symbol, `@`, which can only appear on the right hand side of an assignment statement. This symbol acts as the equivalent of the name on the left hand side of that assignment statement. It was introduced to avoid code duplication: instead of retyping a (potentially long) name, you can use `@`. This symbol denotes a constant, so you can't pass it into [`in`] `out` arguments of a subprogram.

As an example, let's calculate some statistics for `My_Data` array:

Listing 1: statistics.ads

```
pragma Ada_2022;

package Statistics is

   type Statistic is record
      Count : Natural := 0;
      Total : Float := 0.0;
   end record;

   My_Data : array (1 .. 5) of Float := [for J in 1 .. 5 => Float (J)];

   Statistic_For_My_Data : Statistic;

end Statistics;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.Assignment_Tagged_Intro
MD5: 5cc813a4a22d3acc8418b0c1c6df3877
```

To do this, we loop over `My_Data` elements:

Listing 2: main.adb

```
pragma Ada_2022;
with Ada.Text_IO;

procedure Main is

   type Statistic is record
      Count : Natural := 0;
```

(continues on next page)

(continued from previous page)

```
      Total : Float := 0.0;
   end record;

   My_Data : constant array (1 .. 5) of Float :=
     [for J in 1 .. 5 => Float (J)];

   Statistic_For_My_Data : Statistic;

begin
   for Data of My_Data loop
      Statistic_For_My_Data.Count := @ + 1;
      Statistic_For_My_Data.Total := @ + Data;
   end loop;

   Ada.Text_IO.Put_Line (Statistic_For_My_Data'Image);
end Main;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.Assignment_Tagged_2
MD5: 10dd019f4c09bc950895a93b3a88b778
```

Runtime output

```
(COUNT =>  5,
 TOTAL =>  1.50000E+01)
```

Each right hand side is evaluated only once, no matter how many @ symbols it contains. Let's verify this by introducing a function call that prints a line each time it's called:

Listing 3: main.adb

```
pragma Ada_2022;
with Ada.Text_IO;

procedure Main is

   My_Data : array (1 .. 5) of Float := [for J in 1 .. 5 => Float (J)];

   function To_Index (Value : Positive) return Positive is
   begin
      Ada.Text_IO.Put_Line ("To_Index is called.");
      return Value;
   end To_Index;

begin
   My_Data (To_Index (1)) := @ ** 2 - 3.0 * @;
   Ada.Text_IO.Put_Line (My_Data'Image);
end Main;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.Assignment_Tagged_3
MD5: 98d6afbaea5c0f6cd2bebe6b39962ad3
```

Runtime output

```
To_Index is called.

[-2.00000E+00,  2.00000E+00,  3.00000E+00,  4.00000E+00,  5.00000E+00]
```

This use of @ may look a bit cryptic, but it's the best solution that was found. Unlike other languages (e.g., `sum += x;` in C), this approach lets you use @ an arbitrary number of times within the right hand side of an assignment statement.

48.1 Alternatives

In C++, the previous statement could be written with a reference type (one line longer!):

```
auto& a = my_data[to_index(1)];
a = a * a - 3.0 * a;
```

In Ada 2022, you can use a similar renaming:

```
declare
   A renames My_Data (To_Index (1));
begin
   A := A ** 2 - 3.0 * A;
end;
```

Here we use a new short form of the rename declaration, but this still looks too heavy, and even worse, it can't be used for discriminant-dependent components.

CHAPTER

FORTYNINE

ENUMERATION REPRESENTATION

Note: Enumeration representation attributes are supported by

- GNAT Community Edition 2019
- GCC 9

Enumeration types in Ada are represented as integers at the machine level. But there are actually two mappings from enumeration to integer: a literal position and a representation value.

49.1 Literal positions

Each enumeration literal has a corresponding position in the type declaration. We can easily obtain it from the `Type'Pos (Enum)` attribute.

Listing 1: main.adb

```
with Ada.Text_IO;
with Ada.Integer_Text_IO;

procedure Main is
begin
   Ada.Text_IO.Put ("Pos(False) =");
   Ada.Integer_Text_IO.Put (Boolean'Pos (False));
   Ada.Text_IO.New_Line;
   Ada.Text_IO.Put ("Pos(True)  =");
   Ada.Integer_Text_IO.Put (Boolean'Pos (True));
end Main;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.Enum_Val.Pos
MD5: de7c39f83f7df231dd648606579996a8
```

Runtime output

```
Pos(False) =           0
Pos(True)  =           1
```

For the reverse mapping, we use `Type'Val (Int)`:

Listing 2: main.adb

```
with Ada.Text_IO;

procedure Main is
begin
   Ada.Text_IO.Put_Line (Boolean'Val (0)'Image);
   Ada.Text_IO.Put_Line (Boolean'Val (1)'Image);
end Main;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.Enum_Val.Val
MD5: 43f712d25552970bccc4c0c84089d927
```

Runtime output

```
FALSE
TRUE
```

49.2 Representation values

The representation value defines the *internal* code, used to store enumeration values in memory or CPU registers. By default, enumeration representation values are the same as the corresponding literal positions, but you can redefine them. Here, we created a copy of **Boolean** type and assigned it a custom representation.

In Ada 2022, we can get an integer value of the representation with **Type**'Enum_Rep(Enum) attribute:

Listing 3: main.adb

```
with Ada.Text_IO;
with Ada.Integer_Text_IO;

procedure Main is
   type My_Boolean is new Boolean;
   for My_Boolean use (False => 3, True => 6);
begin
   Ada.Text_IO.Put ("Enum_Rep(False) =");
   Ada.Integer_Text_IO.Put (My_Boolean'Enum_Rep (False));
   Ada.Text_IO.New_Line;
   Ada.Text_IO.Put ("Enum_Rep(True)  =");
   Ada.Integer_Text_IO.Put (My_Boolean'Enum_Rep (True));
end Main;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.Enum_Val.Enum_Rep
MD5: 384ad9de7124c8131aa83ab71da58964
```

Runtime output

```
Enum_Rep(False) =           3
Enum_Rep(True)  =           6
```

And, for the reverse mapping, we can use **Type**'Enum_Val (Int):

Listing 4: main.adb

```
with Ada.Text_IO;
with Ada.Integer_Text_IO;

procedure Main is
   type My_Boolean is new Boolean;
   for My_Boolean use (False => 3, True => 6);
begin
   Ada.Text_IO.Put_Line (My_Boolean'Enum_Val (3)'Image);
   Ada.Text_IO.Put_Line (My_Boolean'Enum_Val (6)'Image);

   Ada.Text_IO.Put ("Pos(False) =");
   Ada.Integer_Text_IO.Put (My_Boolean'Pos (False));
   Ada.Text_IO.New_Line;
   Ada.Text_IO.Put ("Pos(True)  =");
   Ada.Integer_Text_IO.Put (My_Boolean'Pos (True));
end Main;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.Enum_Val.Enum_Val
MD5: 6e06202472d4cf0ea7c68461ac7afcb1
```

Runtime output

```
FALSE
TRUE
Pos(False) =          0
Pos(True)  =          1
```

Note that the `'Val(X)/'Pos(X)` behaviour still is the same.

Custom representations can be useful for integration with a low level protocol or hardware.

49.3 Before Ada 2022

This doesn't initially look like an important feature, but let's see how we'd do the equivalent with Ada 2012 and earlier versions. First, we need an integer type of matching size, then we instantiate `Ada.Unchecked_Conversion`. Next, we call `To_Int/From_Int` to work with representation values. And finally an extra type conversion is needed:

Listing 5: main.adb

```
with Ada.Text_IO;
with Ada.Integer_Text_IO;
with Ada.Unchecked_Conversion;

procedure Main is

   type My_Boolean is new Boolean;
   for My_Boolean use (False => 3, True => 6);
   type My_Boolean_Int is range 3 .. 6;
   for My_Boolean_Int'Size use My_Boolean'Size;

   function To_Int is new Ada.Unchecked_Conversion
     (My_Boolean, My_Boolean_Int);

   function From_Int is new Ada.Unchecked_Conversion
```

(continues on next page)

(continued from previous page)

```
16       (My_Boolean_Int, My_Boolean);
17
18    begin
19       Ada.Text_IO.Put ("To_Int(False) =");
20       Ada.Integer_Text_IO.Put (Integer (To_Int (False)));
21       Ada.Text_IO.New_Line;
22       Ada.Text_IO.Put ("To_Int(True)  =");
23       Ada.Integer_Text_IO.Put (Integer (To_Int (True)));
24       Ada.Text_IO.New_Line;
25       Ada.Text_IO.Put ("From_Int (3)  =");
26       Ada.Text_IO.Put_Line (From_Int (3)'Image);
27       Ada.Text_IO.New_Line;
28       Ada.Text_IO.Put ("From_Int (6)  =");
29       Ada.Text_IO.Put_Line (From_Int (6)'Image);
30    end Main;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.Enum_Val.Conv
MD5: 7c7624ed024b26036389f77dbd6cb109
```

Runtime output

```
To_Int(False) =          3
To_Int(True)  =          6
From_Int (3)  =TRUE

From_Int (6)  =TRUE
```

Even with all that, this solution doesn't work for generic formal type (because T'Size must be a static value)!

We should note that these new attributes may already be familiar to GNAT users because they've been in the GNAT compiler for many years.

CHAPTER

FIFTY

BIG NUMBERS

Note: Big numbers are supported by

- GNAT Community Edition 2020
- GCC 11
- GCC 10 (draft, no user defined literals)

Ada 2022 introduces big integers and big real types.

50.1 Big Integers

The package `Ada.Numerics.Big_Numbers.Big_Integers` contains a type `Big_Integer` and corresponding operations such as comparison (`=`, `<`, `>`, `<=`, `>=`), arithmetic (`+`, `-`, `*`, `/`, **`rem`**, **`mod`**, **`abs`**, `**`), `Min`, `Max` and `Greatest_Common_Divisor`. The type also has `Integer_Literal` and `Put_Image` aspects redefined, so you can use it in a natural manner.

```
Ada.Text_IO.Put_Line (Big_Integer'Image(2 ** 256));
```

```
115792089237316195423570985008687907853269984665640564039457584007913129639936
```

50.2 Tiny RSA implementation

Note: Note that you shouldn't use `Big_Numbers` for cryptography because it's vulnerable to timing side-channels attacks.

We can implement the RSA algorithm[307] in a few lines of code. The main operation of RSA is (m^d) mod n. But you can't just write `m ** d`, because these are really big numbers and the result won't fit into memory. However, if you keep intermediate result **`mod`** n during the m^d calculation, it will work. Let's write this operation as a function:

Listing 1: power_mod.ads

```
1 pragma Ada_2022;
2
3 with Ada.Numerics.Big_Numbers.Big_Integers;
4 use  Ada.Numerics.Big_Numbers.Big_Integers;
```

(continues on next page)

[307] https://en.wikipedia.org/wiki/RSA_(cryptosystem)

(continued from previous page)

```
5
6  --  Calculate M ** D mod N
7
8  function Power_Mod (M, D, N : Big_Integer) return Big_Integer;
```

Listing 2: power_mod.adb

```
1  function Power_Mod (M, D, N : Big_Integer) return Big_Integer is
2
3     function Is_Odd (X : Big_Integer) return Boolean is
4       (X mod 2 /= 0);
5
6     Result : Big_Integer := 1;
7     Exp    : Big_Integer := D;
8     Mult   : Big_Integer := M mod N;
9  begin
10    while Exp /= 0 loop
11       --  Loop invariant is Power_Mod'Result = Result * Mult**Exp mod N
12       if Is_Odd (Exp) then
13          Result := (Result * Mult) mod N;
14       end if;
15
16       Mult := Mult ** 2 mod N;
17       Exp := Exp / 2;
18    end loop;
19
20    return Result;
21 end Power_Mod;
```

Code block metadata

```
Project: Courses.Ada_2022_Whats_New.Big_Integers
MD5: 217c2aa3535952b68e2f088d262e6f60
```

Let's check this with the example from Wikipedia[308]. In that example, the *public key* is (n = 3233, e = 17) and the message is m = 65. The encrypted message is m^e mod n = 65^{17} mod 3233 = 2790 = c.

```
Ada.Text_IO.Put_Line (Power_Mod (M => 65, D => 17, N => 3233)'Image);
```

```
2790
```

To decrypt it with the public key (n = 3233, d = 413), we need to calculate c^d mod n = 2790^{413} mod 3233:

```
Ada.Text_IO.Put_Line (Power_Mod (M => 2790, D => 413, N => 3233)'Image);
```

```
65
```

So 65 is the original message m. Easy!

Here is the complete code snippet:

Listing 3: main.adb

```
1  pragma Ada_2022;
2
3  with Ada.Text_IO;
```

(continues on next page)

[308] https://en.wikipedia.org/wiki/RSA_(cryptosystem)

(continued from previous page)

```
with Ada.Numerics.Big_Numbers.Big_Integers;
use  Ada.Numerics.Big_Numbers.Big_Integers;

procedure Main is

   --  Calculate M ** D mod N

   function Power_Mod (M, D, N : Big_Integer) return Big_Integer is

      function Is_Odd (X : Big_Integer) return Boolean is
        (X mod 2 /= 0);

         Result : Big_Integer := 1;
         Exp    : Big_Integer := D;
         Mult   : Big_Integer := M mod N;
   begin
      while Exp /= 0 loop
         --  Loop invariant is Power_Mod'Result = Result * Mult**Exp mod N
         if Is_Odd (Exp) then
            Result := (Result * Mult) mod N;
         end if;

         Mult := Mult ** 2 mod N;
         Exp := Exp / 2;
      end loop;

      return Result;
   end Power_Mod;

begin
   Ada.Text_IO.Put_Line (Big_Integer'Image (2 ** 256));
   --  Encrypt:
   Ada.Text_IO.Put_Line (Power_Mod (M => 65, D => 17, N => 3233)'Image);
   --  Decrypt:
   Ada.Text_IO.Put_Line (Power_Mod (M => 2790, D => 413, N => 3233)'Image);
end Main;
```

Code block metadata

Project: Courses.Ada_2022_Whats_New.Big_Numbers_Tiny_RSA
MD5: 6178da9d6998db6d51f31fd5c7cc5391
```

Runtime output

```
115792089237316195423570985008687907853269984665640564039457584007913129639936
2790
65
```

50.3 Big Reals

In addition to Big_Integer, Ada 2022 provides Big Reals[309].

CHAPTER

FIFTYONE

INTERFACING C VARIADIC FUNCTIONS

Note: Variadic convention is supported by

- GNAT Community Edition 2020
- GCC 11

In C, variadic functions[313] take a variable number of arguments and an ellipsis as the last parameter of the declaration. A typical and well-known example is:

```
int printf (const char* format, ...);
```

Usually, in Ada, we bind such a function with just the parameters we want to use:

```
procedure printf_double
  (format : Interfaces.C.char_array;
   value  : Interfaces.C.double)
     with Import,
       Convention    => C,
       External_Name => "printf";
```

Then we call it as a normal Ada function:

```
printf_double (Interfaces.C.To_C ("Pi=%f"), Ada.Numerics.π);
```

Unfortunately, doing it this way doesn't always work because some ABI[314]s use different calling conventions for variadic functions. For example, the AMD64 ABI[315] specifies:

- %rax — with variable arguments passes information about the number of vector registers used;
- %xmm0–%xmm1 — used to pass and return floating point arguments.

This means, if we write (in C):

```
printf("%d", 5);
```

The compiler will place 0 into %rax, because we don't pass any float argument. But in Ada, if we write:

```
procedure printf_int
  (format : Interfaces.C.char_array;
   value  : Interfaces.C.int)
     with Import,
       Convention    => C,
```

(continues on next page)

[313] https://en.cppreference.com/w/c/variadic
[314] https://en.wikipedia.org/wiki/Application_binary_interface
[315] https://software.intel.com/sites/default/files/article/402129/mpx-linux64-abi.pdf

(continued from previous page)

```
       External_Name => "printf";

printf_int (Interfaces.C.To_C ("d=%d"), 5);
```

the compiler won't use the `%rax` register at all. (You can't include any float argument because there's no float parameter in the Ada wrapper function declaration.) As result, you will get a crash, stack corruption, or other undefined behavior.

To fix this, Ada 2022 provides a new family of calling convention names — `C_Variadic_N`:

> The convention `C_Variadic_n` is the calling convention for a variadic C function taking *n* fixed parameters and then a variable number of additional parameters.

Therefore, the correct way to bind the `printf` function is:

```
procedure printf_int
  (format : Interfaces.C.char_array;
   value  : Interfaces.C.int)
     with Import,
       Convention    => C_Variadic_1,
       External_Name => "printf";
```

And the following call won't crash on any supported platform:

```
printf_int (Interfaces.C.To_C ("d=%d"), 5);
```

Without this convention, problems cause by this mismatch can be very hard to debug. So, this is a very useful extension to the Ada-to-C interfacing facility.

Here is the complete code snippet:

Listing 1: main.adb

```
with Interfaces.C;

procedure Main is

   procedure printf_int
     (format : Interfaces.C.char_array;
      value  : Interfaces.C.int)
     with Import,
       Convention    => C_Variadic_1,
       External_Name => "printf";

begin
   printf_int (Interfaces.C.To_C ("d=%d"), 5);
end Main;
```

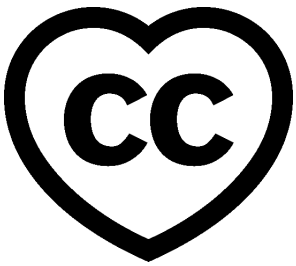
Part VI

Ada for the C++ or Java Developer

Warning: This version of the website contains UNPUBLISHED contents. Please do not share it externally!

Copyright © 2013 – 2022, AdaCore

This book is published under a CC BY-SA license, which means that you can copy, redistribute, remix, transform, and build upon the content for any purpose, even commercially, as long as you give appropriate credit, provide a link to the license, and indicate if changes were made. If you remix, transform, or build upon the material, you must distribute your contributions under the same license as the original. You can find license details on this page[318]



This document will present the Ada language using terminology and examples that are familiar to developers that understand the C++ or Java languages.

This document was prepared by Quentin Ochem, with contributions and review from Richard Kenner, Albert Lee, and Ben Brosgol.

Note: The code examples in this course use an 80-column limit, which is a typical limit for Ada code. Note that, on devices with a small screen size, some code examples might be difficult to read.

Note: Each code example from this book has an associated "code block metadata", which contains the name of the "project" and an MD5 hash value. This information is used to identify a single code example.

You can find all code examples in a zip file, which you can download from the learn website[319]. The directory structure in the zip file is based on the code block metadata. For example, if you're searching for a code example with this metadata:

- Project: Courses.Intro_To_Ada.Imperative_Language.Greet
- MD5: cba89a34b87c9dfa71533d982d05e6ab

you will find it in this directory:

```
projects/Courses/Intro_To_Ada/Imperative_Language/Greet/
cba89a34b87c9dfa71533d982d05e6ab/
```

In order to use this code example, just follow these steps:

1. Unpack the zip file;
2. Go to target directory;
3. Start GNAT Studio on this directory;
4. Build (or compile) the project;
5. Run the application (if a main procedure is available in the project).

CHAPTER

FIFTYTWO

PREFACE

Nowadays it seems like talking about programming languages is a bit passé. The technical wars of the past decade have subsided and today we see a variety of high-level and well-established languages offering functionality that can meet the needs of any programmer.

Python, Java, C++, C#, and Visual Basic are recent examples. Indeed, these languages make it easier to write code very quickly, are very flexible, offer features with highly dynamic behavior, and some even allow compilers to deduce the developer's probable intent.

Why, then, talk about yet another language? Well, by addressing the general programming market, the aforementioned languages have become poorly suited for working within the domain of high-integrity systems. In highly reliable, secure and safe applications such as those found in and around airplanes, rockets, satellites, trains, and in any device whose failure could jeopardize human life or critical assets, the programming languages used must support the high standard of software engineering necessary to maintain the integrity of the system.

The concept of verification — the practice of showing that the system behaves and performs as intended — is key in such environments. Verification can be accomplished by some combination of review, testing, static analysis, and formal proof techniques. The increasing reliance on software and increasing complexity of today's systems has made this task more difficult. Technologies and practices that might have been perfectly acceptable ten or fifteen years ago are insufficient today. Thankfully, the state of the art in analysis and proof tools and techniques has also advanced.

The latest revisions of the Ada language, Ada 2005 and Ada 2012, make enhanced software integrity possible. From its inception in the 1980s, Ada was designed to meet the requirements of high-integrity systems, and continues to be well-suited for the implementation of critical embedded or native applications. And it has been receiving increased attention recently. Every language revision has enhanced expressiveness in many areas. Ada 2012, in particular, has introduced new features for contract-based programming that are valuable to any project where verification is part of the engineering lifecycle. Along with these language enhancements, Ada compiler and tool technology has also kept pace with general computing developments over the past few years. Ada development environments are available on a wide range of platforms and are being used for the most demanding applications.

It is no secret that we at AdaCore are very enthusiastic about Ada, but we will not claim that Ada is always the solution; Ada is no more a silver bullet than any other language. In some domains other languages make sense because of the availability of particular libraries or development frameworks. For example, C++ and Java are considered good choices for desktop programs or applications where a shortened time to market is a major objective. Other areas, such as website programming or system administration, tend to rely on different formalisms such as scripting and interpreted languages. The key is to select the proper technical approach, in terms of the language and tools, to meet the requirements. Ada's strength is in areas where reliability is paramount.

Learning a new language shouldn't be complicated. Programming paradigms have not evolved much since object oriented programming gained a foothold, and the same

paradigms are present one way or another in many widely used languages. This document will thus give you an overview of the Ada language using analogies to C++ and Java — these are the languages you're already likely to know. No prior knowledge of Ada is assumed. If you are working on an Ada project now and need more background, if you are interested in learning to program in Ada, or if you need to perform an assessment of possible languages to be used for a new development, this guide is for you.

CHAPTER

FIFTYTHREE

BASICS

Ada implements the vast majority of programming concepts that you're accustomed to in C++ and Java: classes, inheritance, templates (generics), etc. Its syntax might seem peculiar, though. It's not derived from the popular C style of notation with its ample use of brackets; rather, it uses a more expository syntax coming from Pascal. In many ways, Ada is a simpler language — its syntax favors making it easier to conceptualize and read program code, rather than making it faster to write in a cleverly condensed manner. For example, full words like **`begin`** and **`end`** are used in place of curly braces. Conditions are written using **`if`**, **`then`**, **`elsif`**, **`else`**, and **`end if`**. Ada's assignment operator does not double as an expression, smoothly eliminating any frustration that could be caused by `=` being used where `==` should be.

All languages provide one or more ways to express comments. In Ada, two consecutive hyphens `--` mark the start of a comment that continues to the end of the line. This is exactly the same as using `//` for comments in C++ and Java. There is no equivalent of `/* ... */` block comments in Ada; use multiple `--` lines instead.

Ada compilers are stricter with type and range checking than most C++ and Java programmers are used to. Most beginning Ada programmers encounter a variety of warnings and error messages when coding more creatively, but this helps detect problems and vulnerabilities at compile time — early on in the development cycle. In addition, dynamic checks (such as array bounds checks) provide verification that could not be done at compile time. Dynamic checks are performed at run time, similar to what is done in Java.

Ada identifiers and reserved words are case insensitive. The identifiers `VAR`, `var` and `VaR` are treated as the same; likewise **`begin`**, **`BEGIN`**, **`Begin`**, etc. Language-specific characters, such as accents, Greek or Russian letters, and Asian alphabets, are acceptable to use. Identifiers may include letters, digits, and underscores, but must always start with a letter. There are 73 reserved keywords in Ada that may not be used as identifiers, and these are:

abort	else	null	select
abs	elsif	of	separate
abstract	end	or	some
accept	entry	others	subtype
access	exception	out	synchronized
aliased	exit	overriding	tagged
all	for	package	task
and	function	pragma	terminate
array	generic	private	then
at	goto	procedure	type
begin	if	protected	until
body	in	raise	use
case	interface	range	when
constant	is	record	while
declare	limited	rem	with
delay	loop	renames	xor
delta	mod	requeue	
digits	new	return	
do	not	reverse	

Ada is designed to be portable. Ada compilers must follow a precisely defined international (ISO) standard language specification with clearly documented areas of vendor freedom where the behavior depends on the implementation. It's possible, then, to write an implementation-independent application in Ada and to make sure it will have the same effect across platforms and compilers.

Ada is truly a general purpose, multiple paradigm language that allows the programmer to employ or avoid features like run-time contract checking, tasking, object oriented programming, and generics. Efficiently programmed Ada is employed in device drivers, interrupt handlers, and other low-level functions. It may be found today in devices with tight limits on processing speed, memory, and power consumption. But the language is also used for programming larger interconnected systems running on workstations, servers, and supercomputers.

CHAPTER

FIFTYFOUR

COMPILATION UNIT STRUCTURE

C++ programming style usually promotes the use of two distinct files: header files used to define specifications (.h*, *.hxx*, *.hpp*), and implementation files which contain the executable code (*.c*, *.cxx*, *.cpp*). However, the distinction between specification and implementation is not enforced by the compiler and may need to be worked around in order to implement, for example, inlining or templates.

Java compilers expect both the implementation and specification to be in the same *.java* file. (Yes, design patterns allow using interfaces to separate specification from implementation to a certain extent, but this is outside of the scope of this description.)

Ada is superficially similar to the C++ case: Ada compilation units are generally split into two parts, the specification and the body. However, what goes into those files is more predictable for both the compiler and for the programmer. With GNAT, compilation units are stored in files with a *.ads* extension for specifications and with a *.adb* extension for implementations.

Without further ado, we present the famous "Hello World" in three languages:

[Ada]

```
with Ada.Text_IO;
use  Ada.Text_IO;

procedure Main is
begin
   Put_Line ("Hello World");
end Main;
```

[C++]

```
#include <iostream>
using namespace std;

int main(int argc, const char* argv[]) {
   cout << "Hello World" << endl;
}
```

[Java]

```
public class Main {
   public static void main(String [] argv) {
      System.out.println ("Hello World");
   }
}
```

The first line of Ada we see is the **with** clause, declaring that the unit (in this case, the Main subprogram) will require the services of the package `Ada.Text_IO`. This is different from how *#include* works in C++ in that it does not, in a logical sense, copy/paste the code of `Ada.Text_IO` into `Main`. The **with** clause directs the compiler to make the public

interface of the Ada.Text_IO package visible to code in the unit (here Main) containing the **with** clause. Note that this construct does not have a direct analog in Java, where the entire CLASSPATH is always accessible. Also, the name Main for the main subprogram was chosen for consistency with C++ and Java style but in Ada the name can be whatever the programmer chooses.

The **use** clause is the equivalent of **using namespace** in C++, or **import** in Java (though it wasn't necessary to use **import** in the Java example above). It allows you to omit the full package name when referring to **with**'ed units. Without the **use** clause, any reference to Ada.Text_IO items would have had to be fully qualified with the package name. The Put_Line line would then have read:

```
Ada.Text_IO.Put_Line ("Hello World");
```

The word "package" has different meanings in Ada and Java. In Java, a package is used as a namespace for classes. In Ada, it's often a compilation unit. As a result Ada tends to have many more packages than Java. Ada package specifications ("package specs" for short) have the following structure:

```
package Package_Name is

   -- public declarations

private

   -- private declarations

end Package_Name;
```

The implementation in a package body (written in a *.adb* file) has the structure:

```
package body Package_Name is

   -- implementation

end Package_Name;
```

The **private** reserved word is used to mark the start of the private portion of a package spec. By splitting the package spec into private and public parts, it is possible to make an entity available for use while hiding its implementation. For instance, a common use is declaring a **record** (Ada's **struct**) whose fields are only visible to its package and not to the caller. This allows the caller to refer to objects of that type, but not to change any of its contents directly.

The package body contains implementation code, and is only accessible to outside code through declarations in the package spec.

An entity declared in the private part of a package in Ada is roughly equivalent to a protected member of a C++ or Java class. An entity declared in the body of an Ada package is roughly equivalent to a private member of a C++ or Java class.

CHAPTER

FIFTYFIVE

STATEMENTS, DECLARATIONS, AND CONTROL STRUCTURES

55.1 Statements and Declarations

The following code samples are all equivalent, and illustrate the use of comments and working with integer variables:

[Ada]

```
--
--  Ada program to declare and modify Integers
--
procedure Main is
   --  Variable declarations
   A, B : Integer := 0;
   C    : Integer := 100;
   D    : Integer;
begin
   --  Ada uses a regular assignment statement for incrementation.
   A := A + 1;

   --  Regular addition
   D := A + B + C;
end Main;
```

[C++]

```
/*
 *  C++ program to declare and modify ints
 */
int main(int argc, const char* argv[]) {
   //  Variable declarations
   int a = 0, b = 0, c = 100, d;

   //  C++ shorthand for incrementation
   a++;

   //  Regular addition
   d = a + b + c;
}
```

[Java]

```
/*
 *  Java program to declare and modify ints
 */
public class Main {
```

(continues on next page)

(continued from previous page)

```
   public static void main(String [] argv) {
      //  Variable declarations
      int a = 0, b = 0, c = 100, d;

      //  Java shorthand for incrementation
      a++;

      //  Regular addition
      d = a + b + c;
   }
}
```

Statements are terminated by semicolons in all three languages. In Ada, blocks of code are surrounded by the reserved words **begin** and **end** rather than by curly braces. We can use both multi-line and single-line comment styles in the C++ and Java code, and only single-line comments in the Ada code.

Ada requires variable declarations to be made in a specific area called the *declarative part*, seen here before the **begin** keyword. Variable declarations start with the identifier in Ada, as opposed to starting with the type as in C++ and Java (also note Ada's use of the `:` separator). Specifying initializers is different as well: in Ada an initialization expression can apply to multiple variables (but will be evaluated separately for each), whereas in C++ and Java each variable is initialized individually. In all three languages, if you use a function as an initializer and that function returns different values on every invocation, each variable will get initialized to a different value.

Let's move on to the imperative statements. Ada does not provide `++` or `--` shorthand expressions for increment/decrement operations; it is necessary to use a full assignment statement. The `:=` symbol is used in Ada to perform value assignment. Unlike C++'s and Java's `=` symbol, `:=` can not be used as part of an expression. So, a statement like `A := B := C;` doesn't make sense to an Ada compiler, and neither does a clause like **if** `A := B` **then** `...`. Both are compile-time errors.

You can nest a block of code within an outer block if you want to create an inner scope:

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
begin
   Put_Line ("Before the inner block");

   declare
      Alpha : Integer := 0;
   begin
      Alpha := Alpha + 1;
      Put_Line ("Now inside the inner block");
   end;

   Put_Line ("After the inner block");
end Main;
```

It is OK to have an empty declarative part or to omit the declarative part entirely — just start the inner block with **begin** if you have no declarations to make. However it is not OK to have an empty sequence of statements. You must at least provide a **null**; statement, which does nothing and indicates that the omission of statements is intentional.

55.2 Conditions

The use of the **if** statement:

[Ada]

```
if Variable > 0 then
   Put_Line (" > 0 ");
elsif Variable < 0 then
   Put_Line (" < 0 ");
else
   Put_Line (" = 0 ");
end if;
```

[C++]

```
if (Variable > 0)
   cout << " > 0 " << endl;
else if (Variable < 0)
   cout << " < 0 " << endl;
else
   cout << " = 0 " << endl;
```

[Java]

```
if (Variable > 0)
   System.out.println (" > 0 ");
else if (Variable < 0)
   System.out.println (" < 0 ");
else
   System.out.println (" = 0 ");
```

In Ada, everything that appears between the **if** and **then** keywords is the conditional expression — no parentheses required. Comparison operators are the same, except for equality (=) and inequality (/=). The English words **not**, **and**, and **or** replace the symbols !, &, and |, respectively, for performing boolean operations.

It's more customary to use && and || in C++ and Java than & and | when writing boolean expressions. The difference is that && and || are short-circuit operators, which evaluate terms only as necessary, and & and | will unconditionally evaluate all terms. In Ada, **and** and **or** will evaluate all terms; **and then** and **or else** direct the compiler to employ short circuit evaluation.

Here are what switch/case statements look like:

[Ada]

```
case Variable is
   when 0 =>
      Put_Line ("Zero");
   when 1 .. 9 =>
      Put_Line ("Positive Digit");
   when 10 | 12 | 14 | 16 | 18 =>
      Put_Line ("Even Number between 10 and 18");
   when others =>
      Put_Line ("Something else");
end case;
```

[C++]

```
switch (Variable) {
   case 0:
```

(continues on next page)

(continued from previous page)

```
      cout << "Zero" << endl;
      break;
   case 1: case 2: case 3: case 4: case 5:
   case 6: case 7: case 8: case 9:
      cout << "Positive Digit" << endl;
      break;
   case 10: case 12: case 14: case 16: case 18:
      cout << "Even Number between 10 and 18" << endl;
      break;
   default:
      cout << "Something else";
}
```

[Java]

```
switch (Variable) {
   case 0:
      System.out.println ("Zero");
      break;
   case 1: case 2: case 3: case 4: case 5:
   case 6: case 7: case 8: case 9:
      System.out.println ("Positive Digit");
      break;
   case 10: case 12: case 14: case 16: case 18:
      System.out.println ("Even Number between 10 and 18");
      break;
   default:
      System.out.println ("Something else");
}
```

In Ada, the **case** and **end case** lines surround the whole case statement, and each case starts with **when**. So, when programming in Ada, replace **switch** with **case**, and replace **case** with **when**.

Case statements in Ada require the use of discrete types (integers or enumeration types), and require all possible cases to be covered by **when** statements. If not all the cases are handled, or if duplicate cases exist, the program will not compile. The default case, **default**: in C++ and Java, can be specified using **when others** => in Ada.

In Ada, the **break** instruction is implicit and program execution will never fall through to subsequent cases. In order to combine cases, you can specify ranges using .. and enumerate disjoint values using | which neatly replaces the multiple **case** statements seen in the C++ and Java versions.

55.3 Loops

In Ada, loops always start with the **loop** reserved word and end with **end loop**. To leave the loop, use **exit** — the C++ and Java equivalent being **break**. This statement can specify a terminating condition using the **exit when** syntax. The **loop** opening the block can be preceded by a **while** or a **for**.

The **while** loop is the simplest one, and is very similar across all three languages:

[Ada]

```
while Variable < 10_000 loop
   Variable := Variable * 2;
end loop;
```

[C++]

```
while (Variable < 10000) {
   Variable = Variable * 2;
}
```

[Java]

```
while (Variable < 10000) {
    Variable = Variable * 2;
}
```

Ada's **for** loop, however, is quite different from that in C++ and Java. It always increments or decrements a loop index within a discrete range. The loop index (or "loop parameter" in Ada parlance) is local to the scope of the loop and is implicitly incremented or decremented at each iteration of the loop statements; the program cannot directly modify its value. The type of the loop parameter is derived from the range. The range is always given in ascending order even if the loop iterates in descending order. If the starting bound is greater than the ending bound, the interval is considered to be empty and the loop contents will not be executed. To specify a loop iteration in decreasing order, use the **reverse** reserved word. Here are examples of loops going in both directions:

[Ada]

```
--  Outputs 0, 1, 2, ..., 9
for Variable in 0 .. 9 loop
   Put_Line (Integer'Image (Variable));
end loop;

--  Outputs 9, 8, 7, ..., 0
for Variable in reverse 0 .. 9 loop
   Put_Line (Integer'Image (Variable));
end loop;
```

[C++]

```
//  Outputs 0, 1, 2, ..., 9
for (int Variable = 0; Variable <= 9; Variable++) {
   cout << Variable << endl;
}

//  Outputs 9, 8, 7, ..., 0
for (int Variable = 9; Variable >=0; Variable--) {
   cout << Variable << endl;
}
```

[Java]

```
//  Outputs 0, 1, 2, ..., 9
for (int Variable = 0; Variable <= 9; Variable++) {
   System.out.println (Variable);
}

//  Outputs 9, 8, 7, ..., 0
for (int Variable = 9; Variable >= 0; Variable--) {
   System.out.println (Variable);
}
```

Ada uses the **Integer** type's 'Image attribute to convert a numerical value to a String. There is no implicit conversion between **Integer** and **String** as there is in C++ and Java. We'll have a more in-depth look at such attributes later on.

It's easy to express iteration over the contents of a container (for instance, an array, a list,

or a map) in Ada and Java. For example, assuming that `Int_List` is defined as an array of Integer values, you can use:

[Ada]

```
for I of Int_List loop
   Put_Line (Integer'Image (I));
end loop;
```

[Java]

```
for (int i : Int_List) {
   System.out.println (i);
}
```

CHAPTER

FIFTYSIX

TYPE SYSTEM

56.1 Strong Typing

One of the main characteristics of Ada is its strong typing (i.e., relative absence of implicit type conversions). This may take some getting used to. For example, you can't divide an integer by a float. You need to perform the division operation using values of the same type, so one value must be explicitly converted to match the type of the other (in this case the more likely conversion is from integer to float). Ada is designed to guarantee that what's done by the program is what's meant by the programmer, leaving as little room for compiler interpretation as possible. Let's have a look at the following example:

[Ada]

```
procedure Strong_Typing is
   Alpha  : Integer := 1;
   Beta   : Integer := 10;
   Result : Float;
begin
   Result := Float (Alpha) / Float (Beta);
end Strong_Typing;
```

[C++]

```
void weakTyping () {
   int   alpha = 1;
   int   beta = 10;
   float result;

   result = alpha / beta;
}
```

[Java]

```
void weakTyping () {
   int   alpha = 1;
   int   beta = 10;
   float result;

   result = alpha / beta;
}
```

Are the three programs above equivalent? It may seem like Ada is just adding extra complexity by forcing you to make the conversion from Integer to Float explicit. In fact it significantly changes the behavior of the computation. While the Ada code performs a floating point operation `1.0 / 10.0` and stores 0.1 in `Result`, the C++ and Java versions instead store 0.0 in `result`. This is because the C++ and Java versions perform an integer operation between two integer variables: `1 / 10` is `0`. The result of the integer division is then converted to a **`float`** and stored. Errors of this sort can be very hard to locate in complex

pieces of code, and systematic specification of how the operation should be interpreted helps to avoid this class of errors. If an integer division was actually intended in the Ada case, it is still necessary to explicitly convert the final result to **Float**:

```
-- Perform an Integer division then convert to Float
Result := Float (Alpha / Beta);
```

In Ada, a floating point literal must be written with both an integral and decimal part. `10` is not a valid literal for a floating point value, while `10.0` is.

56.2 Language-Defined Types

The principal scalar types predefined by Ada are **Integer**, **Float**, **Boolean**, and **Character**. These correspond to **int**, **float**, **bool**/**boolean**, and **char**, respectively. The names for these types are not reserved words; they are regular identifiers.

56.3 Application-Defined Types

Ada's type system encourages programmers to think about data at a high level of abstraction. The compiler will at times output a simple efficient machine instruction for a full line of source code (and some instructions can be eliminated entirely). The careful programmer's concern that the operation really makes sense in the real world would be satisfied, and so would the programmer's concern about performance.

The next example below defines two different metrics: area and distance. Mixing these two metrics must be done with great care, as certain operations do not make sense, like adding an area to a distance. Others require knowledge of the expected semantics; for example, multiplying two distances. To help avoid errors, Ada requires that each of the binary operators `+`, `-`, `*`, and `/` for integer and floating-point types take operands of the same type and return a value of that type.

```
procedure Main is
   type Distance is new Float;
   type Area is new Float;

   D1 : Distance := 2.0;
   D2 : Distance := 3.0;
   A  : Area;
begin
   D1 := D1 + D2;         -- OK
   D1 := D1 + A;          -- NOT OK: incompatible types for "+" operator
   A  := D1 * D2;         -- NOT OK: incompatible types for ":=" assignment
   A  := Area (D1 * D2); -- OK
end Main;
```

Even though the `Distance` and `Area` types above are just **Float**s, the compiler does not allow arbitrary mixing of values of these different types. An explicit conversion (which does not necessarily mean any additional object code) is necessary.

The predefined Ada rules are not perfect; they admit some problematic cases (for example multiplying two `Distances` yields a `Distance`) and prohibit some useful cases (for example multiplying two `Distances` should deliver an `Area`). These situations can be handled through other mechanisms. A predefined operation can be identified as **abstract** to make it unavailable; overloading can be used to give new interpretations to existing operator symbols, for example allowing an operator to return a value from a type different from its

operands; and more generally, GNAT has introduced a facility that helps perform dimensionality checking.

Ada enumerations work similarly to C++ and Java's **enum**s.

[Ada]

```
type Day is
  (Monday,
   Tuesday,
   Wednesday,
   Thursday,
   Friday,
   Saturday,
   Sunday);
```

[C++]

```
enum Day {
   Monday,
   Tuesday,
   Wednesday,
   Thursday,
   Friday,
   Saturday,
   Sunday};
```

[Java]

```
enum Day {
   Monday,
   Tuesday,
   Wednesday,
   Thursday,
   Friday,
   Saturday,
   Sunday}
```

But even though such enumerations may be implemented using a machine word, at the language level Ada will not confuse the fact that `Monday` is a `Day` and is not an **Integer**. You can compare a `Day` with another `Day`, though. To specify implementation details like the numeric values that correspond with enumeration values in C++ you include them in the original **enum** statement:

[C++]

```
enum Day {
   Monday    = 10,
   Tuesday   = 11,
   Wednesday = 12,
   Thursday  = 13,
   Friday    = 14,
   Saturday  = 15,
   Sunday    = 16};
```

But in Ada you must use both a type definition for `Day` as well as a separate *representation clause* for it like:

[Ada]

```
for Day use
  (Monday    => 10,
   Tuesday   => 11,
```

(continues on next page)

(continued from previous page)

```
   Wednesday => 12,
   Thursday  => 13,
   Friday    => 14,
   Saturday  => 15,
   Sunday    => 16);
```

56.4 Type Ranges

Contracts can be associated with types and variables, to refine values and define what are considered valid values. The most common kind of contract is a *range constraint* introduced with the **range** reserved word, for example:

```
procedure Main is
   type Grade is range 0 .. 100;

   G1, G2  : Grade;
   N       : Integer;
begin
   ...                -- Initialization of N
   G1 := 80;          -- OK
   G1 := N;           -- Illegal (type mismatch)
   G1 := Grade (N);   -- Legal, run-time range check
   G2 := G1 + 10;     -- Legal, run-time range check
   G1 := (G1 + G2)/2; -- Legal, run-time range check
end Main;
```

In the above example, `Grade` is a new integer type associated with a range check. Range checks are dynamic and are meant to enforce the property that no object of the given type can have a value outside the specified range. In this example, the first assignment to `G1` is correct and will not raise a run-time exceprion. Assigning `N` to `G1` is illegal since `Grade` is a different type than **`Integer`**. Converting `N` to `Grade` makes the assignment legal, and a range check on the conversion confirms that the value is within `0 .. 100`. Assigning `G1+10` to `G2` is legal since `+` for `Grade` returns a `Grade` (note that the literal `10` is interpreted as a `Grade` value in this context), and again there is a range check.

The final assignment illustrates an interesting but subtle point. The subexpression `G1 + G2` may be outside the range of `Grade`, but the final result will be in range. Nevertheless, depending on the representation chosen for `Grade`, the addition may overflow. If the compiler represents `Grade` values as signed 8-bit integers (i.e., machine numbers in the range `-128 .. 127`) then the sum `G1+G2` may exceed 127, resulting in an integer overflow. To prevent this, you can use explicit conversions and perform the computation in a sufficiently large integer type, for example:

```
G1 := Grade ((Integer (G1) + Integer (G2)) / 2);
```

Range checks are useful for detecting errors as early as possible. However, there may be some impact on performance. Modern compilers do know how to remove redundant checks, and you can deactivate these checks altogether if you have sufficient confidence that your code will function correctly.

Types can be derived from the representation of any other type. The new derived type can be associated with new constraints and operations. Going back to the `Day` example, one can write:

```
type Business_Day is new Day range Monday .. Friday;
type Weekend_Day is new Day range Saturday .. Sunday;
```

Since these are new types, implicit conversions are not allowed. In this case, it's more natural to create a new set of constraints for the same type, instead of making completely new ones. This is the idea behind *subtypes* in Ada. A subtype is a type with optional additional constraints. For example:

```
subtype Business_Day is Day range Monday .. Friday;
subtype Weekend_Day is Day range Saturday .. Sunday;
subtype Dice_Throw is Integer range 1 .. 6;
```

These declarations don't create new types, just new names for constrained ranges of their base types.

56.5 Generalized Type Contracts: Subtype Predicates

Range checks are a special form of type contracts; a more general method is provided by Ada subtype predicates, introduced in Ada 2012. A subtype predicate is a boolean expression defining conditions that are required for a given type or subtype. For example, the `Dice_Throw` subtype shown above can be defined in the following way:

```
subtype Dice_Throw is Integer
   with Dynamic_Predicate => Dice_Throw in 1 .. 6;
```

The clause beginning with **`with`** introduces an Ada *aspect*, which is additional information provided for declared entities such as types and subtypes. The `Dynamic_Predicate` aspect is the most general form. Within the predicate expression, the name of the (sub)type refers to the current value of the (sub)type. The predicate is checked on assignment, parameter passing, and in several other contexts. There is a `Static_Predicate` form which introduce some optimization and constrains on the form of these predicates, outside of the scope of this document.

Of course, predicates are useful beyond just expressing ranges. They can be used to represent types with arbitrary constraints, in particular types with discontinuities, for example:

```
type Not_Null is new Integer
   with Dynamic_Predicate => Not_Null /= 0;

type Even is new Integer
   with Dynamic_Predicate => Even mod 2 = 0;
```

56.6 Attributes

Attributes start with a single apostrophe ("tick"), and they allow you to query properties of, and perform certain actions on, declared entities such as types, objects, and subprograms. For example, you can determine the first and last bounds of scalar types, get the sizes of objects and types, and convert values to and from strings. This section provides an overview of how attributes work. For more information on the many attributes defined by the language, you can refer directly to the Ada Language Reference Manual.

The `'Image` and `'Value` attributes allow you to transform a scalar value into a **`String`** and vice-versa. For example:

```
declare
   A : Integer := 99;
begin
   Put_Line (Integer'Image (A));
```

(continues on next page)

(continued from previous page)

```
   A := Integer'Value ("99");
end;
```

Certain attributes are provided only for certain kinds of types. For example, the `'Val` and `'Pos` attributes for an enumeration type associates a discrete value with its position among its peers. One circuitous way of moving to the next character of the ASCII table is:

[Ada]

```
declare
   C : Character := 'a';
begin
   C := Character'Val (Character'Pos (C) + 1);
end;
```

A more concise way to get the next value in Ada is to use the `'Succ` attribute:

```
declare
   C : Character := 'a';
begin
   C := Character'Succ (C);
end;
```

You can get the previous value using the `'Pred` attribute. Here is the equivalent in C++ and Java:

[C++]

```
char c = 'a';
c++;
```

[Java]

```
char c = 'a';
c++;
```

Other interesting examples are the `'First` and `'Last` attributes which, respectively, return the first and last values of a scalar type. Using 32-bit integers, for instance, `Integer'First` returns -2^{31} and `Integer'Last` returns $2^{31} - 1$.

56.7 Arrays and Strings

C++ arrays are pointers with offsets, but the same is not the case for Ada and Java. Arrays in the latter two languages are not interchangable with operations on pointers, and array types are considered first-class citizens. Arrays in Ada have dedicated semantics such as the availability of the array's boundaries at run-time. Therefore, unhandled array overflows are impossible unless checks are suppressed. Any discrete type can serve as an array index, and you can specify both the starting and ending bounds — the lower bound doesn't necessarily have to be 0. Most of the time, array types need to be explicitly declared prior to the declaration of an object of that array type.

Here's an example of declaring an array of 26 characters, initializing the values from `'a'` to `'z'`:

[Ada]

```
declare
   type Arr_Type is array (Integer range <>) of Character;
```

(continues on next page)

(continued from previous page)

```
   Arr : Arr_Type (1 .. 26);
   C : Character := 'a';
begin
   for I in Arr'Range loop
      Arr (I) := C;
      C := Character'Succ (C);
   end loop;
end;
```

[C++]

```
char Arr [26];
char C = 'a';

for (int I = 0; I < 26; ++I) {
   Arr [I] = C;
   C = C + 1;
}
```

[Java]

```
char [] Arr = new char [26];
char C = 'a';

for (int I = 0; I < Arr.length; ++I) {
   Arr [I] = C;
   C = C + 1;
}
```

In C++ and Java, only the size of the array is given during declaration. In Ada, array index ranges are specified using two values of a discrete type. In this example, the array type declaration specifies the use of Integer as the index type, but does not provide any constraints (use <>, pronounced *box*, to specify "no constraints"). The constraints are defined in the object declaration to be 1 to 26, inclusive. Arrays have an attribute called `'Range`. In our example, `Arr'Range` can also be expressed as `Arr'First .. Arr'Last`; both expressions will resolve to `1 .. 26`. So the `'Range` attribute supplies the bounds for our **`for`** loop. There is no risk of stating either of the bounds incorrectly, as one might do in C++ where `I <= 26` may be specified as the end-of-loop condition.

As in C++, Ada **`String`**s are arrays of **`Character`**s. The C++ or Java `String` class is the equivalent of the Ada type `Ada.Strings.Unbounded_String` which offers additional capabilities in exchange for some overhead. Ada strings, importantly, are not delimited with the special character `'\0'` like they are in C++. It is not necessary because Ada uses the array's bounds to determine where the string starts and stops.

Ada's predefined **`String`** type is very straighforward to use:

```
My_String : String (1 .. 26);
```

Unlike C++ and Java, Ada does not offer escape sequences such as `'\n'`. Instead, explicit values from the `ASCII` package must be concatenated (via the concatenation operator, `&`). Here for example, is how to initialize a line of text ending with a new line:

```
My_String : String := "This is a line with a end of line" & ASCII.LF;
```

You see here that no constraints are necessary for this variable definition. The initial value given allows the automatic determination of `My_String`'s bounds.

Ada offers high-level operations for copying, slicing, and assigning values to arrays. We'll start with assignment. In C++ or Java, the assignment operator doesn't make a copy of the value of an array, but only copies the address or reference to the target variable. In Ada,

the actual array contents are duplicated. To get the above behavior, actual pointer types would have to be defined and used.

[Ada]

```ada
declare
   type Arr_Type is array (Integer range <>) of Integer;
   A1 : Arr_Type (1 .. 2);
   A2 : Arr_Type (1 .. 2);
begin
   A1 (1) := 0;
   A1 (2) := 1;

   A2 := A1;
end;
```

[C++]

```cpp
int A1 [2];
int A2 [2];

A1 [0] = 0;
A1 [1] = 1;

for (int i = 0; i < 2; ++i) {
   A2 [i] = A1 [i];
}
```

[Java]

```java
int [] A1 = new int [2];
int [] A2 = new int [2];

A1 [0] = 0;
A1 [1] = 1;

A2 = Arrays.copyOf(A1, A1.length);
```

In all of the examples above, the source and destination arrays must have precisely the same number of elements. Ada allows you to easily specify a portion, or slice, of an array. So you can write the following:

[Ada]

```ada
declare
   type Arr_Type is array (Integer range <>) of Integer;
   A1 : Arr_Type (1 .. 10);
   A2 : Arr_Type (1 .. 5);
begin
   A2 (1 .. 3) := A1 (4 .. 6);
end;
```

This assigns the 4th, 5th, and 6th elements of A1 into the 1st, 2nd, and 3rd elements of A2. Note that only the length matters here: the values of the indexes don't have to be equal; they slide automatically.

Ada also offers high level comparison operations which compare the contents of arrays as opposed to their addresses:

[Ada]

```ada
declare
   type Arr_Type is array (Integer range <>) of Integer;
```

(continues on next page)

(continued from previous page)

```
   A1 : Arr_Type (1 .. 2);
   A2 : Arr_Type (1 .. 2);
begin
   if A1 = A2 then
```

[C++]

```
int A1 [2];
int A2 [2];

bool eq = true;

for (int i = 0; i < 2; ++i) {
   if (A1 [i] != A2 [i]) {
      eq = false;
   }
}

if (eq) {
```

[Java]

```
int [] A1 = new int [2];
int [] A2 = new int [2];

if (Arrays.equals (A1, A2)) {
```

You can assign to all the elements of an array in each language in different ways. In Ada, the number of elements to assign can be determined by looking at the right-hand side, the left-hand side, or both sides of the assignment. When bounds are known on the left-hand side, it's possible to use the **others** expression to define a default value for all the unspecified array elements. Therefore, you can write:

```
declare
   type Arr_Type is array (Integer range <>) of Integer;
   A1 : Arr_Type := (1, 2, 3, 4, 5, 6, 7, 8, 9);
   A2 : Arr_Type (-2 .. 42) := (others => 0);
begin
   A1 := (1, 2, 3, others => 10);

   -- use a slice to assign A2 elements 11 .. 19 to 1
   A2 (11 .. 19) := (others => 1);
end;
```

56.8 Heterogeneous Data Structures

In Ada, there's no distinction between **struct** and **class** as there is in C++. All heterogeneous data structures are **record**s. Here are some simple records:

[Ada]

```
declare
   type R is record
      A, B : Integer;
      C    : Float;
   end record;

   V : R;
```

(continues on next page)

(continued from previous page)

```
begin
   V.A := 0;
end;
```

[C++]

```
struct R {
   int A, B;
   float C;
};

R V;
V.A = 0;
```

[Java]

```
class R {
   public int A, B;
   public float C;
}

R V = new R ();
V.A = 0;
```

Ada allows specification of default values for fields just like C++ and Java. The values specified can take the form of an ordered list of values, a named list of values, or an incomplete list followed by `others => <>` to specify that fields not listed will take their default values. For example:

```
type R is record
   A, B : Integer := 0;
   C    : Float := 0.0;
end record;

V1 : R := (1, 2, 1.0);
V2 : R := (A => 1, B => 2, C => 1.0);
V3 : R := (C => 1.0, A => 1, B => 2);
V4 : R := (C => 1.0, others => <>);
```

56.9 Pointers

Pointers, references, and access types differ in significant ways across the languages that we are examining. In C++, pointers are integral to a basic understanding of the language, from array manipulation to proper declaration and use of function parameters. In Java, direct pointer manipulation is abstracted by the Java runtime. And in Ada, direct pointer manipulation is possible, but unlike C++, they are not required for basic usage with arrays and parameter passing.

We'll continue this section by explaining the difference between objects allocated on the stack and objects allocated on the heap using the following example:

[Ada]

```
declare
   type R is record
      A, B : Integer;
   end record;
```

(continues on next page)

(continued from previous page)

```
   V1, V2 : R;
begin
   V1.A := 0;
   V2 := V1;
   V2.A := 1;
end;
```

[C++]

```
struct R {
   int A, B;
};

R V1, V2;
V1.A = 0;
V2 = V1;
V2.A = 1;
```

[Java]

```
public class R {
   public int A, B;
}

R V1, V2;
V1 = new R ();
V1.A = 0;
V2 = V1;
V2.A = 1;
```

There's a fundamental difference between the Ada and C++ semantics above and the semantics for Java. In Ada and C++, objects are allocated on the stack and are directly accessed. V1 and V2 are two different objects and the assignment statement copies the value of V1 into V2. In Java, V1 and V2 are two *references* to objects of class R. Note that when V1 and V2 are declared, no actual object of class R yet exists in memory: it has to be allocated later with the **new** allocator operator. After the assignment V2 = V1, there's only one R object in memory: the assignment is a reference assignment, not a value assignment. At the end of the Java code, V1 and V2 are two references to the same objects and the V2.A = 1 statement changes the field of that one object, while in the Ada and the C++ case V1 and V2 are two distinct objects.

To obtain similar behavior in Ada, you can use pointers. It can be done through Ada's *access type*:

[Ada]

```
declare
   type R is record
      A, B : Integer;
   end record;
   type R_Access is access R;

   V1 : R_Access;
   V2 : R_Access;
begin
   V1 := new R;
   V1.A := 0;
   V2 := V1;
   V2.A := 1;
end;
```

[C++]

```
struct R {
   int A, B;
};

R * V1, * V2;
V1 = new R ();
V1->A = 0;
V2 = V1;
V2->A = 0;
```

For those coming from the Java world: there's no garbage collector in Ada, so objects allocated by the **new** operator need to be expressly freed.

Dereferencing is performed automatically in certain situations, for instance when it is clear that the type required is the dereferenced object rather than the pointer itself, or when accessing record members via a pointer. To explicitly dereference an access variable, append **.all**. The equivalent of V1->A in C++ can be written either as V1.A or V1.**all**.A.

Pointers to scalar objects in Ada and C++ look like:

[Ada]

```
procedure Main is
   type A_Int is access Integer;
   Var : A_Int := new Integer;
begin
   Var.all := 0;
end Main;
```

[C++]

```
int main (int argc, char *argv[]) {
  int * Var = new int;
  *Var = 0;
}
```

An initializer can be specified with the allocation by appending '(value):

```
Var : A_Int := new Integer'(0);
```

When using Ada pointers to reference objects on the stack, the referenced objects must be declared as being **aliased**. This directs the compiler to implement the object using a memory region, rather than using registers or eliminating it entirely via optimization. The access type needs to be declared as either **access all** (if the referenced object needs to be assigned to) or **access constant** (if the referenced object is a constant). The 'Access attribute works like the C++ & operator to get a pointer to the object, but with a "scope accessibility" check to prevent references to objects that have gone out of scope. For example:

[Ada]

```
type A_Int is access all Integer;
Var : aliased Integer;
Ptr : A_Int := Var'Access;
```

[C++]

```
int Var;
int * Ptr = &Var;
```

To deallocate objects from the heap in Ada, it is necessary to use a deallocation subprogram that accepts a specific access type. A generic procedure is provided that can be customized to fit your needs — it's called Ada.Unchecked_Deallocation. To create your customized

deallocator (that is, to instantiate this generic), you must provide the object type as well as the access type as follows:

[Ada]

```
with Ada.Unchecked_Deallocation;
procedure Main is
   type Integer_Access is access all Integer;
   procedure Free is new Ada.Unchecked_Deallocation (Integer, Integer_Access);
   My_Pointer : Integer_Access := new Integer;
begin
   Free (My_Pointer);
end Main;
```

[C++]

```
int main (int argc, char *argv[]) {
  int * my_pointer = new int;
  delete my_pointer;
}
```

CHAPTER

FIFTYSEVEN

FUNCTIONS AND PROCEDURES

57.1 General Form

Subroutines in C++ and Java are always expressed as functions (methods) which may or may not return a value. Ada explicitly differentiates between functions and procedures. Functions must return a value and procedures must not. Ada uses the more general term "subprogram" to refer to both functions and procedures.

Parameters can be passed in three distinct modes: **in**, which is the default, is for input parameters, whose value is provided by the caller and cannot be changed by the subprogram. **out** is for output parameters, with no initial value, to be assigned by the subprogram and returned to the caller. **in out** is a parameter with an initial value provided by the caller, which can be modified by the subprogram and returned to the caller (more or less the equivalent of a non-constant reference in C++). Ada also provides **access** parameters, in effect an explicit pass-by-reference indicator.

In Ada the programmer specifies how the parameter will be used and in general the compiler decides how it will be passed (i.e., by copy or by reference). (There are some exceptions to the "in general". For example, parameters of scalar types are always passed by copy, for all three modes.) C++ has the programmer specify how to pass the parameter, and Java forces primitive type parameters to be passed by copy and all other parameters to be passed by reference. For this reason, a 1:1 mapping between Ada and Java isn't obvious but here's an attempt to show these differences:

[Ada]

```
procedure Proc
 (Var1 : Integer;
  Var2 : out Integer;
  Var3 : in out Integer);

function Func (Var : Integer) return Integer;

procedure Proc
 (Var1 : Integer;
  Var2 : out Integer;
  Var3 : in out Integer)
is
begin
   Var2 := Func (Var1);
   Var3 := Var3 + 1;
end Proc;

function Func (Var : Integer) return Integer
is
begin
   return Var + 1;
end Func;
```

[C++]

```
void Proc
  (int Var1,
   int & Var2,
   int & Var3);

int Func (int Var);

void Proc
  (int Var1,
   int & Var2,
   int & Var3) {

   Var2 = Func (Var1);
   Var3 = Var3 + 1;
}

int Func (int Var) {
   return Var + 1;
}
```

[Java]

```
public class ProcData {
   public int Var2;
   public int Var3;

   public void Proc (int Var1) {
      Var2 = Func (Var1);
      Var3 = Var3 + 1;
   }

   public static int Func (int Var) {
      return Var + 1;
   }
}
```

The first two declarations for Proc and Func are specifications of the subprograms which are being provided later. Although optional here, it's still considered good practice to separately define specifications and implementations in order to make it easier to read the program. In Ada and C++, a function that has not yet been seen cannot be used. Here, Proc can call Func because its specification has been declared. In Java, it's fine to have the declaration of the subprogram later .

Parameters in Ada subprogram declarations are separated with semicolons, because commas are reserved for listing multiple parameters of the same type. Parameter declaration syntax is the same as variable declaration syntax, including default values for parameters. If there are no parameters, the parentheses must be omitted entirely from both the declaration and invocation of the subprogram.

57.2 Overloading

Different subprograms may share the same name; this is called "overloading." As long as the subprogram signatures (subprogram name, parameter types, and return types) are different, the compiler will be able to resolve the calls to the proper destinations. For example:

```
function Value (Str : String) return Integer;
function Value (Str : String) return Float;

V : Integer := Value ("8");
```

The Ada compiler knows that an assignment to `V` requires an `Integer`. So, it chooses the `Value` function that returns an `Integer` to satisfy this requirement.

Operators in Ada can be treated as functions too. This allows you to define local operators that override operators defined at an outer scope, and provide overloaded operators that operate on and compare different types. To express an operator as a function, enclose it in quotes:

[Ada]

```
function "=" (Left : Day; Right : Integer) return Boolean;
```

[C++]

```
bool operator = (Day Left, int Right);
```

57.3 Subprogram Contracts

You can express the expected inputs and outputs of subprograms by specifying subprogram contracts. The compiler can then check for valid conditions to exist when a subprogram is called and can check that the return value makes sense. Ada allows defining contracts in the form of `Pre` and `Post` conditions; this facility was introduced in Ada 2012. They look like:

```
function Divide (Left, Right : Float) return Float
   with Pre  => Right /= 0.0,
        Post => Divide'Result * Right < Left + 0.0001
                and then Divide'Result * Right > Left - 0.0001;
```

The above example adds a `Pre` condition, stating that `Right` cannot be equal to 0.0. While the IEEE floating point standard permits divide-by-zero, you may have determined that use of the result could still lead to issues in a particular application. Writing a contract helps to detect this as early as possible. This declaration also provides a `Post` condition on the result.

Postconditions can also be expressed relative to the value of the input:

```
procedure Increment (V : in out Integer)
   with Pre  => V < Integer'Last,
        Post => V = V'Old + 1;
```

`V'Old` in the postcondition represents the value that `V` had before entering `Increment`.

CHAPTER

FIFTYEIGHT

PACKAGES

58.1 Declaration Protection

The package is the basic modularization unit of the Ada language, as is the class for Java and the header and implementation pair for C++. An Ada package contains three parts that, for GNAT, are separated into two files: *.ads* files contain public and private Ada specifications, and *.adb* files contain the implementation, or Ada bodies.

Java doesn't provide any means to cleanly separate the specification of methods from their implementation: they all appear in the same file. You can use interfaces to emulate having separate specifications, but this requires the use of OOP techniques which is not always practical.

Ada and C++ do offer separation between specifications and implementations out of the box, independent of OOP.

```
package Package_Name is
   -- public specifications
private
   -- private specifications
end Package_Name;

package body Package_Name is
   -- implementation
end Package_Name;
```

Private types are useful for preventing the users of a package's types from depending on the types' implementation details. The **private** keyword splits the package spec into "public" and "private" parts. That is somewhat analogous to C++'s partitioning of the class construct into different sections with different visibility properties. In Java, the encapsulation has to be done field by field, but in Ada the entire definition of a type can be hidden. For example:

```
package Types is
   type Type_1 is private;
   type Type_2 is private;
   type Type_3 is private;
   procedure P (X : Type_1);
   ...
private
   procedure Q (Y : Type_1);
   type Type_1 is new Integer range 1 .. 1000;
   type Type_2 is array (Integer range 1 .. 1000) of Integer;
   type Type_3 is record
      A, B : Integer;
   end record;
end Types;
```

Subprograms declared above the **private** separator (such as P) will be visible to the package user, and the ones below (such as Q) will not. The body of the package, the implementation, has access to both parts.

58.2 Hierarchical Packages

Ada packages can be organized into hierarchies. A child unit can be declared in the following way:

```
-- root-child.ads

package Root.Child is
   --  package spec goes here
end Root.Child;

-- root-child.adb

package body Root.Child is
   --  package body goes here
end Root.Child;
```

Here, `Root.Child` is a child package of `Root`. The public part of `Root.Child` has access to the public part of `Root`. The private part of `Child` has access to the private part of `Root`, which is one of the main advantages of child packages. However, there is no visibility relationship between the two bodies. One common way to use this capability is to define subsystems around a hierarchical naming scheme.

58.3 Using Entities from Packages

Entities declared in the visible part of a package specification can be made accessible using a **with** clause that references the package, which is similar to the C++ *#include* directive. Visibility is implicit in Java: you can always access all classes located in your *CLASSPATH*. After a **with** clause, entities needs to be prefixed by the name of their package, like a C++ namespace or a Java package. This prefix can be omitted if a **use** clause is employed, similar to a C++ **using namespace** or a Java **import**.

[Ada]

```
-- pck.ads

package Pck is
   My_Glob : Integer;
end Pck;

-- main.adb

with Pck;

procedure Main is
begin
   Pck.My_Glob := 0;
end Main;
```

[C++]

```
// pck.h

namespace pck {
   extern int myGlob;
}

// pck.cpp

namespace pck {
   int myGlob;
}

// main.cpp

#include "pck.h"

int main (int argc, char ** argv) {
   pck::myGlob = 0;
}
```

[Java]

```
// Globals.java

package pck;

public class Globals {
   public static int myGlob;
}

// Main.java

public class Main {
   public static void main (String [] argv) {
      pck.Globals.myGlob = 0;
   }
}
```

CHAPTER

FIFTYNINE

CLASSES AND OBJECT ORIENTED PROGRAMMING

59.1 Primitive Subprograms

Primitive subprograms in Ada are basically the subprograms that are eligible for inheritance / derivation. They are the equivalent of C++ member functions and Java instance methods. While in C++ and Java these subprograms are located within the nested scope of the type, in Ada they are simply declared in the same scope as the type. There's no syntactic indication that a subprogram is a primitive of a type.

The way to determine whether P is a primitive of a type T is if

1. it is declared in the same scope as T, and
2. it contains at least one parameter of type T, or returns a result of type T.

In C++ or Java, the self reference **this** is implicitly declared. It may need to be explicitly stated in certain situations, but usually it's omitted. In Ada the self-reference, called the *controlling parameter*, must be explicitly specified in the subprogram parameter list. While it can be any parameter in the profile with any name, we'll focus on the typical case where the first parameter is used as the `self` parameter. Having the controlling parameter listed first also enables the use of OOP prefix notation which is convenient.

A **class** in C++ or Java corresponds to a **tagged type** in Ada. Here's an example of the declaration of an Ada tagged type with two parameters and some dispatching and non-dispatching primitives, with equivalent examples in C++ and Java:

[Ada]

```
type T is tagged record
   V, W : Integer;
end record;

type T_Access is access all T;

function F (V : T) return Integer;

procedure P1 (V : access T);

procedure P2 (V : T_Access);
```

[C++]

```
class T {
   public:
      int V, W;

      int F ();

      void P1 ();
```

(continues on next page)

(continued from previous page)

```
};

void P2 (T * v);
```

[Java]

```
public class T {
      public int V, W;

      public int F () {};

      public void P1 () {};

      public static void P2 (T v) {};
}
```

Note that P2 is not a primitive of T — it does not have any parameters of type T. Its parameter is of type T_Access, which is a different type.

Once declared, primitives can be called like any subprogram with every necessary parameter specified, or called using prefix notation. For example:

[Ada]

```
declare
   V : T;
begin
   V.P1;
end;
```

[C++]

```
{
  T v;
  v.P1 ();
}
```

[Java]

```
{
  T v = new T ();
  v.P1 ();
}
```

59.2 Derivation and Dynamic Dispatch

Despite the syntactic differences, derivation in Ada is similar to derivation (inheritance) in C++ or Java. For example, here is a type hierarchy where a child class overrides a method and adds a new method:

[Ada]

```
type Root is tagged record
   F1 : Integer;
end record;

procedure Method_1 (Self : Root);
```

(continues on next page)

(continued from previous page)

```
type Child is new Root with record
   F2 : Integer;
end record;

overriding
procedure Method_1 (Self : Child);

procedure Method_2 (Self : Child);
```

[C++]

```
class Root {
   public:
      int f1;
      virtual void method1 ();
};

class Child : public Root {
   public:
      int f2;
      virtual void method1 ();
      virtual void method2 ();
};
```

[Java]

```
public class Root {
   public int f1;
   public void method1 ();
}

public class Child extends Root {
   public int f2;
   @Override
   public void method1 ();
   public void method2 ();
}
```

Like Java, Ada primitives on tagged types are always subject to dispatching; there is no need to mark them **virtual**. Also like Java, there's an optional keyword **overriding** to ensure that a method is indeed overriding something from the parent type.

Unlike many other OOP languages, Ada differentiates between a reference to a specific tagged type, and a reference to an entire tagged type hierarchy. While `Root` is used to mean a specific type, `Root'Class` — a class-wide type — refers to either that type or any of its descendants. A method using a parameter of such a type cannot be overridden, and must be passed a parameter whose type is of any of `Root`'s descendants (including `Root` itself).

Next, we'll take a look at how each language finds the appropriate method to call within an OO class hierarchy; that is, their dispatching rules. In Java, calls to non-private instance methods are always dispatching. The only case where static selection of an instance method is possible is when calling from a method to the **super** version.

In C++, by default, calls to virtual methods are always dispatching. One common mistake is to use a by-copy parameter hoping that dispatching will reach the real object. For example:

```
void proc (Root p) {
   p.method1 ();
}
```

(continues on next page)

(continued from previous page)

```
Root * v = new Child ();

proc (*v);
```

In the above code, `p.method1()` will not dispatch. The call to `proc` makes a copy of the `Root` part of `v`, so inside `proc`, `p.method1()` refers to the `method1()` of the root object. The intended behavior may be specified by using a reference instead of a copy:

```
void proc (Root & p) {
   p.method1 ();
}

Root * v = new Child ();

proc (*v);
```

In Ada, tagged types are always passed by reference but dispatching only occurs on class-wide types. The following Ada code is equivalent to the latter C++ example:

```
declare
   procedure Proc (P : Root'Class) is
   begin
      P.Method_1;
   end;

   type Root_Access is access all Root'Class;
   V : Root_Access := new Child;
begin
   Proc (V.all);
end;
```

Dispatching from within primitives can get tricky. Let's consider a call to `Method_1` in the implementation of `Method_2`. The first implementation that might come to mind is:

```
procedure Method_2 (P : Root) is
begin
   P.Method_1;
end;
```

However, `Method_2` is called with a parameter that is of the definite type `Root`. More precisely, it is a definite view of a child. So, this call is not dispatching; it will always call `Method_1` of `Root` even if the object passed is a child of `Root`. To fix this, a view conversion is necessary:

```
procedure Method_2 (P : Root) is
begin
   Root'Class (P).Method_1;
end;
```

This is called "redispatching." Be careful, because this is the most common mistake made in Ada when using OOP. In addition, it's possible to convert from a class wide view to a definite view, and to select a given primitive, like in C++:

[Ada]

```
procedure Proc (P : Root'Class) is
begin
   Root (P).Method_1;
end;
```

[C++]

```
void proc (Root & p) {
   p.Root::method1 ();
}
```

59.3 Constructors and Destructors

Ada does not have constructors and destructors in quite the same way as C++ and Java, but there is analagous functionality in Ada in the form of default initialization and finalization.

Default initialization may be specified for a record component and will occur if a variable of the record type is not assigned a value at initialization. For example:

```
type T is tagged record
   F : Integer := Compute_Default_F;
end record;

function Compute_Default_F return Integer is
begin
   Put_Line ("Compute");
   return 0;
end Compute_Default_F;

V1 : T;
V2 : T := (F => 0);
```

In the declaration of `V1`, `T.F` receives a value computed by the subprogram `Compute_Default_F`. This is part of the default initialization. `V2` is initialized manually and thus will not use the default initialization.

For additional expressive power, Ada provides a type called `Ada.Finalization.Controlled` from which you can derive your own type. Then, by overriding the `Initialize` procedure you can create a constructor for the type:

```
type T is new Ada.Finalization.Controlled with record
   F : Integer;
end record;

procedure Initialize (Self : in out T) is
begin
   Put_Line ("Compute");
   Self.F := 0;
end Initialize;

V1 : T;
V2 : T := (F => 0);
```

Again, this default initialization subprogram is only called for `V1`; `V2` is initialized manually. Furthermore, unlike a C++ or Java constructor, `Initialize` is a normal subprogram and does not perform any additional initialization such as calling the parent's initialization routines.

When deriving from `Controlled`, it's also possible to override the subprogram `Finalize`, which is like a destructor and is called for object finalization. Like `Initialize`, this is a regular subprogram. Do not expect any other finalizers to be automatically invoked for you.

Controlled types also provide functionality that essentially allows overriding the meaning of the assignment operation, and are useful for defining types that manage their own storage reclamation (for example, implementing a reference count reclamation strategy).

59.4 Encapsulation

While done at the class level for C++ and Java, Ada encapsulation occurs at the package level and targets all entities of the language, as opposed to only methods and attributes. For example:

[Ada]

```
package Pck is
   type T is tagged private;
   procedure Method1 (V : T);
private
   type T is tagged record
      F1, F2 : Integer;
   end record;
   procedure Method2 (V : T);
end Pck;
```

[C++]

```
class T {
   public:
      virtual void method1 ();
   protected:
      int f1, f2;
      virtual void method2 ();
};
```

[Java]

```
public class T {
   public void method1 ();
   protected int f1, f2;
   protected void method2 ();
}
```

The C++ and Java code's use of **protected** and the Ada code's use of **private** here demonstrates how to map these concepts between languages. Indeed, the private part of an Ada child package would have visibility of the private part of its parents, mimicking the notion of **protected**. Only entities declared in the package body are completely isolated from access.

59.5 Abstract Types and Interfaces

Ada, C++ and Java all offer similar functionality in terms of abstract classes, or pure virtual classes. It is necessary in Ada and Java to explicitly specify whether a tagged type or class is **abstract**, whereas in C++ the presence of a pure virtual function implicitly makes the class an abstract base class. For example:

[Ada]

```
package P is

    type T is abstract tagged private;

    procedure Method (Self : T) is abstract;
 private
    type T is abstract tagged record
```

(continues on next page)

(continued from previous page)

```
      F1, F2 : Integer;
   end record;

end P;
```

[C++]

```
class T {
   public:
      virtual void method () = 0;
   protected:
      int f1, f2;
};
```

[Java]

```
public abstract class T {
   public abstract void method1 ();
   protected int f1, f2;
};
```

All abstract methods must be implemented when implementing a concrete type based on an abstract type.

Ada doesn't offer multiple inheritance the way C++ does, but it does support a Java-like notion of interfaces. An interface is like a C++ pure virtual class with no attributes and only abstract members. While an Ada tagged type can inherit from at most one tagged type, it may implement multiple interfaces. For example:

[Ada]

```
type Root is tagged record
   F1 : Integer;
end record;
procedure M1 (Self : Root);

type I1 is interface;
procedure M2 (Self : I1) is abstract;

type I2 is interface;
procedure M3 (Self : I2) is abstract;

type Child is new Root and I1 and I2 with record
   F2 : Integer;
end record;

-- M1 implicitly inherited by Child
procedure M2 (Self : Child);
procedure M3 (Self : Child);
```

[C++]

```
class Root {
   public:
      virtual void M1();
      int f1;
};

class I1 {
   public:
      virtual void M2 () = 0;
```

(continues on next page)

(continued from previous page)

```
};

class I2 {
   public:
      virtual void M3 () = 0;
};

class Child : public Root, I1, I2 {
   public:
      int f2;
      virtual void M2 ();
      virtual void M3 ();
};
```

[Java]

```
public class Root {
   public void M1();
   public int f1;
}

public interface I1 {
   public void M2 ();
}

public interface I2 {
   public void M3 ();
}

public class Child extends Root implements I1, I2 {
      public int f2;
      public void M2 ();
      public void M3 ();
}
```

59.6 Invariants

Any private type in Ada may be associated with a Type_Invariant contract. An invariant is a property of a type that must always be true after the return from of any of its primitive subprograms. (The invariant might not be maintained during the execution of the primitive subprograms, but will be true after the return.) Let's take the following example:

```
package Int_List_Pkg is

   type Int_List (Max_Length : Natural) is private
     with Type_Invariant => Is_Sorted (Int_List);

   function Is_Sorted (List : Int_List) return Boolean;

   type Int_Array is array (Positive range <>) of Integer;

   function To_Int_List (Ints : Int_Array) return Int_List;

   function To_Int_Array (List : Int_List) return Int_Array;

   function "&" (Left, Right : Int_List) return Int_List;

   ... -- Other subprograms
```

(continues on next page)

(continued from previous page)

```
private

   type Int_List (Max_Length : Natural) is record
      Length : Natural;
      Data   : Int_Array (1..Max_Length);
   end record;

   function Is_Sorted (List : Int_List) return Boolean is
      (for all I in List.Data'First .. List.Length-1 =>
            List.Data (I) <= List.Data (I+1));

end Int_List_Pkg;

package body Int_List_Pkg is

   procedure Sort (Ints : in out Int_Array) is
   begin
      ... Your favorite sorting algorithm
   end Sort;

   function To_Int_List (Ints : Int_Array) return Int_List is
      List : Int_List :=
       (Max_Length => Ints'Length,
        Length     => Ints'Length,
        Data       => Ints);
   begin
      Sort (List.Data);
      return List;
   end To_Int_List;

   function To_Int_Array (List : Int_List) return Int_Array is
   begin
      return List.Data;
   end To_Int_Array;

   function "&" (Left, Right : Int_List) return Int_List is
      Ints : Int_Array := Left.Data & Right.Data;
   begin
      Sort (Ints);
      return To_Int_List (Ints);
   end "&";

   ... -- Other subprograms
end Int_List_Pkg;
```

The `Is_Sorted` function checks that the type stays consistent. It will be called at the exit of every primitive above. It is permissible if the conditions of the invariant aren't met during execution of the primitive. In `To_Int_List` for example, if the source array is not in sorted order, the invariant will not be satisfied at the "begin", but it will be checked at the end.

CHAPTER

SIXTY

GENERICS

Ada, C++, and Java all have support for generics or templates, but on different sets of language entities. A C++ template can be applied to a class or a function. So can a Java generic. An Ada generic can be either a package or a subprogram.

60.1 Generic Subprograms

In this example, we will swap two generic objects. This is possible in Ada and C++ using a temporary variable. In Java, parameters are a copy of a reference value that is passed into the function, so modifying those references in the function scope has no effect from the caller's context. A generic swap method, like the below Ada or C++ examples is not possible in Java, so we will skip the Java version of this example.

[Ada]

```
generic
   type A_Type is private;
procedure Swap (Left, Right : in out A_Type) is
   Temp : A_Type := Left;
begin
   Left  := Right;
   Right := Temp;
end Swap;
```

[C++]

```
template <class AType>
AType swap (AType & left, AType & right) {
   AType temp = left;
   left  = right;
   right = temp;
}
```

And examples of using these:

[Ada]

```
declare
   type R is record
      F1, F2 : Integer;
   end record;

   procedure Swap_R is new Swap (R);
   A, B : R;
begin
   ...
```

(continues on next page)

(continued from previous page)

```
   Swap_R (A, B);
end;
```

[C++]

```
class R {
   public:
      int f1, f2;
};

R a, b;
...
swap (a, b);
```

The C++ template becomes usable once defined. The Ada generic needs to be explicitly instantiated using a local name and the generic's parameters.

60.2 Generic Packages

Next, we're going to create a generic unit containing data and subprograms. In Java or C++, this is done through a class, while in Ada, it's a *generic package*. The Ada and C++ model is fundamentally different from the Java model. Indeed, upon instantiation, Ada and C++ generic data are duplicated; that is, if they contain global variables (Ada) or static attributes (C++), each instance will have its own copy of the variable, properly typed and independent from the others. In Java, generics are only a mechanism to have the compiler do consistency checks, but all instances are actually sharing the same data where the generic parameters are replaced by *java.lang.Object*. Let's look at the following example:

[Ada]

```
generic
   type T is private;
package Gen is
   type C is tagged record
      V : T;
   end record;

   G : Integer;
end Gen;
```

[C++]

```
template <class T>
class C{
   public:
     T v;
     static int G;
};
```

[Java]

```
public class C <T> {
     public T v;
     public static int G;
}
```

In all three cases, there's an instance variable (v) and a static variable (G). Let's now look at the behavior (and syntax) of these three instantiations:

[Ada]

```
declare
   package I1 is new Gen (Integer);
   package I2 is new Gen (Integer);
   subtype Str10 is String (1..10);
   package I3 is new Gen (Str10);
begin
   I1.G := 0;
   I2.G := 1;
   I3.G := 2;
end;
```

[C++]

```
C <int>::G = 0;
C <int>::G = 1;
C <char *>::G = 2;
```

[Java]

```
C.G = 0;
C.G = 1;
C.G = 2;
```

In the Java case, we access the generic entity directly without using a parametric type. This is because there's really only one instance of C, with each instance sharing the same global variable G. In C++, the instances are implicit, so it's not possible to create two different instances with the same parameters. The first two assignments are manipulating the same global while the third one is manipulating a different instance. In the Ada case, the three instances are explicitly created, named, and referenced individually.

60.3 Generic Parameters

Ada offers a wide variety of generic parameters which is difficult to translate into other languages. The parameters used during instantiation — and as a consequence those on which the generic unit may rely on — may be variables, types, or subprograms with certain properties. For example, the following provides a sort algorithm for any kind of array:

```
generic
   type Component is private;
   type Index is (<>);
   with function "<" (Left, Right : Component) return Boolean;
   type Array_Type is array (Index range <>) of Component;
procedure Sort (A : in out Array_Type);
```

The above declaration states that we need a type (`Component`), a discrete type (`Index`), a comparison subprogram (`"<"`), and an array definition (`Array_Type`). Given these, it's possible to write an algorithm that can sort any `Array_Type`. Note the usage of the **`with`** reserved word in front of the function name, to differentiate between the generic parameter and the beginning of the generic subprogram.

Here is a non-exhaustive overview of the kind of constraints that can be put on types:

```
type T is private; -- T is a constrained type, such as Integer
type T (<>) is private; -- T can be an unconstrained type, such as String
type T is tagged private; -- T is a tagged type
type T is new T2 with private; -- T is an extension of T2
type T is (<>); -- T is a discrete type
```

(continues on next page)

(continued from previous page)

```
type T is range <>; -- T is an integer type
type T is digits <>; -- T is a floating point type
type T is access T2; -- T is an access type, T2 is its designated type
```

CHAPTER

SIXTYONE

EXCEPTIONS

Exceptions are a mechanism for dealing with run-time occurrences that are rare, that usually correspond to errors (such as improperly formed input data), and whose occurrence causes an unconditional transfer of control.

61.1 Standard Exceptions

Compared with Java and C++, the notion of an Ada exception is very simple. An exception in Ada is an object whose "type" is **exception**, as opposed to classes in Java or any type in C++. The only piece of user data that can be associated with an Ada exception is a String. Basically, an exception in Ada can be raised, and it can be handled; information associated with an occurrence of an exception can be interrogated by a handler.

Ada makes heavy use of exceptions especially for data consistency check failures at run time. These include, but are not limited to, checking against type ranges and array boundaries, null pointers, various kind of concurrency properties, and functions not returning a value. For example, the following piece of code will raise the exception `Constraint_Error`:

```
procedure P is
   V : Positive;
begin
   V := -1;
end P;
```

In the above code, we're trying to assign a negative value to a variable that's declared to be positive. The range check takes place during the assignment operation, and the failure raises the `Constraint_Error` exception at that point. (Note that the compiler may give a warning that the value is out of range, but the error is manifest as a run-time exception.) Since there is no local handler, the exception is propagated to the caller; if P is the main procedure, then the program will be terminated.

Java and C++ can **throw** and **catch** exceptions when **try**ing code. All Ada code is already implicitly within **try** blocks, and exceptions are `raised` and handled.

[Ada]

```
begin
   Some_Call;
exception
   when Exception_1 =>
      Put_Line ("Error 1");
   when Exception_2 =>
      Put_Line ("Error 2");
   when others =>
      Put_Line ("Unknown error");
end;
```

[C++]

```
try {
   someCall ();
} catch (Exception1) {
   cout << "Error 1" << endl;
} catch (Exception2) {
   cout << "Error 2" << endl;
} catch (...) {
   cout << "Unknown error" << endl;
}
```

[Java]

```
try {
   someCall ();
} catch (Exception1 e1) {
   System.out.println ("Error 1");
} catch (Exception2 e2) {
   System.out.println ("Error 2");
} catch (Throwable e3) {
   System.out.println ("Unknown error");
}
```

Raising and throwing exceptions is permissible in all three languages.

61.2 Custom Exceptions

Custom exception declarations resemble object declarations, and they can be created in Ada using the **exception** keyword:

```
My_Exception : exception;
```

Your exceptions can then be raised using a **raise** statement, optionally accompanied by a message following the **with** reserved word:

[Ada]

```
raise My_Exception with "Some message";
```

[C++]

```
throw My_Exception ("Some message");
```

[Java]

```
throw new My_Exception ("Some message");
```

Language defined exceptions can also be raised in the same manner:

```
raise Constraint_Error;
```

CHAPTER

SIXTYTWO

CONCURRENCY

62.1 Tasks

Java and Ada both provide support for concurrency in the language. The C++ language has added a concurrency facility in its most recent revision, C++11, but we are assuming that most C++ programmers are not (yet) familiar with these new features. We thus provide the following mock API for C++ which is similar to the Java Thread class:

```
class Thread {
   public:
      virtual void run (); // code to execute
      void start (); // starts a thread and then call run ()
      void join (); // waits until the thread is finished
};
```

Each of the following examples will display the 26 letters of the alphabet twice, using two concurrent threads/tasks. Since there is no synchronization between the two threads of control in any of the examples, the output may be interspersed.

[Ada]

```
procedure Main is -- implicitly called by the environment task
   task My_Task;

   task body My_Task is
   begin
      for I in 'A' .. 'Z' loop
         Put_Line (I);
      end loop;
   end My_Task;
begin
   for I in 'A' .. 'Z' loop
      Put_Line (I);
   end loop;
end Main;
```

[C++]

```
class MyThread : public Thread {
   public:

   void run () {
      for (char i = 'A'; i <= 'Z'; ++i) {
         cout << i << endl;
      }
   }
};
```

(continues on next page)

(continued from previous page)

```
int main (int argc, char ** argv) {
   MyThread myTask;
   myTask.start ();

   for (char i = 'A'; i <= 'Z'; ++i) {
      cout << i << endl;
   }

   myTask.join ();

   return 0;
}
```

[Java]

```
public class Main {
   static class MyThread extends Thread {
      public void run () {
         for (char i = 'A'; i <= 'Z'; ++i) {
            System.out.println (i);
         }
      }
   }

   public static void main (String args) {
      MyThread myTask = new MyThread ();
      myTask.start ();

      for (char i = 'A'; i <= 'Z'; ++i) {
         System.out.println (i);
      }
      myTask.join ();
   }
}
```

Any number of Ada tasks may be declared in any declarative region. A task declaration is very similar to a procedure or package declaration. They all start automatically when control reaches the **begin**. A block will not exit until all sequences of statements defined within that scope, including those in tasks, have been completed.

A task type is a generalization of a task object; each object of a task type has the same behavior. A declared object of a task type is started within the scope where it is declared, and control does not leave that scope until the task has terminated.

An Ada task type is somewhat analogous to a Java Thread subclass, but in Java the instances of such a subclass are always dynamically allocated. In Ada an instance of a task type may either be declared or dynamically allocated.

Task types can be parametrized; the parameter serves the same purpose as an argument to a constructor in Java. The following example creates 10 tasks, each of which displays a subset of the alphabet contained between the parameter and the 'Z' Character. As with the earlier example, since there is no synchronization among the tasks, the output may be interspersed depending on the implementation's task scheduling algorithm.

[Ada]

```
task type My_Task (First : Character);

task body My_Task is
begin
   for I in First .. 'Z' loop
```

(continues on next page)

(continued from previous page)

```
      Put_Line (I);
   end loop;
end My_Task;

procedure Main is
   Tab : array (0 .. 9) of My_Task ('G');
begin
   null;
end Main;
```

[C++]

```
class MyThread : public Thread {
   public:

   char first;

   void run () {
      for (char i = first; i <= 'Z'; ++i) {
         cout << i << endl;
      }
   }
};

int main (int argc, char ** argv) {
   MyThread tab [10];

   for (int i = 0; i < 9; ++i) {
      tab [i].first = 'G';
      tab [i].start ();
   }

   for (int i = 0; i < 9; ++i) {
      tab [i].join ();
   }

   return 0;
}
```

[Java]

```
public class MyThread extends Thread {
   public char first;

   public MyThread (char first){
      this.first = first;
   }

   public void run () {
      for (char i = first; i <= 'Z'; ++i) {
         cout << i << endl;
      }
   }
}

public class Main {
   public static void main (String args) {
      MyThread [] tab = new MyThread [10];

      for (int i = 0; i < 9; ++i) {
         tab [i] = new MyThread ('G');
```

(continues on next page)

(continued from previous page)

```
         tab [i].start ();
      }

      for (int i = 0; i < 9; ++i) {
         tab [i].join ();
      }
   }
}
```

In Ada a task may be allocated on the heap as opposed to the stack. The task will then start as soon as it has been allocated, and terminates when its work is completed. This model is probably the one that's the most similar to Java:

[Ada]

```
type Ptr_Task is access My_Task;

procedure Main is
   T : Ptr_Task;
begin
   T := new My_Task ('G');
end Main;
```

[C++]

```
int main (int argc, char ** argv) {
   MyThread * t = new MyThread ();
   t->first = 'G';
   t->start ();
   return 0;
}
```

[Java]

```
public class Main {
   public static void main (String args) {
      MyThread t = new MyThread ('G');

      t.start ();
   }
}
```

62.2 Rendezvous

A rendezvous is a synchronization between two tasks, allowing them to exchange data and coordinate execution. Ada's rendezvous facility cannot be modeled with C++ or Java without complex machinery. Therefore, this section will just show examples written in Ada.

Let's consider the following example:

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is

   task After is
      entry Go;
   end After ;
```

(continues on next page)

(continued from previous page)

```
   task body After is
   begin
      accept Go;
      Put_Line ("After");
   end After;

begin
   Put_Line ("Before");
   After.Go;
end;
```

The Go **entry** declared in `After` is the external interface to the task. In the task body, the **accept** statement causes the task to wait for a call on the entry. This particular **entry** and **accept** pair doesn't do much more than cause the task to wait until `Main` calls `After.Go`. So, even though the two tasks start simultaneously and execute independently, they can coordinate via Go. Then, they both continue execution independently after the rendezvous.

The **entry**/**accept** pair can take/pass parameters, and the **accept** statement can contain a sequence of statements; while these statements are executed, the caller is blocked.

Let's look at a more ambitious example. The rendezvous below accepts parameters and executes some code:

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is

   task After is
      entry Go (Text : String);
   end After ;

   task body After is
   begin
      accept Go (Text : String) do
         Put_Line ("After: " & Text);
      end Go;
   end After;

begin
   Put_Line ("Before");
   After.Go ("Main");
end;
```

In the above example, the `Put_Line` is placed in the **accept** statement. Here's a possible execution trace, assuming a uniprocessor:

1. At the **begin** of `Main`, task `After` is started and the main procedure is suspended.
2. `After` reaches the **accept** statement and is suspended, since there is no pending call on the Go entry.
3. The main procedure is awakened and executes the `Put_Line` invocation, displaying the string "Before".
4. The main procedure calls the Go entry. Since `After` is suspended on its **accept** statement for this entry, the call succeeds.
5. The main procedure is suspended, and the task `After` is awakened to execute the body of the **accept** statement. The actual parameter `"Main"` is passed to the **accept** statement, and the `Put_Line` invocation is executed. As a result, the string `"After: Main"` is displayed.
6. When the **accept** statement is completed, both the `After` task and the main proce-

dure are ready to run. Suppose that the `Main` procedure is given the processor. It reaches its **end**, but the local task `After` has not yet terminated. The main procedure is suspended.

7. The `After` task continues, and terminates since it is at its **end**. The main procedure is resumed, and it too can terminate since its dependent task has terminated.

The above description is a conceptual model; in practice the implementation can perform various optimizations to avoid unnecessary context switches.

62.3 Selective Rendezvous

The accept statement by itself can only wait for a single event (call) at a time. The **select** statement allows a task to listen for multiple events simultaneously, and then to deal with the first event to occur. This feature is illustrated by the task below, which maintains an integer value that is modified by other tasks that call `Increment`, `Decrement`, and `Get`:

```
task Counter is
   entry Get (Result : out Integer);
   entry Increment;
   entry Decrement;
end Counter;

task body Counter is
   Value : Integer := 0;
begin
   loop
      select
         accept Increment do
            Value := Value + 1;
         end Increment;
      or
         accept Decrement do
            Value := Value - 1;
         end Decrement;
      or
         accept Get (Result : out Integer) do
            Result := Value;
         end Get;
      or
         delay 60.0;  --  delay 1 minute
         exit;
      end select;
   end loop;
end Counter;
```

When the task's statement flow reaches the **select**, it will wait for all four events — three entries and a delay — in parallel. If the delay of one minute is exceeded, the task will execute the statements following the **delay** statement (and in this case will exit the loop, in effect terminating the task). The accept bodies for the `Increment`, `Decrement`, or `Get` entries will be otherwise executed as they're called. These four sections of the **select** statement are mutually exclusive: at each iteration of the loop, only one will be invoked. This is a critical point; if the task had been written as a package, with procedures for the various operations, then a "race condition" could occur where multiple tasks simultaneously calling, say, `Increment`, cause the value to only get incremented once. In the tasking version, if multiple tasks simultaneously call `Increment` then only one at a time will be accepted, and the value will be incremented by each of the tasks when it is accepted.

More specifically, each entry has an associated queue of pending callers. If a task calls one of the entries and `Counter` is not ready to accept the call (i.e., if `Counter` is not suspended

at the **select** statement) then the calling task is suspended, and placed in the queue of the entry that it is calling. From the perspective of the `Counter` task, at any iteration of the loop there are several possibilities:

- There is no call pending on any of the entries. In this case `Counter` is suspended. It will be awakened by the first of two events: a call on one of its entries (which will then be immediately accepted), or the expiration of the one minute delay (whose effect was noted above).
- There is a call pending on exactly one of the entries. In this case control passes to the **select** branch with an **accept** statement for that entry. The choice of which caller to accept, if more than one, depends on the queuing policy, which can be specified via a pragma defined in the Real-Time Systems Annex of the Ada standard; the default is First-In First-Out.
- There are calls pending on more than one entry. In this case one of the entries with pending callers is chosen, and then one of the callers is chosen to be de-queued (the choices depend on the queueing policy).

62.4 Protected Objects

Although the rendezvous may be used to implement mutually exclusive access to a shared data object, an alternative (and generally preferable) style is through a *protected object*, an efficiently implementable mechanism that makes the effect more explicit. A protected object has a public interface (its *protected operations*) for accessing and manipulating the object's components (its private part). Mutual exclusion is enforced through a conceptual lock on the object, and encapsulation ensures that the only external access to the components are through the protected operations.

Two kinds of operations can be performed on such objects: read-write operations by procedures or entries, and read-only operations by functions. The lock mechanism is implemented so that it's possible to perform concurrent read operations but not concurrent write or read/write operations.

Let's reimplement our earlier tasking example with a protected object called `Counter`:

```
protected Counter is
   function Get return Integer;
   procedure Increment;
   procedure Decrement;
private
   Value : Integer := 0;
end Counter;

protected body Counter is
   function Get return Integer is
   begin
      return Value;
   end Get;

   procedure Increment is
   begin
     Value := Value + 1;
   end Increment;

   procedure Decrement is
   begin
      Value := Value - 1;
   end Decrement;
end Counter;
```

Having two completely different ways to implement the same paradigm might seem complicated. However, in practice the actual problem to solve usually drives the choice between an active structure (a task) or a passive structure (a protected object).

A protected object can be accessed through prefix notation:

```
Counter.Increment;
Counter.Decrement;
Put_Line (Integer'Image (Counter.Get));
```

A protected object may look like a package syntactically, since it contains declarations that can be accessed externally using prefix notation. However, the declaration of a protected object is extremely restricted; for example, no public data is allowed, no types can be declared inside, etc. And besides the syntactic differences, there is a critical semantic distinction: a protected object has a conceptual lock that guarantees mutual exclusion; there is no such lock for a package.

Like tasks, it's possible to declare protected types that can be instantiated several times:

```
declare
   protected type Counter is
      -- as above
   end Counter;

   protected body Counter is
      -- as above
   end Counter;

   C1 : Counter;
   C2 : Counter;
begin
   C1.Increment;
   C2.Decrement;
   ...
end;
```

Protected objects and types can declare a procedure-like operation known as an "entry". An entry is somewhat similar to a procedure but includes a so-called *barrier condition* that must be true in order for the entry invocation to succeed. Calling a protected entry is thus a two step process: first, acquire the lock on the object, and then evaluate the barrier condition. If the condition is true then the caller will execute the entry body. If the condition is false, then the caller is placed in the queue for the entry, and relinquishes the lock. Barrier conditions (for entries with non-empty queues) are reevaluated upon completion of protected procedures and protected entries.

Here's an example illustrating protected entries: a protected type that models a binary semaphore / persistent signal.

```
protected type Binary_Semaphore is
  entry Wait;
  procedure Signal;
private
  Signaled : Boolean := False;
end Binary_Semaphore;

protected body Binary_Semaphore is
  entry Wait when Signaled is
  begin
    Signaled := False;
  end Wait;

  procedure Signal is
```

(continues on next page)

(continued from previous page)

```
  begin
    Signaled := True;
  end Signal;
end Binary_Semaphore;
```

Ada concurrency features provide much further generality than what's been presented here. For additional information please consult one of the works cited in the *References* section.

CHAPTER

SIXTYTHREE

LOW LEVEL PROGRAMMING

63.1 Representation Clauses

We've seen in the previous chapters how Ada can be used to describe high level semantics and architecture. The beauty of the language, however, is that it can be used all the way down to the lowest levels of the development, including embedded assembly code or bit-level data management.

One very interesting feature of the language is that, unlike C, for example, there are no data representation constraints unless specified by the developer. This means that the compiler is free to choose the best trade-off in terms of representation vs. performance. Let's start with the following example:

[Ada]

```
type R is record
   V  : Integer range 0 .. 255;
   B1 : Boolean;
   B2 : Boolean;
end record
with Pack;
```

[C++]

```
struct R {
   unsigned int v:8;
   bool b1;
   bool b2;
};
```

[Java]

```
public class R {
   public byte v;
   public boolean b1;
   public boolean b2;
}
```

The Ada and the C++ code above both represent efforts to create an object that's as small as possible. Controlling data size is not possible in Java, but the language does specify the size of values for the primitive types.

Although the C++ and Ada code are equivalent in this particular example, there's an interesting semantic difference. In C++, the number of bits required by each field needs to be specified. Here, we're stating that v is only 8 bits, effectively representing values from 0 to 255. In Ada, it's the other way around: the developer specifies the range of values required and the compiler decides how to represent things, optimizing for speed or size. The Pack

aspect declared at the end of the record specifies that the compiler should optimize for size even at the expense of decreased speed in accessing record components.

Other representation clauses can be specified as well, along with compile-time consistency checks between requirements in terms of available values and specified sizes. This is particularly useful when a specific layout is necessary; for example when interfacing with hardware, a driver, or a communication protocol. Here's how to specify a specific data layout based on the previous example:

```
type R is record
   V  : Integer range 0 .. 255;
   B1 : Boolean;
   B2 : Boolean;
end record;

for R use record
   --  Occupy the first bit of the first byte.
   B1 at 0 range 0 .. 0;

   --  Occupy the last 7 bits of the first byte,
   --  as well as the first bit of the second byte.
   V  at 0 range 1 .. 8;

   --  Occupy the second bit of the second byte.
   B2 at 1 range 1 .. 1;
end record;
```

We omit the `with Pack` directive and instead use a record representation clause following the record declaration. The compiler is directed to spread objects of type R across two bytes. The layout we're specifying here is fairly inefficient to work with on any machine, but you can have the compiler construct the most efficient methods for access, rather than coding your own machine-dependent bit-level methods manually.

63.2 Embedded Assembly Code

When performing low-level development, such as at the kernel or hardware driver level, there can be times when it is necessary to implement functionality with assembly code.

Every Ada compiler has its own conventions for embedding assembly code, based on the hardware platform and the supported assembler(s). Our examples here will work with GNAT and GCC on the x86 architecture.

All x86 processors since the Intel Pentium offer the `rdtsc` instruction, which tells us the number of cycles since the last processor reset. It takes no inputs and places an unsigned 64 bit value split between the edx and eax registers.

GNAT provides a subprogram called `System.Machine_Code.Asm` that can be used for assembly code insertion. You can specify a string to pass to the assembler as well as source-level variables to be used for input and output:

```
with System.Machine_Code; use System.Machine_Code;
with Interfaces;          use Interfaces;

function Get_Processor_Cycles return Unsigned_64 is
   Low, High : Unsigned_32;
   Counter   : Unsigned_64;
begin
   Asm ("rdtsc",
        Outputs =>
          (Unsigned_32'Asm_Output ("=a", Low),
```

(continues on next page)

(continued from previous page)

```
           Unsigned_32'Asm_Output ("=d", High)),
        Volatile => True);

   Counter :=
     Unsigned_64 (High) * 2 ** 32 +
     Unsigned_64 (Low);

   return Counter;
end Get_Processor_Cycles;
```

The `Unsigned_32'Asm_Output` clauses above provide associations between machine registers and source-level variables to be updated. `"=a"` and `"=d"` refer to the eax and edx machine registers, respectively. The use of the `Unsigned_32` and `Unsigned_64` types from package `Interfaces` ensures correct representation of the data. We assemble the two 32-bit values to form a single 64 bit value.

We set the `Volatile` parameter to **`True`** to tell the compiler that invoking this instruction multiple times with the same inputs can result in different outputs. This eliminates the possibility that the compiler will optimize multiple invocations into a single call.

With optimization turned on, the GNAT compiler is smart enough to use the eax and edx registers to implement the `High` and `Low` variables, resulting in zero overhead for the assembly interface.

The machine code insertion interface provides many features beyond what was shown here. More information can be found in the GNAT User's Guide, and the GNAT Reference manual.

63.3 Interfacing with C

Much effort was spent making Ada easy to interface with other languages. The `Interfaces` package hierarchy and the pragmas `Convention`, `Import`, and `Export` allow you to make inter-language calls while observing proper data representation for each language.

Let's start with the following C code:

```
struct my_struct {
   int A, B;
};

void call (my_struct * p) {
   printf ("%d", p->A);
}
```

To call that function from Ada, the Ada compiler requires a description of the data structure to pass as well as a description of the function itself. To capture how the C **`struct my_struct`** is represented, we can use the following record along with a **`pragma`** *`Convention`*. The pragma directs the compiler to lay out the data in memory the way a C compiler would.

```
type my_struct is record
   A : Interfaces.C.int;
   B : Interfaces.C.int;
end record;
pragma Convention (C, my_struct);
```

Describing a foreign subprogram call to Ada code is called "binding" and it is performed in two stages. First, an Ada subprogram specification equivalent to the C function is coded. A C function returning a value maps to an Ada function, and a **`void`** function maps to an

Ada procedure. Then, rather than implementing the subprogram using Ada code, we use a **pragma** *Import*:

```
procedure Call (V : my_struct);
pragma Import (C, Call, "call"); -- Third argument optional
```

The `Import` pragma specifies that whenever `Call` is invoked by Ada code, it should invoke the `call` function with the C calling convention.

And that's all that's necessary. Here's an example of a call to `Call`:

```
declare
   V : my_struct := (A => 1, B => 2);
begin
   Call (V);
end;
```

You can also make Ada subprograms available to C code, and examples of this can be found in the GNAT User's Guide. Interfacing with C++ and Java use implementation-dependent features that are also available with GNAT.

CHAPTER

SIXTYFOUR

CONCLUSION

All the usual paradigms of imperative programming can be found in all three languages that we surveyed in this document. However, Ada is different from the rest in that it's more explicit when expressing properties and expectations. This is a good thing: being more formal affords better communication among programmers on a team and between programmers and machines. You also get more assurance of the coherence of a program at many levels. Ada can help reduce the cost of software maintenance by shifting the effort to creating a sound system the first time, rather than working harder, more often, and at greater expense, to fix bugs found later in systems already in production. Applications that have reliability needs, long term maintenance requirements, or safety/security concerns are those for which Ada has a proven track record.

It's becoming increasingly common to find systems implemented in multiple languages, and Ada has standard interfacing facilities to allow Ada code to invoke subprograms and/or reference data structures from other language environments, or vice versa. Use of Ada thus allows easy interfacing between different technologies, using each for what it's best at.

We hope this guide has provided some insight into the Ada software engineer's world and has made Ada more accessible to programmers already familiar with programming in other languages.

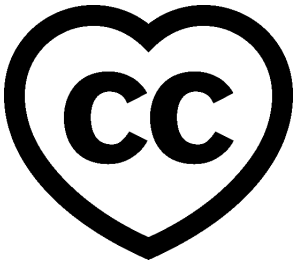
If you remix, transform, or build upon the material, you must distribute your contributions under the same license as the original. You can find license details on this page[320]



This course introduces you to the Ada language by comparing it to C. It assumes that you have good knowledge of the C language. It also assumes that the choice of learning Ada is guided by considerations linked to reliability, safety or security. In that sense, it teaches you Ada paradigms that should be applied in replacement of those usually applied in C.

This course also introduces you to the SPARK subset of the Ada programming language, which removes a few features of the language with undefined behavior, so that the code is fit for sound static analysis techniques.

This course was written by Quentin Ochem, Robert Tice, Gustavo A. Hoffmann, and Patrick Rogers and reviewed by Patrick Rogers, Filip Gajowniczek, and Tucker Taft.

Note: The code examples in this course use an 80-column limit, which is a typical limit for Ada code. Note that, on devices with a small screen size, some code examples might be difficult to read.

Note: Each code example from this book has an associated "code block metadata", which contains the name of the "project" and an MD5 hash value. This information is used to identify a single code example.

You can find all code examples in a zip file, which you can download from the learn website[321]. The directory structure in the zip file is based on the code block metadata. For example, if you're searching for a code example with this metadata:

- Project: Courses.Intro_To_Ada.Imperative_Language.Greet
- MD5: cba89a34b87c9dfa71533d982d05e6ab

you will find it in this directory:

```
projects/Courses/Intro_To_Ada/Imperative_Language/Greet/
cba89a34b87c9dfa71533d982d05e6ab/
```

In order to use this code example, just follow these steps:

1. Unpack the zip file;

[320] http://creativecommons.org/licenses/by-sa/4.0
[321] https://learn.adacore.com/zip/learning-ada_code.zip

2. Go to target directory;
3. Start GNAT Studio on this directory;
4. Build (or compile) the project;
5. Run the application (if a main procedure is available in the project).

CHAPTER

SIXTYSIX

INTRODUCTION

66.1 So, what is this Ada thing anyway?

To answer this question let's introduce Ada as it compares to C for an embedded application. C developers are used to a certain coding semantic and style of programming. Especially in the embedded domain, developers are used to working at a very low level near the hardware to directly manipulate memory and registers. Normal operations involve mathematical operations on pointers, complex bit shifts, and logical bitwise operations. C is well designed for such operations as it is a low level language that was designed to replace assembly language for faster, more efficient programming. Because of this minimal abstraction, the programmer has to model the data that represents the problem they are trying to solve using the language of the physical hardware.

Let's look at an example of this problem in action by comparing the same program in Ada and C:

[C]

Listing 1: main.c

```c
#include <stdio.h>
#include <stdlib.h>

#define DEGREES_MAX           (360)
typedef unsigned int degrees;

#define MOD_DEGREES(x)   (x % DEGREES_MAX)

degrees add_angles(degrees* list, int length)
{
  degrees sum = 0;
  for(int i = 0; i < length; ++i) {
    sum += list[i];
  }

  return sum;
}

int main(int argc, char** argv)
{
  degrees list[argc - 1];

  for(int i = 1; i < argc; ++i) {
    list[i - 1] = MOD_DEGREES(atoi(argv[i]));
  }

  printf("Sum: %d\n", add_angles(list, argc - 1));

```

(continues on next page)

(continued from previous page)

```
  return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Introduction.Add_Angles_C
MD5: a6d184caaec372c538634c578b5e144b
```

Runtime output

```
Sum: 0
```

[Ada]

Listing 2: sum_angles.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO; use Ada.Text_IO;

procedure Sum_Angles is

   DEGREES_MAX : constant := 360;
   type Degrees is mod DEGREES_MAX;

   type Degrees_List is array (Natural range <>) of Degrees;

   function Add_Angles (List : Degrees_List) return Degrees
   is
      Sum : Degrees := 0;
   begin
      for I in List'Range loop
         Sum := Sum + List (I);
      end loop;

      return Sum;
   end Add_Angles;

   List : Degrees_List (1 .. Argument_Count);
begin
   for I in List'Range loop
      List (I) := Degrees (Integer'Value (Argument (I)));
   end loop;

   Put_Line ("Sum:" & Add_Angles (List)'Img);
end Sum_Angles;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Introduction.Add_Angles_Ada
MD5: b5a446e5c27aa18c917ae8c2cc6c1605
```

Runtime output

```
Sum: 0
```

Here we have a piece of code in C and in Ada that takes some numbers from the command line and stores them in an array. We then sum all of the values in the array and print the result. The tricky part here is that we are working with values that model an angle in degrees. We know that angles are modular types, meaning that angles greater than 360° can also be represented as `Angle mod 360`. So if we have an angle of 400°, this is equivalent to 40°. In order to model this behavior in C we had to create the `MOD_DEGREES`

macro, which performs the modulus operation. As we read values from the command line, we convert them to integers and perform the modulus before storing them into the array. We then call add_angles which returns the sum of the values in the array. Can you spot the problem with the C code?

Try running the Ada and C examples using the input sequence `340 2 50 70`. What does the C program output? What does the Ada program output? Why are they different?

The problem with the C code is that we forgot to call `MOD_DEGREES` in the for loop of add_angles. This means that it is possible for add_angles to return values greater than `DEGREES_MAX`. Let's look at the equivalent Ada code now to see how Ada handles the situation. The first thing we do in the Ada code is to create the type `Degrees` which is a modular type. This means that the compiler is going to handle performing the modulus operation for us. If we use the same for loop in the `Add_Angles` function, we can see that we aren't doing anything special to make sure that our resulting value is within the 360° range we need it to be in.

The takeaway from this example is that Ada tries to abstract some concepts from the developer so that the developer can focus on solving the problem at hand using a data model that models the real world rather than using data types prescribed by the hardware. The main benefit of this is that the compiler takes some responsibility from the developer for generating correct code. In this example we forgot to put in a check in the C code. The compiler inserted the check for us in the Ada code because we told the compiler what we were trying to accomplish by defining strong types.

Ideally, we want all the power that the C programming language can give us to manipulate the hardware we are working on while also allowing us the ability to more accurately model data in a safe way. So, we have a dilemma; what can give us the power of operations like the C language, but also provide us with features that can minimize the potential for developer error? Since this course is about Ada, it's a good bet we're about to introduce the Ada language as the answer to this question...

Unlike C, the Ada language was designed as a higher level language from its conception; giving more responsibility to the compiler to generate correct code. As mentioned above, with C, developers are constantly shifting, masking, and accessing bits directly on memory pointers. In Ada, all of these operations are possible, but in most cases, there is a better way to perform these operations using higher level constructs that are less prone to mistakes, like off-by-one or unintentional buffer overflows. If we were to compare the same application written using C and with Ada using high level constructs, we would see similar performance in terms of speed and memory efficiency. If we compare the object code generated by both compilers, it's possible that they even look identical!

66.2 Ada — The Technical Details

Like C, Ada is a compiled language. This means that the compiler will parse the source code and emit machine code native to the target hardware. The Ada compiler we will be discussing in this course is the GNAT compiler. This compiler is based on the GCC technology like many C and C++ compilers available. When the GNAT compiler is invoked on Ada code, the GNAT front-end expands and translates the Ada code into an intermediate language which is passed to GCC where the code is optimized and translated to machine code. A C compiler based on GCC performs the same steps and uses the same intermediate GCC representation. This means that the optimizations we are used to seeing with a GCC based C compiler can also be applied to Ada code. The main difference between the two compilers is that the Ada compiler is expanding high level constructs into intermediate code. After expansion, the Ada code will be very similar to the equivalent C code.

It is possible to do a line-by-line translation of C code to Ada. This feels like a natural step for a developer used to C paradigms. However, there may be very little benefit to doing so. For the purpose of this course, we're going to assume that the choice of Ada over C is guided by

considerations linked to reliability, safety or security. In order to improve upon the reliability, safety and security of our application, Ada paradigms should be applied in replacement of those usually applied in C. Constructs such as pointers, preprocessor macros, bitwise operations and defensive code typically get expressed in Ada in very different ways, improving the overall reliability and readability of the applications. Learning these new ways of coding, often, requires effort by the developer at first, but proves more efficient once the paradigms are understood.

In this course we will also introduce the SPARK subset of the Ada programming language. The SPARK subset removes a few features of the language, i.e., those that make proof difficult, such as pointer aliasing. By removing these features we can write code that is fit for sound static analysis techniques. This means that we can run mathematical provers on the SPARK code to prove certain safety or security properties about the code.

CHAPTER

SIXTYSEVEN

THE C DEVELOPER'S PERSPECTIVE ON ADA

67.1 What we mean by Embedded Software

The Ada programming language is a general programming language, which means it can be used for many different types of applications. One type of application where it particularly shines is reliable and safety-critical embedded software; meaning, a platform with a microprocessor such as ARM, PowerPC, x86, or RISC-V. The application may be running on top of an embedded operating system, such as an embedded Linux, or directly on bare metal. And the application domain can range from small entities such as firmware or device controllers to flight management systems, communication based train control systems, or advanced driver assistance systems.

67.2 The GNAT Toolchain

The toolchain used throughout this course is called GNAT, which is a suite of tools with a compiler based on the GCC environment. It can be obtained from AdaCore, either as part of a commercial contract with GNAT Pro[322] or at no charge with the GNAT Community edition[323]. The information in this course will be relevant no matter which edition you're using. Most examples will be runnable on the native Linux or Windows version for convenience. Some will only be relevant in the context of a cross toolchain, in which case we'll be using the embedded ARM bare metal toolchain.

As for any Ada compiler, GNAT takes advantage of implementation permissions and offers a project management system. Because we're talking about embedded platforms, there are a lot of topics that we'll go over which will be specific to GNAT, and sometimes to specific platforms supported by GNAT. We'll try to make the distinction between what is GNAT-specific and Ada generic as much as possible throughout this course.

For an introduction to the GNAT Toolchain for the GNAT Community edition, you may refer to the *Introduction to GNAT Toolchain* (page 1681) course.

[322] https://www.adacore.com/gnatpro
[323] https://www.adacore.com/community

67.3 The GNAT Toolchain for Embedded Targets

When we're discussing embedded programming, our target device is often different from the host, which is the device we're using to actually write and build an application. In this case, we're talking about cross compilation platforms (concisely referred to as cross platforms).

The GNAT toolchain supports cross platform compilation for various target devices. This section provides a short introduction to the topic. For more details, please refer to the GNAT User's Guide Supplement for Cross Platforms[324]

GNAT supports two types of cross platforms:

- **cross targets**, where the target device has an embedded operating system.
  - ARM-Linux, which is commonly found in a Raspberry-Pi, is a prominent example.
- **bareboard targets**, where the run-times do not depend on an operating system.
  - In this case, the application has direct access to the system hardware.

For each platform, a set of run-time libraries is available. Run-time libraries implement a subset of the Ada language for different use cases, and they're different for each target platform. They may be selected via an attribute in the project's GPR project file or as a command-line switch to **`GPRbuild`**. Although the run-time libraries may vary from target to target, the user interface stays the same, providing portability for the application.

Run-time libraries consists of:

1. Files that are dependent on the target board.
   - These files are responsible for configuring and interacting with the hardware.
   - They are known as a Board Support Package — commonly referred to by their abbrevation *BSP*.
2. Code that is target-independent.
   - This code implements language-defined functionality.

The bareboard run-time libraries are provided as customized run-times that are configured to target a very specific micro-controller or processor. Therefore, for different micro-controllers and processors, the run-time libraries need to be ported to the specific target. These are some examples of what needs to be ported:

- startup code / scripts;
- clock frequency initializations;
- memory mapping / allocation;
- interrupts and interrupt priorities;
- register descriptions.

For more details on the topic, please refer to the following chapters of the GNAT User's Guide Supplement for Cross Platforms[325]:

- Bareboard Topics[326]
- Customized Run-Time Libraries[327]

67.4 Hello World in Ada

The first piece of code to translate from C to Ada is the usual Hello World program:

[C]

Listing 1: main.c

```c
#include <stdio.h>

int main(int argc, const char * argv[])
{
    printf("Hello World\n");
    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Hello_World_C
MD5: 59685c72296a032893cda71dade24196
```

Runtime output

```
Hello World
```

[Ada]

Listing 2: hello_world.adb

```ada
with Ada.Text_IO;

procedure Hello_World
is
begin
   Ada.Text_IO.Put_Line ("Hello World");
end Hello_World;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Hello_World_Ada
MD5: f1a7c6a4fd679c4caea7ee31d14aab2e
```

Runtime output

```
Hello World
```

The resulting program will print `Hello World` on the screen. Let's now dissect the Ada version to describe what is going on:

The first line of the Ada code is giving us access to the `Ada.Text_IO` library which contains the `Put_Line` function we will use to print the text to the console. This is similar to C's `#include <stdio.h>`. We then create a procedure which executes `Put_Line` which prints to the console. This is similar to C's `printf` function. For now, we can assume these Ada and C features have similar functionality. In reality, they are very different. We will explore that more as we delve further into the Ada language.

You may have noticed that the Ada syntax is more verbose than C. Instead of using braces {} to declare scope, Ada uses keywords. **`is`** opens a declarative scope — which is empty here as there's no variable to declare. **`begin`** opens a sequence of statements. Within this sequence, we're calling the function `Put_Line`, prefixing explicitly with the name of the library unit where it's declared, `Ada.Text_IO`. The absence of the end of line `\n` can also be noted, as `Put_Line` always terminates by an end of line.

67.5 The Ada Syntax

Ada syntax might seem peculiar at first glance. Unlike many other languages, it's not derived from the popular C style of notation with its ample use of brackets; rather, it uses a more expository syntax coming from Pascal. In many ways, Ada is a more explicit language — its syntax was designed to increase readability and maintainability, rather than making it faster to write in a condensed manner. For example:

- full words like **`begin`** and **`end`** are used in place of curly braces.
- Conditions are written using **`if`**, **`then`**, **`elsif`**, **`else`**, and **`end if`**.
- Ada's assignment operator does not double as an expression, eliminating potential mistakes that could be caused by `=` being used where `==` should be.

All languages provide one or more ways to express comments. In Ada, two consecutive hyphens `--` mark the start of a comment that continues to the end of the line. This is exactly the same as using `//` for comments in C. Multi line comments like C's `/* */` do not exist in Ada.

Ada compilers are stricter with type and range checking than most C programmers are used to. Most beginning Ada programmers encounter a variety of warnings and error messages when coding, but this helps detect problems and vulnerabilities at compile time — early on in the development cycle. In addition, checks (such as array bounds checks) provide verification that could not be done at compile time but can be performed either at run-time, or through formal proof (with the SPARK tooling).

Ada identifiers and reserved words are case insensitive. The identifiers `VAR`, `var` and `VaR` are treated as the same identifier; likewise **`begin`**, **`BEGIN`**, **`Begin`**, etc. Identifiers may include letters, digits, and underscores, but must always start with a letter. There are 73 reserved keywords in Ada that may not be used as identifiers, and these are:

abort	else	null	select
abs	elsif	of	separate
abstract	end	or	some
accept	entry	others	subtype
access	exception	out	synchronized
aliased	exit	overriding	tagged
all	for	package	task
and	function	pragma	terminate
array	generic	private	then
at	goto	procedure	type
begin	if	protected	until
body	in	raise	use
case	interface	range	when
constant	is	record	while
declare	limited	rem	with
delay	loop	renames	xor
delta	mod	requeue	
digits	new	return	
do	not	reverse	

67.6 Compilation Unit Structure

Both C and Ada were designed with the idea that the code specification and code implementation could be separated into two files. In C, the specification typically lives in the .h, or header file, and the implementation lives in the .c file. Ada is superficially similar to C. With the GNAT toolchain, compilation units are stored in files with an .ads extension for specifications and with an .adb extension for implementations.

One main difference between the C and Ada compilation structure is that Ada compilation units are structured into something called packages.

67.7 Packages

The package is the basic modularization unit of the Ada language, as is the class for Java and the header and implementation pair for C. A specification defines a package and the implementation implements the package. We saw this in an earlier example when we included the `Ada.Text_IO` package into our application. The package specification has the structure:

[Ada]

```
--  my_package.ads
package My_Package is

   --  public declarations

private

   --  private declarations

end My_Package;
```

The package implementation, or body, has the structure:

```
--  my_package.adb
package body My_Package is

   --  implementation

end My_Package;
```

67.7.1 Declaration Protection

An Ada package contains three parts that, for GNAT, are separated into two files: `.ads` files contain public and private Ada specifications, and `.adb` files contain the implementation, or Ada bodies.

[Ada]

```
package Package_Name is
   -- public specifications
private
   -- private specifications
end Package_Name;

package body Package_Name is
```

(continues on next page)

(continued from previous page)

```
   -- implementation
end Package_Name;
```

Private types are useful for preventing the users of a package's types from depending on the types' implementation details. Another use-case is the prevention of package users from accessing package state/data arbitrarily. The private reserved word splits the package spec into *public* and *private* parts. For example:

[Ada]

Listing 3: types.ads

```
package Types is
   type Type_1 is private;
   type Type_2 is private;
   type Type_3 is private;
   procedure P (X : Type_1);
   --  ...
private
   procedure Q (Y : Type_1);
   type Type_1 is new Integer range 1 .. 1000;
   type Type_2 is array (Integer range 1 .. 1000) of Integer;
   type Type_3 is record
      A, B : Integer;
   end record;
end Types;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Private_Types
MD5: ae4a9e4d10b55e7efd92d7952ba22f4f
```

Subprograms declared above the **private** separator (such as P) will be visible to the package user, and the ones below (such as Q) will not. The body of the package, the implementation, has access to both parts. A package specification does not require a private section.

67.7.2 Hierarchical Packages

Ada packages can be organized into hierarchies. A child unit can be declared in the following way:

[Ada]

```
-- root-child.ads

package Root.Child is
   --  package spec goes here
end Root.Child;

-- root-child.adb

package body Root.Child is
   --  package body goes here
end Root.Child;
```

Here, `Root.Child` is a child package of `Root`. The public part of `Root.Child` has access to the public part of `Root`. The private part of `Child` has access to the private part of `Root`, which is one of the main advantages of child packages. However, there is no visibility

relationship between the two bodies. One common way to use this capability is to define subsystems around a hierarchical naming scheme.

67.7.3 Using Entities from Packages

Entities declared in the visible part of a package specification can be made accessible using a **with** clause that references the package, which is similar to the C *#include* directive. After a **with** clause makes a package available, references to the package contents require the name of the package as a prefix, with a dot after the package name. This prefix can be omitted if a **use** clause is employed.

[Ada]

Listing 4: pck.ads

```ada
--  pck.ads

package Pck is
   My_Glob : Integer;
end Pck;
```

Listing 5: main.adb

```ada
--  main.adb

with Pck;

procedure Main is
begin
   Pck.My_Glob := 0;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Using_Pkg_Entities
MD5: 4215ba710eb54478538dc001bb74ce09
```

In contrast to C, the Ada **with** clause is a *semantic inclusion* mechanism rather than a *text inclusion* mechanism; for more information on this difference please refer to *Packages* (page 35).

67.8 Statements and Declarations

The following code samples are all equivalent, and illustrate the use of comments and working with integer variables:

[C]

Listing 6: main.c

```c
#include <stdio.h>

int main(int argc, const char * argv[])
{
    // variable declarations
    int a = 0, b = 0, c = 100, d;

```

(continues on next page)

(continued from previous page)

```c
    // c shorthand for increment
    a++;

    // regular addition
    d = a + b + c;

    // printing the result
    printf("d = %d\n", d);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Var_Decl_C
MD5: ba258dac5c052a97da475239e2f2ce96
```

Runtime output

```
d = 101
```

[Ada]

Listing 7: main.adb

```ada
with Ada.Text_IO;

procedure Main
is
   --  variable declaration
   A, B : Integer := 0;
   C    : Integer := 100;
   D    : Integer;
begin
   --  Ada does not have a shortcut format for increment like in C
   A := A + 1;

   --  regular addition
   D := A + B + C;

   --  printing the result
   Ada.Text_IO.Put_Line ("D =" & D'Img);
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Var_Decl_Ada
MD5: eaff76f36d5f938bd806d29048df7865
```

Runtime output

```
D = 101
```

You'll notice that, in both languages, statements are terminated with a semicolon. This means that you can have multi-line statements.

The shortcuts of incrementing and decrementing

You may have noticed that Ada does not have something similar to the a`++` or a`--` operators. Instead you must use the full assignment `A := A + 1` or `A := A - 1`.

In the Ada example above, there are two distinct sections to the **procedure** Main. This first section is delimited by the **is** keyword and the **begin** keyword. This section is called the declarative block of the subprogram. The declarative block is where you will define all the local variables which will be used in the subprogram. C89 had something similar, where developers were required to declare their variables at the top of the scope block. Most C developers may have run into this before when trying to write a for loop:

[C]

Listing 8: main.c

```c
/* The C89 version */

#include <stdio.h>

int average(int* list, int length)
{
    int i;
    int sum = 0;

    for(i = 0; i < length; ++i) {
        sum += list[i];
    }
    return (sum / length);
}

int main(int argc, const char * argv[])
{
    int vals[] = { 2, 2, 4, 4 };

    printf("Average: %d\n", average(vals, 4));

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Average_C89
MD5: 5c89aa28cba0bae4d963b235c53aedf2
```

Runtime output

```
Average: 3
```

[C]

Listing 9: main.c

```c
// The modern C way

#include <stdio.h>

int average(int* list, int length)
{
    int sum = 0;

    for(int i = 0; i < length; ++i) {
        sum += list[i];
    }

    return (sum / length);
}
```

(continues on next page)

(continued from previous page)

```c

int main(int argc, const char * argv[])
{
    int vals[] = { 2, 2, 4, 4 };

    printf("Average: %d\n", average(vals, 4));

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Average_C_Modern
MD5: 6354863137d78adb974743915d1d4530
```

Runtime output

```
Average: 3
```

For the fun of it, let's also see the Ada way to do this:

[Ada]

Listing 10: main.adb

```ada
with Ada.Text_IO;

procedure Main is
   type Int_Array is array (Natural range <>) of Integer;

   function Average (List : Int_Array) return Integer
   is
      Sum : Integer := 0;
   begin
      for I in List'Range loop
         Sum := Sum + List (I);
      end loop;

      return (Sum / List'Length);
   end Average;

   Vals : constant Int_Array (1 .. 4) := (2, 2, 4, 4);
begin
   Ada.Text_IO.Put_Line ("Average: " & Integer'Image (Average (Vals)));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Average_Ada
MD5: 52abb574d7a8b3bdb56715735dcd1d54
```

Runtime output

```
Average:  3
```

We will explore more about the syntax of loops in Ada in a future section of this course; but for now, notice that the I variable used as the loop index is not declared in the declarative section!

Declaration Flippy Floppy

Something peculiar that you may have noticed about declarations in Ada is that they are backwards from the way C does declarations. The C language expects the type followed by the variable name. Ada expects the variable name followed by a colon and then the type.

The next block in the Ada example is between the **begin** and **end** keywords. This is where your statements will live. You can create new scopes by using the **declare** keyword:

[Ada]

Listing 11: main.adb

```ada
with Ada.Text_IO;

procedure Main
is
   --  variable declaration
   A, B : Integer := 0;
   C    : Integer := 100;
   D    : Integer;
begin
   --  Ada does not have a shortcut format for increment like in C
   A := A + 1;

   --  regular addition
   D := A + B + C;

   --  printing the result
   Ada.Text_IO.Put_Line ("D =" & D'Img);

   declare
      E : constant Integer := D * 100;
   begin
      --  printing the result
      Ada.Text_IO.Put_Line ("E =" & E'Img);
   end;

end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Var_Decl_Block_Ada
MD5: 9239b993a7eadb13a27bd3618a03431f
```

Runtime output

```
D = 101
E = 10100
```

Notice that we declared a new variable E whose scope only exists in our newly defined block. The equivalent C code is:

[C]

Listing 12: main.c

```c
#include <stdio.h>

int main(int argc, const char * argv[])
{
    // variable declarations
    int a = 0, b = 0, c = 100, d;

```

(continues on next page)

(continued from previous page)

```
    // c shorthand for increment
    a++;

    // regular addition
    d = a + b + c;

    // printing the result
    printf("d = %d\n", d);

    {
        const int e = d * 100;
        printf("e = %d\n", e);
    }

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Var_Decl_Block_C
MD5: 1a837795575ddc026738d92c8655ab6c
```

Runtime output

```
d = 101
e = 10100
```

Fun Fact about the C language assignment operator `=`: Did you know that an assignment in C can be used in an expression? Let's look at an example:

[C]

Listing 13: main.c

```
#include <stdio.h>

int main(int argc, const char * argv[])
{
    int a = 0;

    if (a = 10)
        printf("True\n");
    else
        printf("False\n");

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Equal_C
MD5: 2d00ddf7e154cb888082c86b8fd36c58
```

Runtime output

```
True
```

Run the above code example. What does it output? Is that what you were expecting?

The author of the above code example probably meant to test if `a == 10` in the if statement but accidentally typed `=` instead of `==`. Because C treats assignment as an expression, it was able to evaluate `a = 10`.

Let's look at the equivalent Ada code:

[Ada]

Listing 14: main.adb

```ada
with Ada.Text_IO; use Ada.Text_IO;

procedure Main
is
   A : Integer := 0;
begin

   if A := 10 then
      Put_Line ("True");
   else
      Put_Line ("False");
   end if;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Equal_Ada
MD5: 1500b264531dfcc7a62eeed2f22f511b
```

The above code will not compile. This is because Ada does no allow assignment as an expression.

The "use" clause

You'll notice in the above code example, after `with Ada.Text_IO;` there is a new statement we haven't seen before — `use Ada.Text_IO;`. You may also notice that we are not using the `Ada.Text_IO` prefix before the `Put_Line` statements. When we add the use clause it tells the compiler that we won't be using the prefix in the call to subprograms of that package. The use clause is something to use with caution. For example: if we use the `Ada.Text_IO` package and we also have a `Put_Line` subprogram in our current compilation unit with the same signature, we have a (potential) collision!

67.9 Conditions

The syntax of an if statement:

[C]

Listing 15: main.c

```c
#include <stdio.h>

int main(int argc, const char * argv[])
{
    // try changing the initial value to change the
    //    output of the program
    int v = 0;

    if (v > 0) {
        printf("Positive\n");
    }
    else if (v < 0) {
```

(continues on next page)

(continued from previous page)

```
        printf("Negative\n");
    }
    else {
        printf("Zero\n");
    }

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Condition_C
MD5: 69203e679085e73394d3620a5954262a
```

Runtime output

```
Zero
```

[Ada]

Listing 16: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main
is
   --  try changing the initial value to change the
   --    output of the program
   V : constant Integer := 0;
begin
   if V > 0 then
      Put_Line ("Positive");
   elsif V < 0 then
      Put_Line ("Negative");
   else
      Put_Line ("Zero");
   end if;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Condition_Ada
MD5: 417e557708472f9022db7d8c1ed6aa33
```

Runtime output

```
Zero
```

In Ada, everything that appears between the **if** and **then** keywords is the conditional expression, no parentheses are required. Comparison operators are the same except for:

Operator	C	Ada
Equality	==	=
Inequality	!=	/=
Not	!	**not**
And	&&	**and**
Or	||	**or**

The syntax of a switch/case statement:

[C]

Listing 17: main.c

```c
#include <stdio.h>

int main(int argc, const char * argv[])
{
    // try changing the initial value to change the
    //    output of the program
    int v = 0;

    switch(v) {
        case 0:
            printf("Zero\n");
            break;
        case 1: case 2: case 3: case 4: case 5:
        case 6: case 7: case 8: case 9:
            printf("Positive\n");
            break;
        case 10: case 12: case 14: case 16: case 18:
            printf("Even number between 10 and 18\n");
            break;
        default:
            printf("Something else\n");
            break;
    }

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Switch_Case_C
MD5: 1bdb3d0c151d71280ef9039841f7ee58
```

Runtime output

```
Zero
```

[Ada]

Listing 18: main.adb

```ada
with Ada.Text_IO; use Ada.Text_IO;

procedure Main
is
   --  try changing the initial value to change the
   --    output of the program
   V : constant Integer := 0;
begin
   case V is
      when 0 =>
         Put_Line ("Zero");
      when 1 .. 9 =>
         Put_Line ("Positive");
      when 10 | 12 | 14 | 16 | 18 =>
         Put_Line ("Even number between 10 and 18");
      when others =>
         Put_Line ("Something else");
   end case;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Switch_Case_Ada
MD5: 09e2318b56069281c95f23310dc121d1
```

Runtime output

```
Zero
```

Switch or Case?

A switch statement in C is the same as a case statement in Ada. This may be a little strange because C uses both keywords in the statement syntax. Let's make an analogy between C and Ada: C's **switch** is to Ada's **case** as C's **case** is to Ada's **when**.

Notice that in Ada, the case statement does not use the **break** keyword. In C, we use **break** to stop the execution of a case branch from falling through to the next branch. Here is an example:

[C]

Listing 19: main.c

```c
#include <stdio.h>

int main(int argc, const char * argv[])
{
    int v = 0;

    switch(v) {
        case 0:
            printf("Zero\n");
        case 1:
            printf("One\n");
        default:
            printf("Other\n");
    }

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Switch_Case_Break_C
MD5: fd0389205476f161655caf32244d9054
```

Runtime output

```
Zero
One
Other
```

Run the above code with `v = 0`. What prints? What prints when we change the assignment to `v = 1`?

When `v = 0` the program outputs the strings `Zero` then `One` then `Other`. This is called fall through. If you add the **break** statements back into the **switch** you can stop this fall through behavior from happening. The reason why fall through is allowed in C is to allow the behavior from the previous example where we want a specific branch to execute for multiple inputs. Ada solves this a different way because it is possible, or even probable, that the developer might forget a **break** statement accidentally. So Ada does not allow

fall through. Instead, you can use Ada's syntax to identify when a specific branch can be executed by more than one input. If you want a range of values for a specific branch you can use the `First .. Last` notation. If you want a few non-consecutive values you can use the `Value1 | Value2 | Value3` notation.

Instead of using the word **`default`** to denote the catch-all case, Ada uses the **`others`** keyword.

67.10 Loops

Let's start with some syntax:

[C]

Listing 20: main.c

```c
#include <stdio.h>

int main(int argc, const char * argv[])
{
    int v;

    // this is a while loop
    v = 1;
    while(v < 100) {
        v *= 2;
    }
    printf("v = %d\n", v);

    // this is a do while loop
    v = 1;
    do {
        v *= 2;
    } while(v < 200);
    printf("v = %d\n", v);

    // this is a for loop
    v = 0;
    for(int i = 0; i < 5; ++i) {
        v += (i * i);
    }
    printf("v = %d\n", v);

    // this is a forever loop with a conditional exit
    v = 0;
    while(1) {
        // do stuff here
        v += 1;
        if(v == 10)
            break;
    }
    printf("v = %d\n", v);

    // this is a loop over an array
    {
        #define ARR_SIZE (10)
        const int arr[ARR_SIZE] = { 1, 2, 3, 4, 5, 6, 7, 8, 9, 10 };
        int sum = 0;

        for(int i = 0; i < ARR_SIZE; ++i) {
```

(continues on next page)

(continued from previous page)

```
            sum += arr[i];
        }
        printf("sum = %d\n", sum);
    }

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Loops_C
MD5: bcd8963884e2b2a5e364219f9b6b8fbc
```

Runtime output

```
v = 128
v = 256
v = 30
v = 10
sum = 55
```

[Ada]

Listing 21: main.adb

```
with Ada.Text_IO;

procedure Main is
   V : Integer;
begin
   --  this is a while loop
   V := 1;
   while V < 100 loop
      V := V * 2;
   end loop;
   Ada.Text_IO.Put_Line ("V = " & Integer'Image (V));

   --  Ada doesn't have an explicit do while loop
   --  instead you can use the loop and exit keywords
   V := 1;
   loop
      V := V * 2;
      exit when V >= 200;
   end loop;
   Ada.Text_IO.Put_Line ("V = " & Integer'Image (V));

   --  this is a for loop
   V := 0;
   for I in 0 .. 4 loop
      V := V + (I * I);
   end loop;
   Ada.Text_IO.Put_Line ("V = " & Integer'Image (V));

   --  this is a forever loop with a conditional exit
   V := 0;
   loop
      --  do stuff here
      V := V + 1;
      exit when V = 10;
   end loop;
   Ada.Text_IO.Put_Line ("V = " & Integer'Image (V));
```

(continues on next page)

V =  256
V =  30
V =  10
Sum =  55
```

The loop syntax in Ada is pretty straightforward. The **loop** and **end loop** keywords are used to open and close the loop scope. Instead of using the **break** keyword to exit the loop, Ada has the **exit** statement. The **exit** statement can be combined with a logic expression using the **exit when** syntax.

The major deviation in loop syntax is regarding for loops. You'll notice, in C, that you sometimes declare, and at least initialize a loop counter variable, specify a loop predicate, or an expression that indicates when the loop should continue executing or complete, and last you specify an expression to update the loop counter.

[C]

```
for (initialization expression; loop predicate; update expression) {
    // some statements
}
```

In Ada, you don't declare or initialize a loop counter or specify an update expression. You only name the loop counter and give it a range to loop over. The loop counter is **read-only**! You cannot modify the loop counter inside the loop like you can in C. And the loop counter will increment consecutively along the specified range. But what if you want to loop over the range in reverse order?

[C]

Listing 22: main.c

```
1  #include <stdio.h>
2
3  #define MY_RANGE (10)
4
5  int main(int argc, const char * argv[])
6  {
7
```

Tick Image

Strangely enough, Ada people call the single apostrophe symbol, ', "tick". This "tick" says the we are accessing an attribute of the variable. When we do 'Img on a variable of a numerical type, we are going to return the string version of that numerical type. So in the for loop above, I'Img, or "I tick image" will return the string representation of the numerical value stored in I. We have to do this because Put_Line is expecting a string as an input parameter.

We'll discuss attributes in more details *later in this chapter* (page 1389).

In the above example, we are traversing over the range in reverse order. In Ada, we use the **reverse** keyword to accomplish this.

In many cases, when we are writing a for loop, it has something to do with traversing an array. In C, this is a classic location for off-by-one errors. Let's see an example in action:

[C]

Listing 24: main.c

```c
#include <stdio.h>

#define LIST_LENGTH (100)

int main(int argc, const char * argv[])
{
    int list[LIST_LENGTH];

    for(int i = LIST_LENGTH; i > 0; --i) {
        list[i] = LIST_LENGTH - i;
    }

    for (int i = 0; i < LIST_LENGTH; ++i)
    {
        printf("%d ", list[i]);

        if (i % 10 == 0) {
            printf("\n");
        }
    }

    return 0;
}
```

 39  38  37  36  35  34  33  32  31  30
 29  28  27  26  25  24  23  22  21  20
 19  18  17  16  15  14  13  12  11  10
 9  8  7  6  5  4  3  2  1  0
```

The above Ada and C code should initialize an array using a for loop. The initial values in the array should be contiguously decreasing from 99 to 0 as we index from the first index to the last index. In other words, the first index has a value of 99, the next has 98, the next 97 ... the last has a value of 0.

If you run both the C and Ada code above you'll notice that the outputs of the two programs are different. Can you spot why?

In the C code there are two problems:

1. There's a buffer overflow in the first iteration of the loop. We would need to modify the loop initialization to `int i = LIST_LENGTH - 1;`. The loop predicate should be modified to `i >= 0;`
2. The C code also has another off-by-one problem in the math to compute the value stored in `list[i]`. The expression should be changed to be `list[i] = LIST_LENGTH - i - 1;`.

These are typical off-by-one problems that plagues C programs. You'll notice that we didn't have this problem with the Ada code because we aren't defining the loop with arbitrary

numeric literals. Instead we are accessing attributes of the array we want to manipulate and are using a keyword to determine the indexing direction.

We can actually simplify the Ada for loop a little further using iterators:

[Ada]

Listing 26: main.adb

```ada
with Ada.Text_IO; use Ada.Text_IO;

procedure Main
is
   type Int_Array is array (Natural range 1 .. 100) of Integer;

   List : Int_Array;
begin

   for I in reverse List'Range loop
      List (I) := List'Last - I;
   end loop;

   for I of List loop
      Put (I'Img & " ");

      if I mod 10 = 0 then
         New_Line;
      end if;
   end loop;

end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Loop_Reverse_Ada_Simplified
MD5: 612046826199b00ed61271d6215596fe
```

Runtime output

```
 99  98  97  96  95  94  93  92  91  90
 89  88  87  86  85  84  83  82  81  80
 79  78  77  76  75  74  73  72  71  70
 69  68  67  66  65  64  63  62  61  60
 59  58  57  56  55  54  53  52  51  50
 49  48  47  46  45  44  43  42  41  40
 39  38  37  36  35  34  33  32  31  30
 29  28  27  26  25  24  23  22  21  20
 19  18  17  16  15  14  13  12  11  10
 9  8  7  6  5  4  3  2  1  0
```

In the second for loop, we changed the syntax to `for I of List`. Instead of I being the index counter, it is now an iterator that references the underlying element. This example of Ada code is identical to the last bit of Ada code. We just used a different method to index over the second for loop. There is no C equivalent to this Ada feature, but it is similar to C++'s range based for loop.

67.11 Type System

67.11.1 Strong Typing

Ada is considered a "strongly typed" language. This means that the language does not define any implicit type conversions. C does define implicit type conversions, sometimes referred to as *integer promotion*. The rules for promotion are fairly straightforward in simple expressions but can get confusing very quickly. Let's look at a typical place of confusion with implicit type conversion:

[C]

Listing 27: main.c

```c
#include <stdio.h>

int main(int argc, const char * argv[])
{
    unsigned char a = 0xFF;
    char b = 0xFF;

    printf("Does a == b?\n");
    if(a == b)
        printf("Yes.\n");
    else
        printf("No.\n");

    printf("a: 0x%08X, b: 0x%08X\n", a, b);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Strong_Typing_C
MD5: cab1ac9e2c86076d8435d53904783ba0
```

Runtime output

```
Does a == b?
No.
a: 0x000000FF, b: 0xFFFFFFFF
```

Run the above code. You will notice that a `!=` b! If we look at the output of the last `printf` statement we will see the problem. a is an unsigned number where b is a signed number. We stored a value of `0xFF` in both variables, but a treated this as the decimal number `255` while b treated this as the decimal number `-1`. When we compare the two variables, of course they aren't equal; but that's not very intuitive. Let's look at the equivalent Ada example:

[Ada]

Listing 28: main.adb

```ada
with Ada.Text_IO; use Ada.Text_IO;

procedure Main
is
   type Char is range 0 .. 255;
   type Unsigned_Char is mod 256;

```

(continues on next page)

(continued from previous page)

```
   A : Char := 16#FF#;
   B : Unsigned_Char := 16#FF#;
begin

   Put_Line ("Does A = B?");

   if A = B then
      Put_Line ("Yes");
   else
      Put_Line ("No");
   end if;

end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Strong_Typing_Ada
MD5: d6ef2668809159e9fb0d42f91e893222
```

Build output

```
main.adb:14:09: error: invalid operand types for operator "="
main.adb:14:09: error: left operand has type "Char" defined at line 5
main.adb:14:09: error: right operand has type "Unsigned_Char" defined at line 6
gprbuild: *** compilation phase failed
```

If you try to run this Ada example you will get a compilation error. This is because the compiler is telling you that you cannot compare variables of two different types. We would need to explicitly cast one side to make the comparison against two variables of the same type. By enforcing the explicit cast we can't accidentally end up in a situation where we assume something will happen implicitly when, in fact, our assumption is incorrect.

Another example: you can't divide an integer by a float. You need to perform the division operation using values of the same type, so one value must be explicitly converted to match the type of the other (in this case the more likely conversion is from integer to float). Ada is designed to guarantee that what's done by the program is what's meant by the programmer, leaving as little room for compiler interpretation as possible. Let's have a look at the following example:

[Ada]

Listing 29: strong_typing.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Strong_Typing is
   Alpha  : constant Integer := 1;
   Beta   : constant Integer := 10;
   Result : Float;
begin
   Result := Float (Alpha) / Float (Beta);

   Put_Line (Float'Image (Result));
end Strong_Typing;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Strong_Typing_Ada_2
MD5: bf91f01b499bcd7da1df751a9f91a767
```

Runtime output

```
 1.00000E-01
```

[C]

Listing 30: main.c

```c
#include <stdio.h>

void weakTyping (void) {
    const int   alpha = 1;
    const int   beta = 10;
    float result;

    result = alpha / beta;

    printf("%f\n", result);
}

int main(int argc, const char * argv[])
{
    weakTyping();

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Strong_Typing_C_2
MD5: e4310900cd1195d6e3d349e0c4aa758a
```

Runtime output

```
0.000000
```

Are the three programs above equivalent? It may seem like Ada is just adding extra complexity by forcing you to make the conversion from **Integer** to **Float** explicit. In fact, it significantly changes the behavior of the computation. While the Ada code performs a floating point operation 1.0 / 10.0 and stores 0.1 in `Result`, the C version instead store 0.0 in `result`. This is because the C version perform an integer operation between two integer variables: 1 / 10 is 0. The result of the integer division is then converted to a **float** and stored. Errors of this sort can be very hard to locate in complex pieces of code, and systematic specification of how the operation should be interpreted helps to avoid this class of errors. If an integer division was actually intended in the Ada case, it is still necessary to explicitly convert the final result to **Float**:

[Ada]

```ada
-- Perform an Integer division then convert to Float
Result := Float (Alpha / Beta);
```

The complete example would then be:

[Ada]

Listing 31: strong_typing.adb

```ada
with Ada.Text_IO; use Ada.Text_IO;

procedure Strong_Typing is
   Alpha  : constant Integer := 1;
   Beta   : constant Integer := 10;
   Result : Float;
```

(continues on next page)

(continued from previous page)

```
begin
   Result := Float (Alpha / Beta);

   Put_Line (Float'Image (Result));
end Strong_Typing;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Strong_Typing_Ada_2
MD5: 50d6a6a3270b51880c43c07f077760b6
```

Runtime output

```
 0.00000E+00
```

Floating Point Literals

In Ada, a floating point literal must be written with both an integral and decimal part. `10` is not a valid literal for a floating point value, while `10.0` is.

67.11.2 Language-Defined Types

The principal scalar types predefined by Ada are **`Integer`**, **`Float`**, **`Boolean`**, and **`Character`**. These correspond to **`int`**, **`float`**, **`int`** (when used for Booleans), and **`char`**, respectively. The names for these types are not reserved words; they are regular identifiers. There are other language-defined integer and floating-point types as well. All have implementation-defined ranges and precision.

67.11.3 Application-Defined Types

Ada's type system encourages programmers to think about data at a high level of abstraction. The compiler will at times output a simple efficient machine instruction for a full line of source code (and some instructions can be eliminated entirely). The careful programmer's concern that the operation really makes sense in the real world would be satisfied, and so would the programmer's concern about performance.

The next example below defines two different metrics: area and distance. Mixing these two metrics must be done with great care, as certain operations do not make sense, like adding an area to a distance. Others require knowledge of the expected semantics; for example, multiplying two distances. To help avoid errors, Ada requires that each of the binary operators +, -, *, and / for integer and floating-point types take operands of the same type and return a value of that type.

[Ada]

Listing 32: main.adb

```
procedure Main is
   type Distance is new Float;
   type Area is new Float;

   D1 : Distance := 2.0;
   D2 : Distance := 3.0;
   A  : Area;
begin
```

(continues on next page)

(continued from previous page)

```
   D1 := D1 + D2; -- OK
   D1 := D1 + A;  -- NOT OK: incompatible types for "+"
   A  := D1 * D2; -- NOT OK: incompatible types for ":="
   A  := Area (D1 * D2); -- OK
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Application_Defined_Types
MD5: 6a21d6281cc529bbf8ce2216d7e4a770
```

Build output

```
main.adb:10:13: error: invalid operand types for operator "+"
main.adb:10:13: error: left operand has type "Distance" defined at line 2
main.adb:10:13: error: right operand has type "Area" defined at line 3
main.adb:11:13: error: expected type "Area" defined at line 3
main.adb:11:13: error: found type "Distance" defined at line 2
gprbuild: *** compilation phase failed
```

Even though the `Distance` and `Area` types above are just **`Float`**, the compiler does not allow arbitrary mixing of values of these different types. An explicit conversion (which does not necessarily mean any additional object code) is necessary.

The predefined Ada rules are not perfect; they admit some problematic cases (for example multiplying two `Distance` yields a `Distance`) and prohibit some useful cases (for example multiplying two `Distances` should deliver an `Area`). These situations can be handled through other mechanisms. A predefined operation can be identified as abstract to make it unavailable; overloading can be used to give new interpretations to existing operator symbols, for example allowing an operator to return a value from a type different from its operands; and more generally, GNAT has introduced a facility that helps perform dimensionality checking.

Ada enumerations work similarly to C **`enum`**:

[Ada]

Listing 33: main.adb

```
procedure Main is
   type Day is
     (Monday,
      Tuesday,
      Wednesday,
      Thursday,
      Friday,
      Saturday,
      Sunday);

   D : Day := Monday;
begin
   null;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Enumeration_Ada
MD5: 51abd1863970e14ff86859c1aae11fe8
```

[C]

Listing 34: main.c

```c
enum Day {
    Monday,
    Tuesday,
    Wednesday,
    Thursday,
    Friday,
    Saturday,
    Sunday
};

int main(int argc, const char * argv[])
{
    enum Day d = Monday;

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Enumeration_C
MD5: d9f6724759375a126a6b5d8dceea3f24
```

But even though such enumerations may be implemented by the compiler as numeric values, at the language level Ada will not confuse the fact that Monday is a Day and is not an **Integer**. You can compare a Day with another Day, though. To specify implementation details like the numeric values that correspond with enumeration values in C you include them in the original **enum** declaration:

[C]

Listing 35: main.c

```c
#include <stdio.h>

enum Day {
    Monday    = 10,
    Tuesday   = 11,
    Wednesday = 12,
    Thursday  = 13,
    Friday    = 14,
    Saturday  = 15,
    Sunday    = 16
};

int main(int argc, const char * argv[])
{
    enum Day d = Monday;

    printf("d = %d\n", d);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Enumeration_Values_C
MD5: 48ae1c84dafabde7a16de5305e106a80
```

Runtime output

```
d = 10
```

But in Ada you must use both a type definition for Day as well as a separate representation clause for it like:

[Ada]

Listing 36: main.adb

```ada
with Ada.Text_IO;

procedure Main is
   type Day is
     (Monday,
      Tuesday,
      Wednesday,
      Thursday,
      Friday,
      Saturday,
      Sunday);

   --  Representation clause for Day type:
   for Day use
     (Monday    => 10,
      Tuesday   => 11,
      Wednesday => 12,
      Thursday  => 13,
      Friday    => 14,
      Saturday  => 15,
      Sunday    => 16);

   D : Day := Monday;
   V : Integer;
begin
   V := Day'Enum_Rep (D);
   Ada.Text_IO.Put_Line (Integer'Image (V));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Enumeration_Values
MD5: 9a4fa1a899cb8c240105bf8ad6dbfde3
```

Runtime output

```
 10
```

Note that however, unlike C, values for enumerations in Ada have to be unique.

67.11.4 Type Ranges

Contracts can be associated with types and variables, to refine values and define what are considered valid values. The most common kind of contract is a *range constraint* introduced with the **range** reserved word, for example:

[Ada]

Listing 37: main.adb

```
procedure Main is
   type Grade is range 0 .. 100;

   G1, G2  : Grade;
   N       : Integer;
begin
   --  ...              --  Initialization of N
   G1 := 80;            --  OK
   G1 := N;             --  Illegal (type mismatch)
   G1 := Grade (N);     --  Legal, run-time range check
   G2 := G1 + 10;       --  Legal, run-time range check
   G1 := (G1 + G2) / 2; --  Legal, run-time range check
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Range_Check
MD5: 0f249b06e373497ae94b6055a37187c8
```

Build output

```
main.adb:9:10: error: expected type "Grade" defined at line 2
main.adb:9:10: error: found type "Standard.Integer"
gprbuild: *** compilation phase failed
```

In the above example, `Grade` is a new integer type associated with a range check. Range checks are dynamic and are meant to enforce the property that no object of the given type can have a value outside the specified range. In this example, the first assignment to `G1` is correct and will not raise a run-time exception. Assigning `N` to `G1` is illegal since `Grade` is a different type than **`Integer`**. Converting `N` to `Grade` makes the assignment legal, and a range check on the conversion confirms that the value is within `0 .. 100`. Assigning `G1 + 10` to `G2` is legal since `+` for `Grade` returns a `Grade` (note that the literal `10` is interpreted as a `Grade` value in this context), and again there is a range check.

The final assignment illustrates an interesting but subtle point. The subexpression `G1 + G2` may be outside the range of `Grade`, but the final result will be in range. Nevertheless, depending on the representation chosen for `Grade`, the addition may overflow. If the compiler represents `Grade` values as signed 8-bit integers (i.e., machine numbers in the range `-128 .. 127`) then the sum `G1 + G2` may exceed 127, resulting in an integer overflow. To prevent this, you can use explicit conversions and perform the computation in a sufficiently large integer type, for example:

[Ada]

Listing 38: main.adb

```
with Ada.Text_IO;

procedure Main is
   type Grade is range 0 .. 100;

   G1, G2 : Grade := 99;
begin
   G1 := Grade ((Integer (G1) + Integer (G2)) / 2);
   Ada.Text_IO.Put_Line (Grade'Image (G1));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Range_And_Explicit_Conversion
MD5: d317fd95099e49017c4a4c1c52b7f8be
```

Runtime output

```
 99
```

Range checks are useful for detecting errors as early as possible. However, there may be some impact on performance. Modern compilers do know how to remove redundant checks, and you can deactivate these checks altogether if you have sufficient confidence that your code will function correctly.

Types can be derived from the representation of any other type. The new derived type can be associated with new constraints and operations. Going back to the Day example, one can write:

[Ada]

Listing 39: main.adb

```
procedure Main is
   type Day is
     (Monday,
      Tuesday,
      Wednesday,
      Thursday,
      Friday,
      Saturday,
      Sunday);

   type Business_Day is new Day range Monday .. Friday;
   type Weekend_Day is new Day range Saturday .. Sunday;
begin
   null;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Enum_Ranges_1
MD5: fd775ad4990d5636607d3a0d9b00044d
```

Since these are new types, implicit conversions are not allowed. In this case, it's more natural to create a new set of constraints for the same type, instead of making completely new ones. This is the idea behind *subtypes* in Ada. A subtype is a type with optional additional constraints. For example:

[Ada]

Listing 40: main.adb

```
procedure Main is
   type Day is
     (Monday,
      Tuesday,
      Wednesday,
      Thursday,
      Friday,
      Saturday,
      Sunday);

   subtype Business_Day is Day range Monday .. Friday;
   subtype Weekend_Day is Day range Saturday .. Sunday;
```

(continues on next page)

(continued from previous page)

```
13    subtype Dice_Throw is Integer range 1 .. 6;
14 begin
15    null;
16 end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Enum_Ranges_2
MD5: 5bcbde5b9f1aea57ff172fcfc89e1c41
```

These declarations don't create new types, just new names for constrained ranges of their base types.

The purpose of numeric ranges is to express some application-specific constraint that we want the compiler to help us enforce. More importantly, we want the compiler to tell us when that constraint cannot be met — when the underlying hardware cannot support the range given. There are two things to consider:

- just a range constraint, such as `A : Integer range 0 .. 10;`, or
- a type declaration, such as `type Result is range 0 .. 1_000_000_000;`.

Both represent some sort of application-specific constraint, but in addition, the type declaration promotes portability because it won't compile on targets that do not have a sufficiently large hardware numeric type. That's a definition of portability that is preferable to having something compile anywhere but not run correctly, as in C.

67.11.5 Unsigned And Modular Types

Unsigned integer numbers are quite common in embedded applications. In C, you can use them by declaring `unsigned int` variables. In Ada, you have two options:

- declare custom *unsigned* range types;
  - In addition, you can declare custom range *subtypes* or use existing subtypes such as `Natural`.
- declare custom modular types.

The following table presents the main features of each type. We discuss these types right after.

Feature	[C] `unsigned int`	[Ada] Unsigned range	[Ada] Modular
Excludes negative value	✓	✓	✓
Wraparound	✓		✓

When declaring custom range types in Ada, you may use the full range in the same way as in C. For example, this is the declaration of a 32-bit unsigned integer type and the X variable in Ada:

[Ada]

Listing 41: main.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Main is
4     type Unsigned_Int_32 is range 0 .. 2 ** 32 - 1;
5
```

(continues on next page)

(continued from previous page)

```
   X : Unsigned_Int_32 := 42;
begin
   Put_Line ("X = " & Unsigned_Int_32'Image (X));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Unsigned_32_Ada
MD5: 0a179ce327c022468f66b6814a981b62
```

Runtime output

```
X =  42
```

In C, when **unsigned int** has a size of 32 bits, this corresponds to the following declaration:

[C]

Listing 42: main.c

```c
#include <stdio.h>
#include <limits.h>

int main(int argc, const char * argv[])
{
    unsigned int x = 42;
    printf("x = %u\n", x);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Unsigned_32_C
MD5: 546068de216de96282490e81a0f7df26
```

Runtime output

```
x = 42
```

Another strategy is to declare subtypes for existing signed types and specify just the range that excludes negative numbers. For example, let's declare a custom 32-bit signed type and its unsigned subtype:

[Ada]

Listing 43: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   type Signed_Int_32 is range -2 ** 31 .. 2 ** 31 - 1;

   subtype Unsigned_Int_31 is Signed_Int_32 range 0 .. Signed_Int_32'Last;
   --  Equivalent to:
   --  subtype Unsigned_Int_31 is Signed_Int_32 range 0 .. 2 ** 31 - 1;

   X : Unsigned_Int_31 := 42;
begin
   Put_Line ("X = " & Unsigned_Int_31'Image (X));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Unsigned_31_Ada
MD5: 2ef2b5bfd54821ceb35faa222e649156
```

Runtime output

```
X =  42
```

In this case, we're just skipping the sign bit of the `Signed_Int_32` type. In other words, while `Signed_Int_32` has a size of 32 bits, `Unsigned_Int_31` has a range of 31 bits, even if the base type has 32 bits.

Note that the declaration above is actually similar to the existing **`Natural`** subtype. Ada provides the following standard subtypes:

```
subtype Natural  is Integer range 0..Integer'Last;
subtype Positive is Integer range 1..Integer'Last;
```

Since they're standard subtypes, you can declare variables of those subtypes directly in your implementation, in the same way as you can declare **`Integer`** variables.

As indicated in the table above, however, there is a difference in behavior for the variables we just declared, which occurs in case of overflow. Let's consider this C example:

[C]

Listing 44: main.c

```
#include <stdio.h>
#include <limits.h>

int main(int argc, const char * argv[])
{
    unsigned int x = UINT_MAX + 1;
    /* Now: x == 0 */

    printf("x = %u\n", x);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Overflow_Wraparound_C
MD5: 7d5dcf65471304ff8f303195359b4790
```

Runtime output

```
x = 0
```

The corresponding code in Ada raises an exception:

[Ada]

Listing 45: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   type Unsigned_Int_32 is range 0 .. 2 ** 32 - 1;

   X : Unsigned_Int_32 := Unsigned_Int_32'Last + 1;
```

(continues on next page)

(continued from previous page)

```
   --  Overflow: exception is raised!
begin
   Put_Line ("X = " & Unsigned_Int_32'Image (X));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Overflow_Wraparound_Ada
MD5: ee4c3e905c59f5c8d87311e13d079836
```

Build output

```
main.adb:6:48: warning: value not in range of type "Unsigned_Int_32" defined at␣
 ↪line 4 [enabled by default]
main.adb:6:48: warning: Constraint_Error will be raised at run time [enabled by␣
 ↪default]
```

Runtime output

```

raised CONSTRAINT_ERROR : main.adb:6 range check failed
```

While the C uses modulo arithmetic for unsigned integer, Ada doesn't use it for the `Unsigned_Int_32` type. Ada does, however, support modular types via type definitions using the **mod** keyword. In this example, we declare a 32-bit modular type:

[Ada]

Listing 46: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   type Unsigned_32 is mod 2**32;

   X : Unsigned_32 := Unsigned_32'Last + 1;
   --  Now: X = 0
begin
   Put_Line ("X = " & Unsigned_32'Image (X));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Overflow_Wraparound_Ada
MD5: 4ed963ab372cafc8e7a19d9c3107276b
```

Runtime output

```
X =  0
```

In this case, the behavior is the same as in the C declaration above.

Modular types, unlike Ada's signed integers, also provide bit-wise operations, a typical application for unsigned integers in C. In Ada, you can use operators such as **and**, **or**, **xor** and **not**. You can also use typical bit-shifting operations, such as `Shift_Left`, `Shift_Right`, `Shift_Right_Arithmetic`, `Rotate_Left` and `Rotate_Right`.

67.11.6 Attributes

Attributes start with a single apostrophe ("tick"), and they allow you to query properties of, and perform certain actions on, declared entities such as types, objects, and subprograms. For example, you can determine the first and last bounds of scalar types, get the sizes of objects and types, and convert values to and from strings. This section provides an overview of how attributes work. For more information on the many attributes defined by the language, you can refer directly to the Ada Language Reference Manual.

The `'Image` and `'Value` attributes allow you to transform a scalar value into a **`String`** and vice-versa. For example:

[Ada]

Listing 47: main.adb

```ada
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   A : Integer := 10;
begin
   Put_Line (Integer'Image (A));
   A := Integer'Value ("99");
   Put_Line (Integer'Image (A));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Image_Attribute
MD5: 1fcfc79ec599a26e21aef7eacffcf96e
```

Runtime output

```
 10
 99
```

Important

Semantically, attributes are equivalent to subprograms. For example, **`Integer`**`'Image` is defined as follows:

```ada
function Integer'Image(Arg : Integer'Base) return String;
```

Certain attributes are provided only for certain kinds of types. For example, the `'Val` and `'Pos` attributes for an enumeration type associates a discrete value with its position among its peers. One circuitous way of moving to the next character of the ASCII table is:

[Ada]

Listing 48: main.adb

```ada
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   C : Character := 'a';
begin
   Put (C);
   C := Character'Val (Character'Pos (C) + 1);
   Put (C);
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Character_1
MD5: 742bbaeb74e5dd9fa73089c0d1aa0fde
```

Runtime output

```
ab
```

A more concise way to get the next value in Ada is to use the `'Succ` attribute:

[Ada]

Listing 49: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   C : Character := 'a';
begin
   Put (C);
   C := Character'Succ (C);
   Put (C);
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Character_1
MD5: 842eeff2b82dcdb8c73547a33d03995b
```

Runtime output

```
ab
```

You can get the previous value using the `'Pred` attribute. Here is the equivalent in C:

[C]

Listing 50: main.c

```
#include <stdio.h>

int main(int argc, const char * argv[])
{
    char c = 'a';
    printf("%c", c);
    c++;
    printf("%c", c);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Loop_Reverse_C
MD5: 40bfbd6a672bc3fdb7e8f2f2d7101b19
```

Runtime output

```
ab
```

Other interesting examples are the `'First` and `'Last` attributes which, respectively, return the first and last values of a scalar type. Using 32-bit integers, for instance, `Integer'First` returns -2^{31} and `Integer'Last` returns $2^{31} - 1$.

67.11.7 Arrays and Strings

C arrays are pointers with offsets, but the same is not the case for Ada. Arrays in Ada are not interchangeable with operations on pointers, and array types are considered first-class citizens. They have dedicated semantics such as the availability of the array's boundaries at run-time. Therefore, unhandled array overflows are impossible unless checks are suppressed. Any discrete type can serve as an array index, and you can specify both the starting and ending bounds — the lower bound doesn't necessarily have to be 0. Most of the time, array types need to be explicitly declared prior to the declaration of an object of that array type.

Here's an example of declaring an array of 26 characters, initializing the values from `'a'` to `'z'`:

[Ada]

Listing 51: main.adb

```ada
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   type Arr_Type is array (Integer range <>) of Character;
   Arr : Arr_Type (1 .. 26);
   C : Character := 'a';
begin
   for I in Arr'Range loop
      Arr (I) := C;
      C := Character'Succ (C);

      Put (Arr (I) & " ");

      if I mod 7 = 0 then
         New_Line;
      end if;
   end loop;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Array_Range_Ada
MD5: 8e0597f6c040c740b35c79bc4706829b
```

Runtime output

```
a b c d e f g
h i j k l m n
o p q r s t u
v w x y z
```

[C]

Listing 52: main.c

```c
#include <stdio.h>

int main(int argc, const char * argv[])
{
    char Arr [26];
    char C = 'a';

    for (int I = 0; I < 26; ++I) {
        Arr [I] = C++;
```

(continues on next page)

(continued from previous page)

```
        printf ("%c ", Arr [I]);

        if ((I + 1) % 7 == 0) {
            printf ("\n");
        }
    }

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Array_Range_C
MD5: 1182155f46a0b69f73cd5937c23ed67d
```

Runtime output

```
a b c d e f g
h i j k l m n
o p q r s t u
v w x y z
```

In C, only the size of the array is given during declaration. In Ada, array index ranges are specified using two values of a discrete type. In this example, the array type declaration specifies the use of **Integer** as the index type, but does not provide any constraints (use <>, pronounced *box*, to specify "no constraints"). The constraints are defined in the object declaration to be 1 to 26, inclusive. Arrays have an attribute called 'Range. In our example, Arr'Range can also be expressed as Arr'First .. Arr'Last; both expressions will resolve to 1 .. 26. So the 'Range attribute supplies the bounds for our **for** loop. There is no risk of stating either of the bounds incorrectly, as one might do in C where I <= 26 may be specified as the end-of-loop condition.

As in C, Ada **String** is an array of **Character**. Ada strings, importantly, are not delimited with the special character '0' like they are in C. It is not necessary because Ada uses the array's bounds to determine where the string starts and stops.

Ada's predefined **String** type is very straightforward to use:

[Ada]

Listing 53: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   My_String : String (1 .. 19) := "This is an example!";
begin
   Put_Line (My_String);
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Constrained_String
MD5: da2e88900c670f80b7380f87f2b89ec2
```

Runtime output

```
This is an example!
```

Unlike C, Ada does not offer escape sequences such as 'n'. Instead, explicit values from the ASCII package must be concatenated (via the concatenation operator, &). Here for example, is how to initialize a line of text ending with a new line:

[Ada]

Listing 54: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   My_String : String := "This is a line" & ASCII.LF;
begin
   Put (My_String);
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Constrained_String
MD5: 684bbbdf99d48ed6fd5c257183a6609f
```

Runtime output

```
This is a line

```

You see here that no constraints are necessary for this variable definition. The initial value given allows the automatic determination of `My_String`'s bounds.

Ada offers high-level operations for copying, slicing, and assigning values to arrays. We'll start with assignment. In C, the assignment operator doesn't make a copy of the value of an array, but only copies the address or reference to the target variable. In Ada, the actual array contents are duplicated. To get the above behavior, actual pointer types would have to be defined and used.

[Ada]

Listing 55: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   type Arr_Type is array (Integer range <>) of Integer;
   A1 : Arr_Type (1 .. 2);
   A2 : Arr_Type (1 .. 2);
begin
   A1 (1) := 0;
   A1 (2) := 1;

   A2 := A1;

   for I in A2'Range loop
      Put_Line (Integer'Image (A2 (I)));
   end loop;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Array_Copy_Ada
MD5: 4d4e9aa063c1f488e7cefa90083d06c2
```

Runtime output

```
 0
 1
```

[C]

Listing 56: main.c

```c
#include <stdio.h>
#include <string.h>

int main(int argc, const char * argv[])
{
    int A1 [2];
    int A2 [2];

    A1 [0] = 0;
    A1 [1] = 1;

    memcpy (A2, A1, sizeof (int) * 2);

    for (int i = 0; i < 2; i++) {
        printf("%d\n", A2[i]);
    }

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Array_Copy_C
MD5: 0dade800452673b7a82afe1c656f07e6
```

Runtime output

```
0
1
```

In all of the examples above, the source and destination arrays must have precisely the same number of elements. Ada allows you to easily specify a portion, or slice, of an array. So you can write the following:

[Ada]

Listing 57: main.adb

```ada
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   type Arr_Type is array (Integer range <>) of Integer;
   A1 : Arr_Type (1 .. 10) := (1, 2, 3, 4, 5, 6, 7, 8, 9, 10);
   A2 : Arr_Type (1 .. 5)  := (1, 2, 3, 4, 5);
begin
   A2 (1 .. 3) := A1 (4 .. 6);

   for I in A2'Range loop
      Put_Line (Integer'Image (A2 (I)));
   end loop;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Array_Slice
MD5: cb2a7de2cff8ea19025363886f8821e4
```

Runtime output

```
4
5
6
4
5
```

This assigns the 4th, 5th, and 6th elements of A1 into the 1st, 2nd, and 3rd elements of A2. Note that only the length matters here: the values of the indexes don't have to be equal; they slide automatically.

Ada also offers high level comparison operations which compare the contents of arrays as opposed to their addresses:

[Ada]

Listing 58: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   type Arr_Type is array (Integer range <>) of Integer;
   A1 : Arr_Type (1 .. 2) := (10, 20);
   A2 : Arr_Type (1 .. 2) := (10, 20);
begin
   if A1 = A2 then
     Put_Line ("A1 = A2");
   else
     Put_Line ("A1 /= A2");
   end if;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Array_Equal_Ada
MD5: 650a734875a02b2fb3678bbc3f8dd82a
```

Runtime output

```
A1 = A2
```

[C]

Listing 59: main.c

```
#include <stdio.h>

int main(int argc, const char * argv[])
{
    int A1 [2] = { 10, 20 };
    int A2 [2] = { 10, 20 };

    int eq = 1;

    for (int i = 0; i < 2; ++i) {
        if (A1 [i] != A2 [i]) {
            eq = 0;
            break;
        }
    }

    if (eq) {
        printf("A1 == A2\n");
```

(continues on next page)

(continued from previous page)

```
    }
    else {
        printf("A1 != A2\n");
    }

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Array_Equal_C
MD5: efe8717d931324bcbe8b70b03693c92e
```

Runtime output

```
A1 == A2
```

You can assign to all the elements of an array in each language in different ways. In Ada, the number of elements to assign can be determined by looking at the right-hand side, the left-hand side, or both sides of the assignment. When bounds are known on the left-hand side, it's possible to use the others expression to define a default value for all the unspecified array elements. Therefore, you can write:

[Ada]

Listing 60: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   type Arr_Type is array (Integer range <>) of Integer;
   A1 : Arr_Type (-2 .. 42) := (others => 0);
begin
   --  use a slice to assign A1 elements 11 .. 19 to 1
   A1 (11 .. 19) := (others => 1);

   Put_Line ("---- A1 ----");
   for I in A1'Range loop
      Put_Line (Integer'Image (I) & " => " &
                Integer'Image (A1 (I)));
   end loop;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Array_Assignment_Ada
MD5: 673d31f633a32b6bb1cce238150cfc80
```

Runtime output

```
---- A1 ----
-2 =>  0
-1 =>  0
 0 =>  0
 1 =>  0
 2 =>  0
 3 =>  0
 4 =>  0
 5 =>  0
 6 =>  0
 7 =>  0
```

(continues on next page)

(continued from previous page)

```
 8 =>  0
 9 =>  0
 10 =>  0
 11 =>  1
 12 =>  1
 13 =>  1
 14 =>  1
 15 =>  1
 16 =>  1
 17 =>  1
 18 =>  1
 19 =>  1
 20 =>  0
 21 =>  0
 22 =>  0
 23 =>  0
 24 =>  0
 25 =>  0
 26 =>  0
 27 =>  0
 28 =>  0
 29 =>  0
 30 =>  0
 31 =>  0
 32 =>  0
 33 =>  0
 34 =>  0
 35 =>  0
 36 =>  0
 37 =>  0
 38 =>  0
 39 =>  0
 40 =>  0
 41 =>  0
 42 =>  0
```

In this example, we're specifying that A1 has a range between -2 and 42. We use (**others** => 0) to initialize all array elements with zero. In the next example, the number of elements is determined by looking at the right-hand side:

[Ada]

Listing 61: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   type Arr_Type is array (Integer range <>) of Integer;
   A1 : Arr_Type := (1, 2, 3, 4, 5, 6, 7, 8, 9);
begin
   A1 := (1, 2, 3, others => 10);

   Put_Line ("---- A1 ----");
   for I in A1'Range loop
      Put_Line (Integer'Image (I) & " => " &
                Integer'Image (A1 (I)));
   end loop;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Array_Assignment_Ada
MD5: 3e3d69815373d1c61208df265903e89d
```

Runtime output

```
---- A1 ----
-2147483648 =>  1
-2147483647 =>  2
-2147483646 =>  3
-2147483645 =>  10
-2147483644 =>  10
-2147483643 =>  10
-2147483642 =>  10
-2147483641 =>  10
-2147483640 =>  10
```

Since A1 is initialized with an aggregate of 9 elements, A1 automatically has 9 elements. Also, we're not specifying any range in the declaration of A1. Therefore, the compiler uses the default range of the underlying array type Arr_Type, which has an unconstrained range based on the **Integer** type. The compiler selects the first element of that type (**Integer**'First) as the start index of A1. If you replaced **Integer range** <> in the declaration of the Arr_Type by **Positive range** <>, then A1's start index would be **Positive**'First — which corresponds to one.

67.11.8 Heterogeneous Data Structures

The structure corresponding to a C **struct** is an Ada **record**. Here are some simple records:

[Ada]

Listing 62: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   type R is record
      A, B : Integer;
      C    : Float;
   end record;

   V : R;
begin
   V.A := 0;
   Put_Line ("V.A = " & Integer'Image (V.A));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Struct_Ada
MD5: 013f27dfc827355f32bea37fb267df9b
```

Runtime output

```
V.A =  0
```

[C]

Listing 63: main.c

```c
#include <stdio.h>

struct R {
    int A, B;
    float C;
};

int main(int argc, const char * argv[])
{
    struct R V;
    V.A = 0;
    printf("V.A = %d\n", V.A);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Struct_C
MD5: 653b65bbb6ea02a512e439d912e11d7f
```

Runtime output

```
V.A = 0
```

Ada allows specification of default values for fields just like C. The values specified can take the form of an ordered list of values, a named list of values, or an incomplete list followed by others => <> to specify that fields not listed will take their default values. For example:

[Ada]

Listing 64: main.adb

```ada
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is

   type R is record
      A, B : Integer := 0;
      C    : Float   := 0.0;
   end record;

   procedure Put_R (V : R; Name : String) is
   begin
      Put_Line (Name & " = ("
                & Integer'Image (V.A) & ", "
                & Integer'Image (V.B) & ", "
                & Float'Image (V.C) & ")");
   end Put_R;

   V1 : constant R := (1, 2, 1.0);
   V2 : constant R := (A => 1, B => 2, C => 1.0);
   V3 : constant R := (C => 1.0, A => 1, B => 2);
   V4 : constant R := (C => 1.0, others => <>);

begin
   Put_R (V1, "V1");
   Put_R (V2, "V2");
   Put_R (V3, "V3");
   Put_R (V4, "V4");
```

(continues on next page)

(continued from previous page)

```
28 end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Struct_Default_Ada
MD5: d0a9713e3bd9804c00ebf68cc7c196b7
```

Runtime output

```
V1 = ( 1,  2,  1.00000E+00)
V2 = ( 1,  2,  1.00000E+00)
V3 = ( 1,  2,  1.00000E+00)
V4 = ( 0,  0,  1.00000E+00)
```

67.11.9 Pointers

As a foreword to the topic of pointers, it's important to keep in mind the fact that most situations that would require a pointer in C do not in Ada. In the vast majority of cases, indirect memory management can be hidden from the developer and thus saves from many potential errors. However, there are situation that do require the use of pointers, or said differently that require to make memory indirection explicit. This section will present Ada access types, the equivalent of C pointers. A further section will provide more details as to how situations that require pointers in C can be done without access types in Ada.

We'll continue this section by explaining the difference between objects allocated on the stack and objects allocated on the heap using the following example:

[Ada]

Listing 65: main.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Main is
4     type R is record
5        A, B : Integer;
6     end record;
7
8     procedure Put_R (V : R; Name : String) is
9     begin
10       Put_Line (Name & " = ("
11                 & Integer'Image (V.A) & ", "
12                 & Integer'Image (V.B) & ")");
13    end Put_R;
14
15    V1, V2 : R;
16
17 begin
18    V1.A := 0;
19    V2 := V1;
20    V2.A := 1;
21
22    Put_R (V1, "V1");
23    Put_R (V2, "V2");
24 end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Pointers_Ada
MD5: dd1367d57574a46df830884b2a7be930
```

Runtime output

```
V1 = ( 0,  0)
V2 = ( 1,  0)
```

[C]

Listing 66: main.c

```c
#include <stdio.h>

struct R {
    int A, B;
};

void print_r(const struct R *v,
             const char     *name)
{
    printf("%s = (%d, %d)\n", name, v->A, v->B);
}

int main(int argc, const char * argv[])
{
    struct R V1, V2;
    V1.A = 0;
    V2 = V1;
    V2.A = 1;

    print_r(&V1, "V1");
    print_r(&V2, "V2");

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Pointers_C
MD5: 4b4b79789444339b504bddc01d2d43da
```

Runtime output

```
V1 = (0, 0)
V2 = (1, 0)
```

There are many commonalities between the Ada and C semantics above. In Ada and C, objects are allocated on the stack and are directly accessed. V1 and V2 are two different objects and the assignment statement copies the value of V1 into V2. V1 and V2 are two distinct objects.

Here's now a similar example, but using heap allocation instead:

[Ada]

Listing 67: main.adb

```ada
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   type R is record
```

(continues on next page)

(continued from previous page)

```
      A, B : Integer;
   end record;

   type R_Access is access R;

   procedure Put_R (V : R; Name : String) is
   begin
      Put_Line (Name & " = ("
                & Integer'Image (V.A) & ", "
                & Integer'Image (V.B) & ")");
   end Put_R;

   V1 : R_Access;
   V2 : R_Access;
begin
   V1 := new R;
   V1.A := 0;
   V2 := V1;
   V2.A := 1;

   Put_R (V1.all, "V1");
   Put_R (V2.all, "V2");
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Heap_Alloc_Ada
MD5: 963b48bb0a8585a9941d8fb2d0eda390
```

Runtime output

```
V1 = ( 1,  0)
V2 = ( 1,  0)
```

[C]

Listing 68: main.c

```
#include <stdio.h>
#include <stdlib.h>

struct R {
    int A, B;
};

void print_r(const struct R *v,
             const char     *name)
{
    printf("%s = (%d, %d)\n", name, v->A, v->B);
}

int main(int argc, const char * argv[])
{
    struct R * V1, * V2;
    V1 = malloc(sizeof(struct R));
    V1->A = 0;
    V2 = V1;
    V2->A = 1;

    print_r(V1, "V1");
    print_r(V2, "V2");
```

(continues on next page)

(continued from previous page)

```
24
25      return 0;
26  }
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Heap_Alloc_C
MD5: 5c832377403dfa8f00d70ef92bfeff65
```

Runtime output

```
V1 = (1, 0)
V2 = (1, 0)
```

In this example, an object of type R is allocated on the heap. The same object is then referred to through V1 and V2. As in C, there's no garbage collector in Ada, so objects allocated by the new operator need to be expressly freed (which is not the case here).

Dereferencing is performed automatically in certain situations, for instance when it is clear that the type required is the dereferenced object rather than the pointer itself, or when accessing record members via a pointer. To explicitly dereference an access variable, append `.all`. The equivalent of `V1->A` in C can be written either as `V1.A` or `V1.all.A`.

Pointers to scalar objects in Ada and C look like:

[Ada]

Listing 69: main.adb

```
1  procedure Main is
2     type A_Int is access Integer;
3     Var : A_Int := new Integer;
4  begin
5     Var.all := 0;
6  end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Access_To_Scalars
MD5: 2e2bf53a9b5dc1098921d811be73a7f0
```

[C]

Listing 70: main.c

```
1  #include <stdlib.h>
2
3  int main(int argc, const char * argv[])
4  {
5      int * Var = malloc (sizeof(int));
6      *Var = 0;
7      return 0;
8  }
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Pointers_To_Scalars
MD5: f22d7b6f8170587009b0f6bb1299c0a0
```

In Ada, an initializer can be specified with the allocation by appending `'(value)`:

[Ada]

Listing 71: main.adb

```
procedure Main is
   type A_Int is access Integer;

   Var : A_Int := new Integer'(0);
begin
   null;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Access_Initialization
MD5: 5789253068f77100eec34919b8de66ec
```

When using Ada pointers to reference objects on the stack, the referenced objects must be declared as being aliased. This directs the compiler to implement the object using a memory region, rather than using registers or eliminating it entirely via optimization. The access type needs to be declared as either **access all** (if the referenced object needs to be assigned to) or **access constant** (if the referenced object is a constant). The 'Access attribute works like the C & operator to get a pointer to the object, but with a *scope accessibility* check to prevent references to objects that have gone out of scope. For example:

[Ada]

Listing 72: main.adb

```
procedure Main is
   type A_Int is access all Integer;
   Var : aliased Integer;
   Ptr : A_Int := Var'Access;
begin
   null;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Access_All
MD5: 520df34083e3517876e10710530380be
```

[C]

Listing 73: main.c

```
int main(int argc, const char * argv[])
{
    int Var;
    int * Ptr = &Var;

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Access_All_C
MD5: a592fcf09dabe15f2aaf12fba047d74f
```

To deallocate objects from the heap in Ada, it is necessary to use a deallocation subprogram that accepts a specific access type. A generic procedure is provided that can be customized to fit your needs, it's called Ada.Unchecked_Deallocation. To create your customized deallocator (that is, to instantiate this generic), you must provide the object type as well as the access type as follows:

[Ada]

Listing 74: main.adb

```ada
with Ada.Unchecked_Deallocation;

procedure Main is
   type Integer_Access is access all Integer;
   procedure Free is new Ada.Unchecked_Deallocation (Integer, Integer_Access);
   My_Pointer : Integer_Access := new Integer;
begin
   Free (My_Pointer);
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Unchecked_Deallocation
MD5: ef6ee170fea1f6c6c01037a09809916f
```

[C]

Listing 75: main.c

```c
#include <stdlib.h>

int main(int argc, const char * argv[])
{
    int * my_pointer = malloc (sizeof(int));
    free (my_pointer);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Free
MD5: 066046816dd1c4f9106b5e822cfe5e44
```

We'll discuss generics later *in this section* (page 1507).

67.12 Functions and Procedures

67.12.1 General Form

Subroutines in C are always expressed as functions which may or may not return a value. Ada explicitly differentiates between functions and procedures. Functions must return a value and procedures must not. Ada uses the more general term *subprogram* to refer to both functions and procedures.

Parameters can be passed in three distinct modes:

- **in**, which is the default, is for input parameters, whose value is provided by the caller and cannot be changed by the subprogram.
- **out** is for output parameters, with no initial value, to be assigned by the subprogram and returned to the caller.
- **in out** is a parameter with an initial value provided by the caller, which can be modified by the subprogram and returned to the caller (more or less the equivalent of a non-constant pointer in C).

Ada also provides **access** and **aliased** parameters, which are in effect explicit pass-by-reference indicators.

In Ada, the programmer specifies how the parameter will be used and in general the compiler decides how it will be passed (i.e., by copy or by reference). C has the programmer specify how to pass the parameter.

Important

There are some exceptions to the "general" rule in Ada. For example, parameters of scalar types are always passed by copy, for all three modes.

Here's a first example:

[Ada]

Listing 76: proc.ads

```
procedure Proc
 (Var1 : Integer;
  Var2 : out Integer;
  Var3 : in out Integer);
```

Listing 77: func.ads

```
function Func (Var : Integer) return Integer;
```

Listing 78: proc.adb

```
with Func;

procedure Proc
 (Var1 : Integer;
  Var2 : out Integer;
  Var3 : in out Integer)
is
begin
   Var2 := Func (Var1);
   Var3 := Var3 + 1;
end Proc;
```

Listing 79: func.adb

```
function Func (Var : Integer) return Integer
is
begin
   return Var + 1;
end Func;
```

Listing 80: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Proc;

procedure Main is
   V1, V2 : Integer;
begin
   V2 := 2;
   Proc (5, V1, V2);

```

(continues on next page)

(continued from previous page)

```
   Put_Line ("V1: " & Integer'Image (V1));
   Put_Line ("V2: " & Integer'Image (V2));
end Main;
```

```

Runtime output

```
V1:  6
V2:  3
```

[C]

Listing 81: proc.h

```
void Proc
    (int   Var1,
     int * Var2,
     int * Var3);
```

Listing 82: func.h

```
int Func (int Var);
```

Listing 83: proc.c

```
#include "func.h"

void Proc
    (int   Var1,
     int * Var2,
     int * Var3)
{
    *Var2 = Func (Var1);
    *Var3 += 1;
}
```

Listing 84: func.c

```
int Func (int Var)
{
    return Var + 1;
}
```

Listing 85: main.c

```
#include <stdio.h>
#include "proc.h"

int main(int argc, const char * argv[])
{
    int v1, v2;

    v2 = 2;
    Proc (5, &v1, &v2);

    printf("v1: %d\n", v1);
```

(continues on next page)

(continued from previous page)

```
12      printf("v2: %d\n", v2);
13
14      return 0;
15  }
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Subroutines_C
MD5: dd5645c832ef00b94061f204852084a3
```

Runtime output

```
v1: 6
v2: 3
```

The first two declarations for `Proc` and `Func` are specifications of the subprograms which are being provided later. Although optional here, it's still considered good practice to separately define specifications and implementations in order to make it easier to read the program. In Ada and C, a function that has not yet been seen cannot be used. Here, `Proc` can call `Func` because its specification has been declared.

Parameters in Ada subprogram declarations are separated with semicolons, because commas are reserved for listing multiple parameters of the same type. Parameter declaration syntax is the same as variable declaration syntax (except for the modes), including default values for parameters. If there are no parameters, the parentheses must be omitted entirely from both the declaration and invocation of the subprogram.

In Ada 202X

Ada 202X allows for using static expression functions, which are evaluated at compile time. To achieve this, we can use an aspect — we'll discuss aspects *later in this chapter* (page 1411).

An expression function is static when the `Static` aspect is specified. For example:

```
procedure Main is

   X1 : constant := (if True then 37 else 42);

   function If_Then_Else (Flag : Boolean; X, Y : Integer)
     return Integer is
      (if Flag then X else Y) with Static;

   X2 : constant := If_Then_Else (True, 37, 42);

begin
   null;
end Main;
```

In this example, we declare X1 using an expression. In the declaration of X2, we call the static expression function `If_Then_Else`. Both X1 and X2 have the same constant value.

67.12.2 Overloading

In C, function names must be unique. Ada allows overloading, in which multiple subprograms can share the same name as long as the subprogram signatures (the parameter types, and function return types) are different. The compiler will be able to resolve the calls to the proper routines or it will reject the calls. For example:

[Ada]

Listing 86: machine.ads

```
package Machine is
   type Status is (Off, On);
   type Code is new Integer range 0 .. 3;
   type Threshold is new Float range 0.0 .. 10.0;

   function Get (S : Status) return Code;
   function Get (S : Status) return Threshold;

end Machine;
```

Listing 87: machine.adb

```
package body Machine is

   function Get (S : Status) return Code is
   begin
      case S is
         when Off => return 1;
         when On  => return 3;
      end case;
   end Get;

   function Get (S : Status) return Threshold is
   begin
      case S is
         when Off => return  2.0;
         when On  => return 10.0;
      end case;
   end Get;

end Machine;
```

Listing 88: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Machine;     use Machine;

procedure Main is
   S : Status;
   C : Code;
   T : Threshold;
begin
   S := On;
   C := Get (S);
   T := Get (S);

   Put_Line ("S: " & Status'Image (S));
   Put_Line ("C: " & Code'Image (C));
   Put_Line ("T: " & Threshold'Image (T));
end Main;
```

Code block metadata

```

```

Runtime output

```
S: ON
C:  3
T:  1.00000E+01
```

The Ada compiler knows that an assignment to C requires a Code value. So, it chooses the Get function that returns a Code to satisfy this requirement.

Operators in Ada are functions too. This allows you to define local operators that override operators defined at an outer scope, and provide overloaded operators that operate on and compare different types. To declare an operator as a function, enclose its "name" in quotes:

[Ada]

Listing 89: machine_2.ads

```
package Machine_2 is
   type Status is (Off, Waiting, On);
   type Input is new Float range 0.0 .. 10.0;

   function Get (I : Input) return Status;

   function "=" (Left : Input; Right : Status) return Boolean;

end Machine_2;
```

Listing 90: machine_2.adb

```
package body Machine_2 is

   function Get (I : Input) return Status is
   begin
      if I >= 0.0 and I < 3.0 then
         return Off;
      elsif I >= 3.0 and I < 6.5 then
         return Waiting;
      else
         return On;
      end if;
   end Get;

   function "=" (Left : Input; Right : Status) return Boolean is
   begin
      return Get (Left) = Right;
   end "=";

end Machine_2;
```

Listing 91: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Machine_2;   use Machine_2;

procedure Main is
   I : Input;
begin
```

(continues on next page)

(continued from previous page)

```
   I := 3.0;
   if I = Off then
      Put_Line ("Machine is off.");
   else
      Put_Line ("Machine is not off.");
   end if;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Overloading_Eq
MD5: c5580f15c1b93f73fff3afc147cd15a1
```

Runtime output

```
Machine is not off.
```

67.12.3 Aspects

Aspect specifications allow you to define certain characteristics of a declaration using the **with** keyword after the declaration:

```
procedure Some_Procedure is <procedure_definition>
  with Some_Aspect => <aspect_specification>;

function Some_Function is <function_definition>
  with Some_Aspect => <aspect_specification>;

type Some_Type is <type_definition>
  with Some_Aspect => <aspect_specification>;

Obj : Some_Type with Some_Aspect => <aspect_specification>;
```

For example, you can inline a subprogram by specifying the `Inline` aspect:

[Ada]

Listing 92: float_arrays.ads

```
package Float_Arrays is

   type Float_Array is array (Positive range <>) of Float;

   function Average (Data : Float_Array) return Float
     with Inline;

end Float_Arrays;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Inline_Aspect
MD5: 6e25e81e4015d907d50aa9cf4a0a3fab
```

We'll discuss inlining *later in this course* (page 1556).

Aspect specifications were introduced in Ada 2012. In previous versions of Ada, you had to use a **pragma** instead. The previous example would be written as follows:

[Ada]

Listing 93: float_arrays.ads

```
package Float_Arrays is

   type Float_Array is array (Positive range <>) of Float;

   function Average (Data : Float_Array) return Float;

   pragma Inline (Average);

end Float_Arrays;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Inline_Aspect
MD5: bd5df14dce9577a054f0ec612d5bbe40
```

Aspects and attributes might refer to the same kind of information. For example, we can use the Size aspect to define the expected minimum size of objects of a certain type:

[Ada]

Listing 94: my_device_types.ads

```
package My_Device_Types is

   type UInt10 is mod 2 ** 10
     with Size => 10;

end My_Device_Types;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Size_Aspect
MD5: 049be992b876dba42cf091afc256db35
```

In the same way, we can use the size attribute to retrieve the size of a type or of an object:

[Ada]

Listing 95: show_device_types.adb

```
with Ada.Text_IO;     use Ada.Text_IO;

with My_Device_Types; use My_Device_Types;

procedure Show_Device_Types is
   UInt10_Obj : constant UInt10 := 0;
begin
   Put_Line ("Size of UInt10 type:   " & Positive'Image (UInt10'Size));
   Put_Line ("Size of UInt10 object: " & Positive'Image (UInt10_Obj'Size));
end Show_Device_Types;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Size_Aspect
MD5: 4e46ad9cf54276b381b960672daa03b9
```

Runtime output

```
Size of UInt10 type:    10
Size of UInt10 object:  16
```

We'll explain both `Size` aspect and `Size` attribute *later in this course* (page 1443).

CHAPTER

SIXTYEIGHT

CONCURRENCY AND REAL-TIME

68.1 Understanding the various options

Concurrent and real-time programming are standard parts of the Ada language. As such, they have the same semantics, whether executing on a native target with an OS such as Linux, on a real-time operating system (RTOS) such as VxWorks, or on a bare metal target with no OS or RTOS at all.

For resource-constrained systems, two subsets of the Ada concurrency facilities are defined, known as the Ravenscar and Jorvik profiles. Though restricted, these subsets have highly desirable properties, including: efficiency, predictability, analyzability, absence of deadlock, bounded blocking, absence of priority inversion, a real-time scheduler, and a small memory footprint. On bare metal systems, this means in effect that Ada comes with its own real-time kernel.

For further information

We'll discuss the Ravenscar profile *later in this chapter* (page 1426). Details about the Jorvik profile can be found elsewhere [Jorvik].

Enhanced portability and expressive power are the primary advantages of using the standard concurrency facilities, potentially resulting in considerable cost savings. For example, with little effort, it is possible to migrate from Windows to Linux to a bare machine without requiring any changes to the code. Thread management and synchronization is all done by the implementation, transparently. However, in some situations, it's critical to be able to access directly the services provided by the platform. In this case, it's always possible to make direct system calls from Ada code. Several targets of the GNAT compiler provide this sort of API by default, for example win32ada for Windows and Florist for POSIX systems.

On native and RTOS-based platforms GNAT typically provides the full concurrency facilities. In contrast, on bare metal platforms GNAT typically provides the two standard subsets: Ravenscar and Jorvik.

68.2 Tasks

Ada offers a high level construct called a *task* which is an independent thread of execution. In GNAT, tasks are either mapped to the underlying OS threads, or use a dedicated kernel when not available.

The following example will display the 26 letters of the alphabet twice, using two concurrent tasks. Since there is no synchronization between the two threads of control in any of the examples, the output may be interspersed.

[Ada]

Listing 1: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is -- implicitly called by the environment task
   subtype A_To_Z is Character range 'A' .. 'Z';

   task My_Task;

   task body My_Task is
   begin
      for I in A_To_Z'Range loop
         Put (I);
      end loop;
      New_Line;
   end My_Task;
begin
   for I in A_To_Z'Range loop
      Put (I);
   end loop;
   New_Line;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Concurrency.My_Task
MD5: 154702197f0c02f5750838e51a99f548
```

Runtime output

```
ABCDEFGABCDEFGHIJKLMNOPQRSTUVWXYZ
HIJKLMNOPQRSTUVWXYZ
```

Any number of Ada tasks may be declared in any declarative region. A task declaration is very similar to a procedure or package declaration. They all start automatically when control reaches the begin. A block will not exit until all sequences of statements defined within that scope, including those in tasks, have been completed.

A task type is a generalization of a task object; each object of a task type has the same behavior. A declared object of a task type is started within the scope where it is declared, and control does not leave that scope until the task has terminated.

Task types can be parameterized; the parameter serves the same purpose as an argument to a constructor in Java. The following example creates 10 tasks, each of which displays a subset of the alphabet contained between the parameter and the 'Z' Character. As with the earlier example, since there is no synchronization among the tasks, the output may be interspersed depending on the underlying implementation of the task scheduling algorithm.

[Ada]

Listing 2: my_tasks.ads

```
package My_Tasks is

   task type My_Task (First : Character);

end My_Tasks;
```

Listing 3: my_tasks.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body My_Tasks is

   task body My_Task is
   begin
      for I in First .. 'Z' loop
         Put (I);
      end loop;
      New_Line;
   end My_Task;

end My_Tasks;
```

Listing 4: main.adb

```
with My_Tasks; use My_Tasks;

procedure Main is
   Dummy_Tab : array (0 .. 3) of My_Task ('W');
begin
   null;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Concurrency.My_Task_Type
MD5: 81d88397b0548fdcc1ba31549a8de4fd
```

Runtime output

```
WXYZ
WXYZ
WXYZ
WXYZ
```

In Ada, a task may be dynamically allocated rather than declared statically. The task will then start as soon as it has been allocated, and terminates when its work is completed.

[Ada]

Listing 5: main.adb

```
with My_Tasks; use My_Tasks;

procedure Main is
   type Ptr_Task is access My_Task;

   T : Ptr_Task;
begin
   T := new My_Task ('W');
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Concurrency.My_Task_Type
MD5: d88a96eecf50ebbcdfe9cb870f232a09
```

Runtime output

```
WXYZ
```

68.3 Rendezvous

A rendezvous is a synchronization between two tasks, allowing them to exchange data and coordinate execution. Let's consider the following example:

[Ada]

Listing 6: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is

   task After is
      entry Go;
   end After;

   task body After is
   begin
      accept Go;
      Put_Line ("After");
   end After;

begin
   Put_Line ("Before");
   After.Go;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Concurrency.Rendezvous
MD5: b0a595b1eecac793e40b6d1d41171766
```

Runtime output

```
Before
After
```

The Go entry declared in `After` is the client interface to the task. In the task body, the **`accept`** statement causes the task to wait for a call on the entry. This particular **`entry`** and **`accept`** pair simply causes the task to wait until `Main` calls `After.Go`. So, even though the two tasks start simultaneously and execute independently, they can coordinate via Go. Then, they both continue execution independently after the rendezvous.

The **`entry`**/**`accept`** pair can take/pass parameters, and the **`accept`** statement can contain a sequence of statements; while these statements are executed, the caller is blocked.

Let's look at a more ambitious example. The rendezvous below accepts parameters and executes some code:

[Ada]

Listing 7: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
```

(continues on next page)

(continued from previous page)

```
4
5     task After is
6        entry Go (Text : String);
7     end After;
8
9     task body After is
10    begin
11       accept Go (Text : String) do
12          Put_Line ("After: " & Text);
13       end Go;
14    end After;
15
16 begin
17    Put_Line ("Before");
18    After.Go ("Main");
19 end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Concurrency.Rendezvous_Params
MD5: 6430e88f5ae349128bb1f1d53f36251e
```

Runtime output

```
Before
After: Main
```

In the above example, the `Put_Line` is placed in the accept statement. Here's a possible execution trace, assuming a uniprocessor:

1. At the begin of `Main`, task `After` is started and the main procedure is suspended.
2. `After` reaches the **`accept`** statement and is suspended, since there is no pending call on the `Go` entry.
3. The main procedure is awakened and executes the `Put_Line` invocation, displaying the string `"Before"`.
4. The main procedure calls the `Go` entry. Since `After` is suspended on its **`accept`** statement for this entry, the call succeeds.
5. The main procedure is suspended, and the task `After` is awakened to execute the body of the **`accept`** statement. The actual parameter `"Main"` is passed to the **`accept`** statement, and the `Put_Line` invocation is executed. As a result, the string `"After: Main"` is displayed.
6. When the **`accept`** statement is completed, both the `After` task and the main procedure are ready to run. Suppose that the `Main` procedure is given the processor. It reaches its end, but the local task `After` has not yet terminated. The main procedure is suspended.
7. The `After` task continues, and terminates since it is at its end. The main procedure is resumed, and it too can terminate since its dependent task has terminated.

The above description is a conceptual model; in practice the implementation can perform various optimizations to avoid unnecessary context switches.

68.4 Selective Rendezvous

The **accept** statement by itself can only wait for a single event (call) at a time. The **select** statement allows a task to listen for multiple events simultaneously, and then to deal with the first event to occur. This feature is illustrated by the task below, which maintains an integer value that is modified by other tasks that call `Increment`, `Decrement`, and `Get`:

[Ada]

Listing 8: counters.ads

```
package Counters is

   task Counter is
      entry Get (Result : out Integer);
      entry Increment;
      entry Decrement;
   end Counter;

end Counters;
```

Listing 9: counters.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Counters is

   task body Counter is
      Value : Integer := 0;
   begin
      loop
         select
            accept Increment do
               Value := Value + 1;
            end Increment;
         or
            accept Decrement do
               Value := Value - 1;
            end Decrement;
         or
            accept Get (Result : out Integer) do
               Result := Value;
            end Get;
         or
            delay 5.0;
            Put_Line ("Exiting Counter task...");
            exit;
         end select;
      end loop;
   end Counter;

end Counters;
```

Listing 10: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Counters;    use Counters;

procedure Main is
   V : Integer;
begin
```

(continues on next page)

(continued from previous page)

```
   Put_Line ("Main started.");

   Counter.Get (V);
   Put_Line ("Got value. Value = " & Integer'Image (V));

   Counter.Increment;
   Put_Line ("Incremented value.");

   Counter.Increment;
   Put_Line ("Incremented value.");

   Counter.Get (V);
   Put_Line ("Got value. Value = " & Integer'Image (V));

   Counter.Decrement;
   Put_Line ("Decremented value.");

   Counter.Get (V);
   Put_Line ("Got value. Value = " & Integer'Image (V));

   Put_Line ("Main finished.");
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Concurrency.Selective_Rendezvous
MD5: 619d009bcfcd8053bc132b2e32a29249
```

Runtime output

```
Main started.
Got value. Value =  0
Incremented value.
Incremented value.
Got value. Value =  2
Decremented value.
Got value. Value =  1
Main finished.
Exiting Counter task...
```

When the task's statement flow reaches the select, it will wait for all four events — three entries and a delay — in parallel. If the delay of five seconds is exceeded, the task will execute the statements following the **delay** statement (and in this case will exit the loop, in effect terminating the task). The **accept** bodies for the `Increment`, `Decrement`, or `Get` entries will be otherwise executed as they're called. These four sections of the select statement are mutually exclusive: at each iteration of the loop, only one will be invoked. This is a critical point; if the task had been written as a package, with procedures for the various operations, then a *race condition* could occur where multiple tasks simultaneously calling, say, `Increment`, cause the value to only get incremented once. In the tasking version, if multiple tasks simultaneously call `Increment` then only one at a time will be accepted, and the value will be incremented by each of the tasks when it is accepted.

More specifically, each entry has an associated queue of pending callers. If a task calls one of the entries and Counter is not ready to accept the call (i.e., if `Counter` is not suspended at the **select** statement) then the calling task is suspended, and placed in the queue of the entry that it is calling. From the perspective of the `Counter` task, at any iteration of the loop there are several possibilities:

- There is no call pending on any of the entries. In this case `Counter` is suspended. It will be awakened by the first of two events: a call on one of its entries (which will then be immediately accepted), or the expiration of the five second delay (whose effect

was noted above).

- There is a call pending on exactly one of the entries. In this case control passes to the **select** branch with an **accept** statement for that entry.
- There are calls pending on more than one entry. In this case one of the entries with pending callers is chosen, and then one of the callers is chosen to be de-queued. The choice of which caller to accept depends on the queuing policy, which can be specified via a **pragma** defined in the Real-Time Systems Annex of the Ada standard; the default is *First-In First-Out*.

68.5 Protected Objects

Although the rendezvous may be used to implement mutually exclusive access to a shared data object, an alternative (and generally preferable) style is through a protected object, an efficiently implementable mechanism that makes the effect more explicit. A protected object has a public interface (its protected operations) for accessing and manipulating the object's components (its private part). Mutual exclusion is enforced through a conceptual lock on the object, and encapsulation ensures that the only external access to the components are through the protected operations.

Two kinds of operations can be performed on such objects: read-write operations by procedures or entries, and read-only operations by functions. The lock mechanism is implemented so that it's possible to perform concurrent read operations but not concurrent write or read/write operations.

Let's reimplement our earlier tasking example with a protected object called `Counter`:

[Ada]

Listing 11: counters.ads

```
package Counters is

   protected Counter is
      function Get return Integer;
      procedure Increment;
      procedure Decrement;
   private
      Value : Integer := 0;
   end Counter;

end Counters;
```

Listing 12: counters.adb

```
package body Counters is

   protected body Counter is
      function Get return Integer is
      begin
         return Value;
      end Get;

      procedure Increment is
      begin
         Value := Value + 1;
      end Increment;

      procedure Decrement is
```

(continues on next page)

(continued from previous page)

```
      begin
         Value := Value - 1;
      end Decrement;
   end Counter;

end Counters;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Concurrency.Protected_Counter
MD5: f29f21621dfcf092580f6a130101788e
```

Having two completely different ways to implement the same paradigm might seem complicated. However, in practice the actual problem to solve usually drives the choice between an active structure (a task) or a passive structure (a protected object).

A protected object can be accessed through prefix notation:

[Ada]

Listing 13: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Counters;    use Counters;

procedure Main is
begin
   Counter.Increment;
   Counter.Decrement;
   Put_Line (Integer'Image (Counter.Get));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Concurrency.Protected_Counter
MD5: 704e3a382fe38caa11ecd3d46fcd2beb
```

Runtime output

```
 0
```

A protected object may look like a package syntactically, since it contains declarations that can be accessed externally using prefix notation. However, the declaration of a protected object is extremely restricted; for example, no public data is allowed, no types can be declared inside, etc. And besides the syntactic differences, there is a critical semantic distinction: a protected object has a conceptual lock that guarantees mutual exclusion; there is no such lock for a package.

Like tasks, it's possible to declare protected types that can be instantiated several times:

```
declare
   protected type Counter is
      -- as above
   end Counter;

   protected body Counter is
      -- as above
   end Counter;

   C1 : Counter;
   C2 : Counter;
```

(continues on next page)

(continued from previous page)

```
begin
   C1.Increment;
   C2.Decrement;
   .. .
end;
```

Protected objects and types can declare a procedure-like operation known as an *entry*. An entry is somewhat similar to a procedure but includes a so-called barrier condition that must be true in order for the entry invocation to succeed. Calling a protected entry is thus a two step process: first, acquire the lock on the object, and then evaluate the barrier condition. If the condition is true then the caller will execute the entry body. If the condition is false, then the caller is placed in the queue for the entry, and relinquishes the lock. Barrier conditions (for entries with non-empty queues) are reevaluated upon completion of protected procedures and protected entries.

Here's an example illustrating protected entries: a protected type that models a binary semaphore / persistent signal.

[Ada]

Listing 14: binary_semaphores.ads

```
package Binary_Semaphores is

   protected type Binary_Semaphore is
      entry Wait;
      procedure Signal;
   private
      Signaled : Boolean := False;
   end Binary_Semaphore;

end Binary_Semaphores;
```

Listing 15: binary_semaphores.adb

```
package body Binary_Semaphores is

   protected body Binary_Semaphore is
      entry Wait when Signaled is
      begin
         Signaled := False;
      end Wait;

      procedure Signal is
      begin
         Signaled := True;
      end Signal;
   end Binary_Semaphore;

end Binary_Semaphores;
```

Listing 16: main.adb

```
with Ada.Text_IO;       use Ada.Text_IO;
with Binary_Semaphores; use Binary_Semaphores;

procedure Main is
   B : Binary_Semaphore;

   task T1;
```

(continues on next page)

(continued from previous page)

```
   task T2;

   task body T1 is
   begin
      Put_Line ("Task T1 waiting...");
      B.Wait;

      Put_Line ("Task T1.");
      delay 1.0;

      Put_Line ("Task T1 will signal...");
      B.Signal;

      Put_Line ("Task T1 finished.");
   end T1;

   task body T2 is
   begin
      Put_Line ("Task T2 waiting...");
      B.Wait;

      Put_Line ("Task T2");
      delay 1.0;

      Put_Line ("Task T2 will signal...");
      B.Signal;

      Put_Line ("Task T2 finished.");
   end T2;

begin
   Put_Line ("Main started.");
   B.Signal;
   Put_Line ("Main finished.");
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Concurrency.Protected_Binary_Semaphore
MD5: aa064a9ec056d44c4217e64cd05726a4
```

Runtime output

```
Task T1 waiting...
Task T2 waiting...
Main started.
Main finished.
Task T1.
Task T1 will signal...
Task T1 finished.
Task T2
Task T2 will signal...
Task T2 finished.
```

Ada concurrency features provide much further generality than what's been presented here. For additional information please consult one of the works cited in the *References* section.

68.6 Ravenscar

The Ravenscar profile is a subset of the Ada concurrency facilities that supports determinism, schedulability analysis, constrained memory utilization, and certification to the highest integrity levels. Four distinct application domains are intended:

- hard real-time applications requiring predictability,
- safety-critical systems requiring formal, stringent certification,
- high-integrity applications requiring formal static analysis and verification,
- embedded applications requiring both a small memory footprint and low execution overhead.

Tasking constructs that preclude analysis, either technically or economically, are disallowed. You can use the **pragma** *Profile* (Ravenscar) to indicate that the Ravenscar restrictions must be observed in your program.

Some of the examples we've seen above will be rejected by the compiler when using the Ravenscar profile. For example:

[Ada]

Listing 17: my_tasks.ads

```
package My_Tasks is

   task type My_Task (First : Character);

end My_Tasks;
```

Listing 18: my_tasks.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body My_Tasks is

   task body My_Task is
   begin
      for C in First .. 'Z' loop
         Put (C);
      end loop;
      New_Line;
   end My_Task;

end My_Tasks;
```

Listing 19: main.adb

```
pragma Profile (Ravenscar);

with My_Tasks; use My_Tasks;

procedure Main is
   Tab : array (0 .. 3) of My_Task ('W');
begin
   null;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Concurrency.Ravenscar
MD5: b7518a039c2b4cecece1de63eeaa208f
```

Build output

```
main.adb:6:04: error: violation of restriction "No_Task_Hierarchy"
main.adb:6:04: error: from profile "Ravenscar" at line 1
gprbuild: *** compilation phase failed
```

This code violates the *No_Task_Hierarchy* restriction of the Ravenscar profile. This is due to the declaration of Tab in the `Main` procedure. Ravenscar requires task declarations to be done at the library level. Therefore, a simple solution is to create a separate package and reference it in the main application:

[Ada]

Listing 20: my_task_inst.ads

```
with My_Tasks; use My_Tasks;

package My_Task_Inst is

   Tab : array (0 .. 3) of My_Task ('W');

end My_Task_Inst;
```

Listing 21: main.adb

```
pragma Profile (Ravenscar);

with My_Task_Inst;

procedure Main is
begin
   null;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Concurrency.Ravenscar
MD5: b38943dc1c962b5e691f2b6d9933a3ec
```

Runtime output

```
WXYZ
WXYZ
WXYZ
WXYZ
```

Also, Ravenscar prohibits entries for tasks. For example, we're not allowed to write this declaration:

```
task type My_Task (First : Character) is
   entry Start;
end My_Task;
```

You can use, however, one entry per protected object. As an example, the declaration of the `Binary_Semaphore` type that we've discussed before compiles fine with Ravenscar:

```
protected type Binary_Semaphore is
   entry Wait;
```

(continues on next page)

(continued from previous page)

```
   procedure Signal;
private
   Signaled : Boolean := False;
end Binary_Semaphore;
```

We could add more procedures and functions to the declaration of `Binary_Semaphore`, but we wouldn't be able to add another entry when using Ravenscar.

Similar to the previous example with the task array declaration, objects of `Binary_Semaphore` cannot be declared in the main application:

```
procedure Main is
   B : Binary_Semaphore;
begin
   null;
end Main;
```

This violates the *No_Local_Protected_Objects* restriction. Again, Ravenscar expects this declaration to be done on a library level, so a solution to make this code compile is to have this declaration in a separate package and reference it in the `Main` procedure.

Ravenscar offers many additional restrictions. Covering those would exceed the scope of this chapter. You can find more examples using the Ravenscar profile on this blog post[328].

CHAPTER

SIXTYNINE

WRITING ADA ON EMBEDDED SYSTEMS

69.1 Understanding the Ada Run-Time

Ada supports a high level of abstractness and expressiveness. In some cases, the compiler translates those constructs directly into machine code. However, there are many high-level constructs for which a direct compilation would be difficult. In those cases, the compiler links to a library containing an implementation of those high-level constructs: this is the so-called run-time library.

One typical example of high-level constructs that can be cumbersome for direct machine code generation is Ada source-code using tasking. In this case, linking to a low-level implementation of multithreading support — for example, an implementation using POSIX threads — is more straightforward than trying to make the compiler generate all the machine code.

In the case of GNAT, the run-time library is implemented using both C and Ada source-code. Also, depending on the operating system, the library will interface with low-level functionality from the target operating system.

There are basically two types of run-time libraries:

- the **standard** run-time library: in many cases, this is the run-time library available on desktop operating systems or on some embedded platforms (such as ARM-Linux on a Raspberry-Pi).
- the **configurable** run-time library: this is a capability that is used to create custom run-time libraries for specific target devices.

Configurable run-time libraries are usually used for constrained target devices where support for the full library would be difficult or even impossible. In this case, configurable run-time libraries may support just a subset of the full Ada language. There are many reasons that speak for this approach:

- Some aspects of the Ada language may not translate well to limited operating systems.
- Memory constraints may require reducing the size of the run-time library, so that developers may need to replace or even remove parts of the library.
- When certification is required, those parts of the library that would require too much certification effort can be removed.

When using a configurable run-time library, the compiler checks whether the library supports certain features of the language. If a feature isn't supported, the compiler will give an error message.

You can find further information about the run-time library on this chapter of the GNAT User's Guide Supplement for Cross Platforms[329]

[329] https://docs.adacore.com/gnat_ugx-docs/html/gnat_ugx/gnat_ugx/the_gnat_configurable_run_time_facility.html

69.2 Low Level Programming

69.2.1 Representation Clauses

We've seen in the previous chapters how Ada can be used to describe high level semantics and architecture. The beauty of the language, however, is that it can be used all the way down to the lowest levels of the development, including embedded assembly code or bit-level data management.

One very interesting feature of the language is that, unlike C, for example, there are no data representation constraints unless specified by the developer. This means that the compiler is free to choose the best trade-off in terms of representation vs. performance. Let's start with the following example:

[Ada]

```
type R is record
   V  : Integer range 0 .. 255;
   B1 : Boolean;
   B2 : Boolean;
end record
  with Pack;
```

[C]

```
struct R {
    unsigned int v:8;
    bool b1;
    bool b2;
};
```

The Ada and the C code above both represent efforts to create an object that's as small as possible. Controlling data size is not possible in Java, but the language does specify the size of values for the primitive types.

Although the C and Ada code are equivalent in this particular example, there's an interesting semantic difference. In C, the number of bits required by each field needs to be specified. Here, we're stating that v is only 8 bits, effectively representing values from 0 to 255. In Ada, it's the other way around: the developer specifies the range of values required and the compiler decides how to represent things, optimizing for speed or size. The Pack aspect declared at the end of the record specifies that the compiler should optimize for size even at the expense of decreased speed in accessing record components. We'll see more details about the Pack aspect in the sections about *bitwise operations* (page 1486) and *mapping structures to bit-fields* (page 1488) in chapter 6.

Other representation clauses can be specified as well, along with compile-time consistency checks between requirements in terms of available values and specified sizes. This is particularly useful when a specific layout is necessary; for example when interfacing with hardware, a driver, or a communication protocol. Here's how to specify a specific data layout based on the previous example:

[Ada]

```
type R is record
   V  : Integer range 0 .. 255;
   B1 : Boolean;
   B2 : Boolean;
end record;

for R use record
   --  Occupy the first bit of the first byte.
```

(continues on next page)

(continued from previous page)

```
   B1 at 0 range 0 .. 0;

   --  Occupy the last 7 bits of the first byte,
   --  as well as the first bit of the second byte.
   V  at 0 range 1 .. 8;

   --  Occupy the second bit of the second byte.
   B2 at 1 range 1 .. 1;
end record;
```

We omit the `with` Pack directive and instead use a record representation clause following the record declaration. The compiler is directed to spread objects of type R across two bytes. The layout we're specifying here is fairly inefficient to work with on any machine, but you can have the compiler construct the most efficient methods for access, rather than coding your own machine-dependent bit-level methods manually.

69.2.2 Embedded Assembly Code

When performing low-level development, such as at the kernel or hardware driver level, there can be times when it is necessary to implement functionality with assembly code.

Every Ada compiler has its own conventions for embedding assembly code, based on the hardware platform and the supported assembler(s). Our examples here will work with GNAT and GCC on the x86 architecture.

All x86 processors since the Intel Pentium offer the `rdtsc` instruction, which tells us the number of cycles since the last processor reset. It takes no inputs and places an unsigned 64-bit value split between the edx and eax registers.

GNAT provides a subprogram called `System.Machine_Code.Asm` that can be used for assembly code insertion. You can specify a string to pass to the assembler as well as source-level variables to be used for input and output:

[Ada]

Listing 1: get_processor_cycles.adb

```
with System.Machine_Code; use System.Machine_Code;
with Interfaces;          use Interfaces;

function Get_Processor_Cycles return Unsigned_64 is
   Low, High : Unsigned_32;
   Counter   : Unsigned_64;
begin
   Asm ("rdtsc",
        Outputs =>
          (Unsigned_32'Asm_Output ("=a", High),
           Unsigned_32'Asm_Output ("=d", Low)),
        Volatile => True);

   Counter :=
     Unsigned_64 (High) * 2 ** 32 +
     Unsigned_64 (Low);

   return Counter;
end Get_Processor_Cycles;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.Assembly_Code
MD5: 092be19e223946ebb9fb9f4786003b94
```

The Unsigned_32'Asm_Output clauses above provide associations between machine registers and source-level variables to be updated. =a and =d refer to the eax and edx machine registers, respectively. The use of the Unsigned_32 and Unsigned_64 types from package Interfaces ensures correct representation of the data. We assemble the two 32-bit values to form a single 64-bit value.

We set the Volatile parameter to **True** to tell the compiler that invoking this instruction multiple times with the same inputs can result in different outputs. This eliminates the possibility that the compiler will optimize multiple invocations into a single call.

With optimization turned on, the GNAT compiler is smart enough to use the eax and edx registers to implement the High and Low variables, resulting in zero overhead for the assembly interface.

The machine code insertion interface provides many features beyond what was shown here. More information can be found in the GNAT User's Guide, and the GNAT Reference manual.

69.3 Interrupt Handling

Handling interrupts is an important aspect when programming embedded devices. Interrupts are used, for example, to indicate that a hardware or software event has happened. Therefore, by handling interrupts, an application can react to external events.

Ada provides built-in support for handling interrupts. We can process interrupts by attaching a handler — which must be a protected procedure — to it. In the declaration of the protected procedure, we use the Attach_Handler aspect and indicate which interrupt we want to handle.

Let's look into a code example that *traps* the quit interrupt (SIGQUIT) on Linux:

[Ada]

Listing 2: signal_handlers.ads

```
with System.OS_Interface;

package Signal_Handlers is

   protected type Quit_Handler is
      function Requested return Boolean;
   private
      Quit_Request : Boolean := False;

      --
      --  Declaration of an interrupt handler for the "quit" interrupt:
      --
      procedure Handle_Quit_Signal
        with Attach_Handler => System.OS_Interface.SIGQUIT;
   end Quit_Handler;

end Signal_Handlers;
```

Listing 3: signal_handlers.adb

```
with Ada.Text_IO; use Ada.Text_IO;

```

(continues on next page)

(continued from previous page)

```
3  package body Signal_Handlers is
4
5     protected body Quit_Handler is
6
7        function Requested return Boolean is
8          (Quit_Request);
9
10       procedure Handle_Quit_Signal is
11       begin
12          Put_Line ("Quit request detected!");
13          Quit_Request := True;
14       end Handle_Quit_Signal;
15
16    end Quit_Handler;
17
18 end Signal_Handlers;
```

Listing 4: test_quit_handler.adb

```
1  with Ada.Text_IO;     use Ada.Text_IO;
2  with Signal_Handlers;
3
4  procedure Test_Quit_Handler is
5     Quit : Signal_Handlers.Quit_Handler;
6
7  begin
8     while True loop
9        delay 1.0;
10       exit when Quit.Requested;
11    end loop;
12
13    Put_Line ("Exiting application...");
14 end Test_Quit_Handler;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.Quit_Handler
MD5: d272c5bc59576444e09007a04a615ccf
```

The specification of the `Signal_Handlers` package from this example contains the declaration of `Quit_Handler`, which is a protected type. In the private part of this protected type, we declare the `Handle_Quit_Signal` procedure. By using the `Attach_Handler` aspect in the declaration of `Handle_Quit_Signal` and indicating the quit interrupt (`System.OS_Interface.SIGQUIT`), we're instructing the operating system to call this procedure for any quit request. So when the user presses CTRL+\ on their keyboard, for example, the application will behave as follows:

- the operating system calls the `Handle_Quit_Signal` procedure , which displays a message to the user ("Quit request detected!") and sets a Boolean variable — `Quit_Request`, which is declared in the `Quit_Handler` type;
- the main application checks the status of the quit handler by calling the `Requested` function as part of the **`while True`** loop;
  - This call is in the **`exit when`** `Quit.Requested` line.
  - The `Requested` function returns **`True`** in this case because the `Quit_Request` flag was set by the `Handle_Quit_Signal` procedure.
- the main applications exits the loop, displays a message and finishes.

Note that the code example above isn't portable because it makes use of interrupts from the Linux operating system. When programming embedded devices, we would use instead

the interrupts available on those specific devices.

Also note that, in the example above, we're declaring a static handler at compilation time. If you need to make use of dynamic handlers, which can be configured at runtime, you can use the subprograms from the `Ada.Interrupts` package. This package includes not only a version of `Attach_Handler` as a procedure, but also other procedures such as:

- `Exchange_Handler`, which lets us exchange, at runtime, the current handler associated with a specific interrupt by a different handler;
- `Detach_Handler`, which we can use to remove the handler currently associated with a given interrupt.

Details about the `Ada.Interrupts` package are out of scope for this course. We'll discuss them in a separate, more advanced course in the future. You can find some information about it in the Interrupts appendix of the Ada Reference Manual[330].

69.4 Dealing with Absence of FPU with Fixed Point

Many numerical applications typically use floating-point types to compute values. However, in some platforms, a floating-point unit may not be available. Other platforms may have a floating-point unit, but using it in certain numerical algorithms can be prohibitive in terms of performance. For those cases, fixed-point arithmetic can be a good alternative.

The difference between fixed-point and floating-point types might not be so obvious when looking at this code snippet:

[Ada]

Listing 5: fixed_definitions.ads

```
package Fixed_Definitions is

   D : constant := 2.0 ** (-31);

   type Fixed is delta D range -1.0 .. 1.0 - D;

end Fixed_Definitions;
```

Listing 6: show_float_and_fixed_point.adb

```
with Ada.Text_IO;       use Ada.Text_IO;

with Fixed_Definitions; use Fixed_Definitions;

procedure Show_Float_And_Fixed_Point is
   Float_Value : Float := 0.25;
   Fixed_Value : Fixed := 0.25;
begin

   Float_Value := Float_Value + 0.25;
   Fixed_Value := Fixed_Value + 0.25;

   Put_Line ("Float_Value = " & Float'Image (Float_Value));
   Put_Line ("Fixed_Value = " & Fixed'Image (Fixed_Value));
end Show_Float_And_Fixed_Point;
```

Code block metadata

[330] http://www.ada-auth.org/standards/12aarm/html/AA-C-3-2.html

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.Fixed_Point
MD5: 881817bb310304bc285f01454ab446f7
```

Runtime output

```
Float_Value =  5.00000E-01
Fixed_Value =  0.5000000000
```

In this example, the application will show the value 0.5 for both `Float_Value` and `Fixed_Value`.

The major difference between floating-point and fixed-point types is in the way the values are stored. Values of ordinary fixed-point types are, in effect, scaled integers. The scaling used for ordinary fixed-point types is defined by the type's `small`, which is derived from the specified **`delta`** and, by default, is a power of two. Therefore, ordinary fixed-point types are sometimes called binary fixed-point types. In that sense, ordinary fixed-point types can be thought of being close to the actual representation on the machine. In fact, ordinary fixed-point types make use of the available integer shift instructions, for example.

Another difference between floating-point and fixed-point types is that Ada doesn't provide standard fixed-point types — except for the **`Duration`** type, which is used to represent an interval of time in seconds. While the Ada standard specifies floating-point types such as **`Float`** and **`Long_Float`**, we have to declare our own fixed-point types. Note that, in the previous example, we have used a fixed-point type named `Fixed`: this type isn't part of the standard, but must be declared somewhere in the source-code of our application.

The syntax for an ordinary fixed-point type is

```
type <type_name> is delta <delta_value> range <lower_bound> .. <upper_bound>;
```

By default, the compiler will choose a scale factor, or `small`, that is a power of 2 no greater than `<delta_value>`.

For example, we may define a normalized range between -1.0 and 1.0 as following:

[Ada]

Listing 7: normalized_fixed_point_type.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Normalized_Fixed_Point_Type is
   D : constant := 2.0 ** (-31);
   type TQ31 is delta D range -1.0 .. 1.0 - D;
begin
   Put_Line ("TQ31 requires " & Integer'Image (TQ31'Size) & " bits");
   Put_Line ("The delta    value of TQ31 is " & TQ31'Image (TQ31'Delta));
   Put_Line ("The minimum  value of TQ31 is " & TQ31'Image (TQ31'First));
   Put_Line ("The maximum  value of TQ31 is " & TQ31'Image (TQ31'Last));
end Normalized_Fixed_Point_Type;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.Normalized_Fixed_Point_Type
MD5: 2fe6e9f9bd20d2cfab959d1c0273280b
```

Runtime output

```
TQ31 requires  32 bits
The delta    value of TQ31 is  0.0000000005
The minimum  value of TQ31 is -1.0000000000
The maximum  value of TQ31 is  0.9999999995
```

In this example, we are defining a 32-bit fixed-point data type for our normalized range. When running the application, we notice that the upper bound is close to one, but not exactly one. This is a typical effect of fixed-point data types — you can find more details in this discussion about the Q format[331]. We may also rewrite this code with an exact type definition:

[Ada]

Listing 8: normalized_adapted_fixed_point_type.ads

```
package Normalized_Adapted_Fixed_Point_Type is

   type TQ31 is delta 2.0 ** (-31) range -1.0 .. 1.0 - 2.0 ** (-31);

end Normalized_Adapted_Fixed_Point_Type;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.Normalized_Adapted_Fixed_Point_
 ↪Type
MD5: abe5f4e029c7c3c7a069890882b17f50
```

We may also use any other range. For example:

[Ada]

Listing 9: custom_fixed_point_range.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with Ada.Numerics; use Ada.Numerics;

procedure Custom_Fixed_Point_Range is
   type Inv_Trig is delta 2.0 ** (-15) * Pi range -Pi / 2.0 .. Pi / 2.0;
begin
   Put_Line ("Inv_Trig requires " & Integer'Image (Inv_Trig'Size)
             & " bits");
   Put_Line ("The delta    value of Inv_Trig is "
             & Inv_Trig'Image (Inv_Trig'Delta));
   Put_Line ("The minimum  value of Inv_Trig is "
             & Inv_Trig'Image (Inv_Trig'First));
   Put_Line ("The maximum  value of Inv_Trig is "
             & Inv_Trig'Image (Inv_Trig'Last));
end Custom_Fixed_Point_Range;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.Custom_Fixed_Point_Range
MD5: 0d9a4bc96191d1341bbb1c081555b613
```

Runtime output

```
Inv_Trig requires  16 bits
The delta    value of Inv_Trig is  0.00006
The minimum  value of Inv_Trig is -1.57080
The maximum  value of Inv_Trig is  1.57080
```

In this example, we are defining a 16-bit type called `Inv_Trig`, which has a range from -π/2 to π/2.

All standard operations are available for fixed-point types. For example:

[Ada]

[331] https://en.wikipedia.org/wiki/Q_(number_format)

Listing 10: fixed_point_op.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Fixed_Point_Op is
   type TQ31 is delta 2.0 ** (-31) range -1.0 .. 1.0 - 2.0 ** (-31);

   A, B, R : TQ31;
begin
   A := 0.25;
   B := 0.50;
   R := A + B;
   Put_Line ("R is " & TQ31'Image (R));
end Fixed_Point_Op;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.Fixed_Point_Op
MD5: 78bafd93b25da898c00cc38c9d518e2a
```

Runtime output

```
R is  0.7500000000
```

As expected, R contains 0.75 after the addition of A and B.

In the case of C, since the language doesn't support fixed-point arithmetic, we need to emulate it using integer types and custom operations via functions. Let's look at this very rudimentary example:

[C]

Listing 11: main.c

```
#include <stdio.h>
#include <math.h>

#define SHIFT_FACTOR  32

#define TO_FIXED(x)     ((int)   ((x) * pow (2.0, SHIFT_FACTOR - 1)))
#define TO_FLOAT(x)     ((float) ((double)(x) * (double)pow (2.0, -(SHIFT_FACTOR - 1))))

typedef int fixed;

fixed add (fixed a, fixed b)
{
    return a + b;
}

fixed mult (fixed a, fixed b)
{
    return (fixed)(((long)a * (long)b) >> (SHIFT_FACTOR - 1));
}

void display_fixed (fixed x)
{
    printf("value (integer) = %d\n",    x);
    printf("value (float)   = %3.5f\n\n", TO_FLOAT (x));
}

int main(int argc, const char * argv[])
```

(continues on next page)

(continued from previous page)

```c
{
    int fixed_value = TO_FIXED(0.25);

    printf("Original value\n");
    display_fixed(fixed_value);

    printf("... + 0.25\n");
    fixed_value = add(fixed_value, TO_FIXED(0.25));
    display_fixed(fixed_value);

    printf("... * 0.5\n");
    fixed_value = mult(fixed_value, TO_FIXED(0.5));
    display_fixed(fixed_value);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.Fixed_Point_C
MD5: 61016e8fc0dbc4d0eefd2c86915489e5
```

Runtime output

```
Original value
value (integer) = 536870912
value (float)   = 0.25000

... + 0.25
value (integer) = 1073741824
value (float)   = 0.50000

... * 0.5
value (integer) = 536870912
value (float)   = 0.25000
```

Here, we declare the fixed-point type `fixed` based on **`int`** and two operations for it: addition (via the add function) and multiplication (via the `mult` function). Note that, while fixed-point addition is quite straightforward, multiplication requires right-shifting to match the correct internal representation. In Ada, since fixed-point operations are part of the language specification, they don't need to be emulated. Therefore, no extra effort is required from the programmer.

Also note that the example above is very rudimentary, so it doesn't take some of the side-effects of fixed-point arithmetic into account. In C, you have to manually take all side-effects deriving from fixed-point arithmetic into account, while in Ada, the compiler takes care of selecting the right operations for you.

69.5 Volatile and Atomic data

Ada has built-in support for handling both volatile and atomic data. Let's start by discussing volatile objects.

69.5.1 Volatile

A volatile[332] object can be described as an object in memory whose value may change between two consecutive memory accesses of a process A — even if process A itself hasn't changed the value. This situation may arise when an object in memory is being shared by multiple threads. For example, a thread *B* may modify the value of that object between two read accesses of a thread *A*. Another typical example is the one of memory-mapped I/O[333], where the hardware might be constantly changing the value of an object in memory.

Because the value of a volatile object may be constantly changing, a compiler cannot generate code that stores the value of that object into a register and use the value from the register in subsequent operations. Storing into a register is avoided because, if the value is stored there, it would be outdated if another process had changed the volatile object in the meantime. Instead, the compiler generates code in such a way that the process must read the value of the volatile object from memory for each access.

Let's look at a simple example of a volatile variable in C:

[C]

Listing 12: main.c

```c
#include <stdio.h>

int main(int argc, const char * argv[])
{
    volatile double val = 0.0;
    int i;

    for (i = 0; i < 1000; i++)
    {
        val += i * 2.0;
    }
    printf ("val: %5.3f\n", val);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.Volatile_Object_C
MD5: 863c7dda4acb3286976a1edab29bab08
```

Runtime output

```
val: 999000.000
```

In this example, `val` has the modifier **`volatile`**, which indicates that the compiler must handle `val` as a volatile object. Therefore, each read and write access in the loop is performed by accessing the value of `val` in then memory.

This is the corresponding implementation in Ada:

[332] https://en.wikipedia.org/wiki/Volatile_(computer_programming)
[333] https://en.wikipedia.org/wiki/Memory-mapped_I/O

[Ada]

Listing 13: show_volatile_object.adb

```ada
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Volatile_Object is
   Val : Long_Float with Volatile;
begin
   Val := 0.0;
   for I in 0 .. 999 loop
      Val := Val + 2.0 * Long_Float (I);
   end loop;

   Put_Line ("Val: " & Long_Float'Image (Val));
end Show_Volatile_Object;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.Volatile_Object_Ada
MD5: aa1e276e64e69813bfc3e3ef39f3dd47
```

Runtime output

```
Val:  9.99000000000000E+05
```

In this example, `Val` has the `Volatile` aspect, which makes the object volatile. We can also use the `Volatile` aspect in type declarations. For example:

[Ada]

Listing 14: show_volatile_type.adb

```ada
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Volatile_Type is
   type Volatile_Long_Float is new Long_Float with Volatile;

   Val : Volatile_Long_Float;
begin
   Val := 0.0;
   for I in 0 .. 999 loop
      Val := Val + 2.0 * Volatile_Long_Float (I);
   end loop;

   Put_Line ("Val: " & Volatile_Long_Float'Image (Val));
end Show_Volatile_Type;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.Volatile_Type
MD5: 41ecf028803a58ce244c421eaeb118e4
```

Runtime output

```
Val:  9.99000000000000E+05
```

Here, we're declaring a new type `Volatile_Long_Float` based on the **`Long_Float`** type and using the `Volatile` aspect. Any object of this type is automatically volatile.

In addition to that, we can declare components of an array to be volatile. In this case, we can use the `Volatile_Components` aspect in the array declaration. For example:

[Ada]

Listing 15: show_volatile_array_components.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Volatile_Array_Components is
   Arr : array (1 .. 2) of Long_Float with Volatile_Components;
begin
   Arr := (others => 0.0);

   for I in 0 .. 999 loop
      Arr (1) := Arr (1) +  2.0 * Long_Float (I);
      Arr (2) := Arr (2) + 10.0 * Long_Float (I);
   end loop;

   Put_Line ("Arr (1): " & Long_Float'Image (Arr (1)));
   Put_Line ("Arr (2): " & Long_Float'Image (Arr (2)));
end Show_Volatile_Array_Components;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.Volatile_Array_Components
MD5: 601d61dd01888c60ae1a51ec513138d5
```

Runtime output

```
Arr (1):  9.99000000000000E+05
Arr (2):  4.99500000000000E+06
```

Note that it's possible to use the `Volatile` aspect for the array declaration as well:

[Ada]

```
Arr : array (1 .. 2) of Long_Float with Volatile;
```

69.5.2 Atomic

An atomic object is an object that only accepts atomic reads and updates. The Ada standard specifies that "for an atomic object (including an atomic component), all reads and updates of the object as a whole are indivisible." In this case, the compiler must generate Assembly code in such a way that reads and updates of an atomic object must be done in a single instruction, so that no other instruction could execute on that same object before the read or update completes.

In other contexts

Generally, we can say that operations are said to be atomic when they can be completed without interruptions. This is an important requirement when we're performing operations on objects in memory that are shared between multiple processes.

This definition of atomicity above is used, for example, when implementing databases. However, for this section, we're using the term "atomic" differently. Here, it really means that reads and updates must be performed with a single Assembly instruction.

For example, if we have a 32-bit object composed of four 8-bit bytes, the compiler cannot generate code to read or update the object using four 8-bit store / load instructions, or even two 16-bit store / load instructions. In this case, in order to maintain atomicity, the compiler must generate code using one 32-bit store / load instruction.

Because of this strict definition, we might have objects for which the `Atomic` aspect cannot be specified. Lots of machines support integer types that are larger than the native word-

sized integer. For example, a 16-bit machine probably supports both 16-bit and 32-bit integers, but only 16-bit integer objects can be marked as atomic — or, more generally, only objects that fit into at most 16 bits.

Atomicity may be important, for example, when dealing with shared hardware registers. In fact, for certain architectures, the hardware may require that memory-mapped registers are handled atomically. In Ada, we can use the `Atomic` aspect to indicate that an object is atomic. This is how we can use the aspect to declare a shared hardware register:

[Ada]

Listing 16: show_shared_hw_register.adb

```
with System;

procedure Show_Shared_HW_Register is
   R   : Integer
     with Atomic, Address => System'To_Address (16#FFFF00A0#);
begin
   null;
end Show_Shared_HW_Register;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.Atomic_Object
MD5: 7ef148adf393819fc3fbc25eb45afe46
```

Note that the **Address** aspect allows for assigning a variable to a specific location in the memory. In this example, we're using this aspect to specify the address of the memory-mapped register. We'll discuss more about the **Address** aspect later in the section about *mapping structures to bit-fields* (page 1488) (in chapter 6).

In addition to atomic objects, we can declare atomic types and atomic array components — similarly to what we've seen before for volatile objects. For example:

[Ada]

Listing 17: show_shared_hw_register.adb

```
with System;

procedure Show_Shared_HW_Register is
   type Atomic_Integer is new Integer with Atomic;

   R : Atomic_Integer with Address => System'To_Address (16#FFFF00A0#);

   Arr : array (1 .. 2) of Integer with Atomic_Components;
begin
   null;
end Show_Shared_HW_Register;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.Atomic_Types_Arrays
MD5: 11475b5152087eff7f36abfe2c5ae9a1
```

In this example, we're declaring the `Atomic_Integer` type, which is an atomic type. Objects of this type — such as R in this example — are automatically atomic. This example also includes the declaration of the `Arr` array, which has atomic components.

69.6 Interfacing with Devices

Previously, we've seen that we can use *representation clauses* (page 1430) to specify a particular layout for a record type. As mentioned before, this is useful when interfacing with hardware, drivers, or communication protocols. In this section, we'll extend this concept for two specific use-cases: register overlays and data streams. Before we discuss those use-cases, though, we'll first explain the `Size` aspect and the `Size` attribute.

69.6.1 `Size` aspect and attribute

The `Size` aspect indicates the minimum number of bits required to represent an object. When applied to a type, the `Size` aspect is telling the compiler to not make record or array components of a type T any smaller than X bits. Therefore, a common usage for this aspect is to just confirm expectations: developers specify `'Size` to tell the compiler that T should fit X bits, and the compiler will tell them if they are right (or wrong).

When the specified size value is larger than necessary, it can cause objects to be bigger in memory than they would be otherwise. For example, for some enumeration types, we could say `for type Enum'Size use 32;` when the number of literals would otherwise have required only a byte. That's useful for unchecked conversions because the sizes of the two types need to be the same. Likewise, it's useful for interfacing with C, where `enum` types are just mapped to the `int` type, and thus larger than Ada might otherwise require. We'll discuss unchecked conversions *later in the course* (page 1502).

Let's look at an example from an earlier chapter:

[Ada]

Listing 18: my_device_types.ads

```
package My_Device_Types is

   type UInt10 is mod 2 ** 10
     with Size => 10;

end My_Device_Types;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Size_Aspect
MD5: 049be992b876dba42cf091afc256db35
```

Here, we're saying that objects of type `UInt10` must have at least 10 bits. In this case, if the code compiles, it is a confirmation that such values can be represented in 10 bits when packed into an enclosing record or array type.

If the size specified was larger than what the compiler would use by default, then it could affect the size of objects. For example, for `UInt10`, anything up to and including 16 would make no difference on a typical machine. However, anything over 16 would then push the compiler to use a larger object representation. That would be important for unchecked conversions, for example.

The `Size` attribute indicates the number of bits required to represent a type or an object. We can use the size attribute to retrieve the size of a type or of an object:

[Ada]

Listing 19: show_device_types.adb

```
with Ada.Text_IO;     use Ada.Text_IO;

with My_Device_Types; use My_Device_Types;

procedure Show_Device_Types is
   UInt10_Obj : constant UInt10 := 0;
begin
   Put_Line ("Size of UInt10 type:   " & Positive'Image (UInt10'Size));
   Put_Line ("Size of UInt10 object: " & Positive'Image (UInt10_Obj'Size));
end Show_Device_Types;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Perspective.Size_Aspect
MD5: 4e46ad9cf54276b381b960672daa03b9
```

Runtime output

```
Size of UInt10 type:    10
Size of UInt10 object:  16
```

Here, we're retrieving the actual sizes of the `UInt10` type and an object of that type. Note that the sizes don't necessarily need to match. For example, although the size of `UInt10` type is expected to be 10 bits, the size of `UInt10_Obj` may be 16 bits, depending on the platform. Also, components of this type within composite types (arrays, records) will probably be 16 bits as well unless they are packed.

69.6.2 Register overlays

Register overlays make use of representation clauses to create a structure that facilitates manipulating bits from registers. Let's look at a simplified example of a power management controller containing registers such as a system clock enable register. Note that this example is based on an actual architecture:

[Ada]

Listing 20: registers.ads

```
with System;

package Registers is

   type Bit    is mod 2 ** 1
     with Size => 1;
   type UInt5  is mod 2 ** 5
     with Size => 5;
   type UInt10 is mod 2 ** 10
     with Size => 10;

   subtype USB_Clock_Enable is Bit;

   --  System Clock Enable Register
   type PMC_SCER_Register is record
      --  Reserved bits
      Reserved_0_4   : UInt5            := 16#0#;
      --  Write-only. Enable USB FS Clock
      USBCLK         : USB_Clock_Enable := 16#0#;
```

(continues on next page)

(continued from previous page)

```
20       --  Reserved bits
21       Reserved_6_15  : UInt10           := 16#0#;
22    end record
23      with
24        Volatile,
25        Size      => 16,
26        Bit_Order => System.Low_Order_First;
27
28    for PMC_SCER_Register use record
29       Reserved_0_4   at 0 range 0 .. 4;
30       USBCLK         at 0 range 5 .. 5;
31       Reserved_6_15  at 0 range 6 .. 15;
32    end record;
33
34    --  Power Management Controller
35    type PMC_Peripheral is record
36       --  System Clock Enable Register
37       PMC_SCER       : aliased PMC_SCER_Register;
38       --  System Clock Disable Register
39       PMC_SCDR       : aliased PMC_SCER_Register;
40    end record
41      with Volatile;
42
43    for PMC_Peripheral use record
44       --  16-bit register at byte 0
45       PMC_SCER       at 16#0# range 0 .. 15;
46       --  16-bit register at byte 2
47       PMC_SCDR       at 16#2# range 0 .. 15;
48    end record;
49
50    --  Power Management Controller
51    PMC_Periph : aliased PMC_Peripheral
52      with Import, Address => System'To_Address (16#400E0600#);
53
54 end Registers;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.PMC_Peripheral
MD5: d6f37976ca653d65d71ee5ea463df81c
```

First, we declare the system clock enable register — this is `PMC_SCER_Register` type in the code example. Most of the bits in that register are reserved. However, we're interested in bit #5, which is used to activate or deactivate the system clock. To achieve a correct representation of this bit, we do the following:

- We declare the `USBCLK` component of this record using the `USB_Clock_Enable` type, which has a size of one bit; and
- we use a representation clause to indicate that the `USBCLK` component is specifically at bit #5 of byte #0.

After declaring the system clock enable register and specifying its individual bits as components of a record type, we declare the power management controller type — `PMC_Peripheral` record type in the code example. Here, we declare two 16-bit registers as record components of `PMC_Peripheral`. These registers are used to enable or disable the system clock. The strategy we use in the declaration is similar to the one we've just seen above:

- We declare these registers as components of the `PMC_Peripheral` record type;
- we use a representation clause to specify that the `PMC_SCER` register is at byte #0 and the `PMC_SCDR` register is at byte #2.

- Since these registers have 16 bits, we use a range of bits from 0 to 15.

The actual power management controller becomes accessible by the declaration of the PMC_Periph object of PMC_Peripheral type. Here, we specify the actual address of the memory-mapped registers (*400E0600* in hexadecimal) using the **Address** aspect in the declaration. When we use the **Address** aspect in an object declaration, we're indicating the address in memory of that object.

Because we specify the address of the memory-mapped registers in the declaration of PMC_Periph, this object is now an overlay for those registers. This also means that any operation on this object corresponds to an actual operation on the registers of the power management controller. We'll discuss more details about overlays in the section about *mapping structures to bit-fields* (page 1488) (in chapter 6).

Finally, in a test application, we can access any bit of any register of the power management controller with simple record component selection. For example, we can set the USBCLK bit of the PMC_SCER register by using PMC_Periph.PMC_SCER.USBCLK:

[Ada]

Listing 21: enable_usb_clock.adb

```
with Registers;

procedure Enable_USB_Clock is
begin
   Registers.PMC_Periph.PMC_SCER.USBCLK := 1;
end Enable_USB_Clock;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.PMC_Peripheral
MD5: b8f35a80d5f04cd362e5309aef33a100
```

This code example makes use of many aspects and keywords of the Ada language. One of them is the Volatile aspect, which we've discussed in the section about *volatile and atomic objects* (page 1439). Using the Volatile aspect for the PMC_SCER_Register type ensures that objects of this type won't be stored in a register.

In the declaration of the PMC_SCER_Register record type of the example, we use the Bit_Order aspect to specify the bit ordering of the record type. Here, we can select one of these options:

- High_Order_First: first bit of the record is the most significant bit;
- Low_Order_First: first bit of the record is the least significant bit.

The declarations from the Registers package also makes use of the Import, which is sometimes necessary when creating overlays. When used in the context of object declarations, it avoids default initialization (for data types that have it.). Aspect Import will be discussed in the section that explains how to *map structures to bit-fields* (page 1488) in chapter 6. Please refer to that chapter for more details.

Details about 'Size

In the example above, we're using the Size aspect in the declaration of the PMC_SCER_Register type. In this case, the effect is that it has the compiler confirm that the record type will fit into the expected 16 bits.

That's what the aspect does for type PMC_SCER_Register in the example above, as well as for the types Bit, UInt5 and UInt10. For example, we may declare a stand-alone object of type Bit:

Listing 22: show_bit_declaration.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Bit_Declaration is

   type Bit    is mod 2 ** 1
     with Size => 1;

   B : constant Bit := 0;
   --  ^ Although Bit'Size is 1, B'Size is almost certainly 8
begin
   Put_Line ("Bit'Size = " & Positive'Image (Bit'Size));
   Put_Line ("B'Size   = " & Positive'Image (B'Size));
end Show_Bit_Declaration;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.Bit_Declaration
MD5: 1778bb96b4bf77292885bdedfee7c596
```

Runtime output

```
Bit'Size =  1
B'Size   =  8
```

In this case, B is almost certainly going to be 8-bits wide on a typical machine, even though the language requires that `Bit'Size` is 1 by default.

In the declaration of the components of the `PMC_Peripheral` record type, we use the **`aliased`** keyword to specify that those record components are accessible via other paths besides the component name. Therefore, the compiler won't store them in registers. This makes sense because we want to ensure that we're accessing specific memory-mapped registers, and not registers assigned by the compiler. Note that, for the same reason, we also use the **`aliased`** keyword in the declaration of the `PMC_Periph` object.

69.6.3 Data streams

Creating data streams — in the context of interfacing with devices — means the serialization of arbitrary information and its transmission over a communication channel. For example, we might want to transmit the content of memory-mapped registers as byte streams using a serial port. To do this, we first need to get a serialized representation of those registers as an array of bytes, which we can then transmit over the serial port.

Serialization of arbitrary record types — including register overlays — can be achieved by declaring an array of bytes as an overlay. By doing this, we're basically interpreting the information from those record types as bytes while ignoring their actual structure — i.e. their components and representation clause. We'll discuss details about overlays in the section about *mapping structures to bit-fields* (page 1488) (in chapter 6).

Let's look at a simple example of serialization of an arbitrary record type:

[Ada]

Listing 23: arbitrary_types.ads

```
package Arbitrary_Types is

   type Arbitrary_Record is record
```

(continues on next page)

(continued from previous page)

```
      A : Integer;
      B : Integer;
      C : Integer;
   end record;

end Arbitrary_Types;
```

Listing 24: serialize_data.ads

```
with Arbitrary_Types;

procedure Serialize_Data (Some_Object : Arbitrary_Types.Arbitrary_Record);
```

Listing 25: serialize_data.adb

```
with Arbitrary_Types;

procedure Serialize_Data (Some_Object : Arbitrary_Types.Arbitrary_Record) is
   type UByte is new Natural range 0 .. 255
     with Size => 8;

   type UByte_Array is array (Positive range <>) of UByte;

   --
   --  We can access the serialized data in Raw_TX, which is our overlay
   --
   Raw_TX : UByte_Array (1 .. Some_Object'Size / 8)
     with Address => Some_Object'Address;
begin
   null;
   --
   --  Now, we could stream the data from Some_Object.
   --
   --  For example, we could send the bytes (from Raw_TX) via the
   --  serial port.
   --
end Serialize_Data;
```

Listing 26: data_stream_declaration.adb

```
with Arbitrary_Types;
with Serialize_Data;

procedure Data_Stream_Declaration is
   Dummy_Object : Arbitrary_Types.Arbitrary_Record;

begin
    Serialize_Data (Dummy_Object);
end Data_Stream_Declaration;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Embedded.Data_Stream_Declaration
MD5: 1de6f518520010c28fd8deb29a2bf209
```

The most important part of this example is the implementation of the Serialize_Data procedure, where we declare Raw_TX as an overlay for our arbitrary object (Some_Object of Arbitrary_Record type). In simple terms, by writing `with Address => Some_Object'Address;` in the declaration of Raw_TX, we're specifying that Raw_TX and Some_Object have the same address in memory. Here, we are:

- taking the address of `Some_Object` — using the **`Address`** attribute —, and then
- using it as the address of Raw_TX — which is specified with the **`Address`** aspect.

By doing this, we're essentially saying that both Raw_TX and `Some_Object` are different representations of the same object in memory.

Because the Raw_TX overlay is completely agnostic about the actual structure of the record type, the `Arbitrary_Record` type could really be anything. By declaring Raw_TX, we create an array of bytes that we can use to stream the information from `Some_Object`.

We can use this approach and create a data stream for the register overlay example that we've seen before. This is the corresponding implementation:

[Ada]

Listing 27: registers.ads

```
with System;

package Registers is

   type Bit is mod 2 ** 1
     with Size => 1;
   type UInt5 is mod 2 ** 5
     with Size => 5;
   type UInt10 is mod 2 ** 10
     with Size => 10;

   subtype USB_Clock_Enable is Bit;

   --  System Clock Register
   type PMC_SCER_Register is record
      --  Reserved bits
      Reserved_0_4   : UInt5 := 16#0#;
      --  Write-only. Enable USB FS Clock
      USBCLK         : USB_Clock_Enable := 16#0#;
      --  Reserved bits
      Reserved_6_15  : UInt10 := 16#0#;
   end record
     with
       Volatile,
       Size      => 16,
       Bit_Order => System.Low_Order_First;

   for PMC_SCER_Register use record
      Reserved_0_4   at 0 range 0 .. 4;
      USBCLK         at 0 range 5 .. 5;
      Reserved_6_15  at 0 range 6 .. 15;
   end record;

   --  Power Management Controller
   type PMC_Peripheral is record
      --  System Clock Enable Register
      PMC_SCER       : aliased PMC_SCER_Register;
      --  System Clock Disable Register
      PMC_SCDR       : aliased PMC_SCER_Register;
   end record
     with Volatile;

   for PMC_Peripheral use record
      --  16-bit register at byte 0
      PMC_SCER       at 16#0# range 0 .. 15;
      --  16-bit register at byte 2
```

(continues on next page)

(continued from previous page)

```
      PMC_SCDR       at 16#2# range 0 .. 15;
   end record;

   --  Power Management Controller
   PMC_Periph : aliased PMC_Peripheral;
--     with Import, Address => System'To_Address (16#400E0600#);

end Registers;
```

Listing 28: serial_ports.ads

```
package Serial_Ports is

   type UByte is new Natural range 0 .. 255
     with Size => 8;

   type UByte_Array is array (Positive range <>) of UByte;

   type Serial_Port is null record;

   procedure Read (Port : in out Serial_Port;
                   Data :    out UByte_Array);

   procedure Write (Port : in out Serial_Port;
                    Data :        UByte_Array);

end Serial_Ports;
```

Listing 29: serial_ports.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Serial_Ports is

   procedure Display (Data : UByte_Array) is
   begin
      Put_Line ("---- Data ----");
      for E of Data loop
         Put_Line (UByte'Image (E));
      end loop;
      Put_Line ("--------------");
   end Display;

   procedure Read (Port : in out Serial_Port;
                   Data :    out UByte_Array) is
      pragma Unreferenced (Port);
   begin
      Put_Line ("Reading data...");
      Data := (0, 0, 32, 0);
   end Read;

   procedure Write (Port : in out Serial_Port;
                    Data :        UByte_Array) is
      pragma Unreferenced (Port);
   begin
      Put_Line ("Writing data...");
      Display (Data);
   end Write;

end Serial_Ports;
```

Listing 30: data_stream.ads

```
with Serial_Ports; use Serial_Ports;

In this example, we can find the overlay in the implementation of the Send and Receive procedures from the `Data_Stream` package. Because the overlay doesn't need to know the internals of the `PMC_Peripheral` type, we're declaring it in the same way as in the previous example (where we created an overlay for `Some_Object`). In this case, we're creating an overlay for the PMC parameter.

Note that, for this section, we're not really interested in the details about the serial port. Thus, package `Serial_Ports` in this example is just a stub. However, because the `Serial_Port` type in that package only *sees* arrays of bytes, after implementing an actual serial port interface for a specific device, we could create data streams for any type.

69.7 ARM and svd2ada

As we've seen in the previous section about *interfacing with devices* (page 1443), Ada offers powerful features to describe low-level details about the hardware architecture without giving up its strong typing capabilities. However, it can be cumbersome to create a specification for all those low-level details when you have a complex architecture. Fortunately, for ARM Cortex-M devices, the GNAT toolchain offers an Ada binding generator called **svd2ada**, which takes CMSIS-SVD descriptions for those devices and creates Ada specifications that match the architecture. CMSIS-SVD description files are based on the Cortex Microcontroller Software Interface Standard (CMSIS), which is a hardware abstraction layer for ARM Cortex microcontrollers.

Please refer to the svd2ada project page[334] for details about this tool.

CHAPTER

SEVENTY

ENHANCING VERIFICATION WITH SPARK AND ADA

70.1 Understanding Exceptions and Dynamic Checks

In Ada, several common programming errors that are not already detected at compile-time are detected instead at run-time, triggering "exceptions" that interrupt the normal flow of execution. For example, an exception is raised by an attempt to access an array component via an index that is out of bounds. This simple check precludes exploits based on buffer overflow. Several other cases also raise language-defined exceptions, such as scalar range constraint violations and null pointer dereferences. Developers may declare and raise their own application-specific exceptions too. (Exceptions are software artifacts, although an implementation may map hardware events to exceptions.)

Exceptions are raised during execution of what we will loosely define as a "frame." A frame is a language construct that has a call stack entry when called, for example a procedure or function body. There are a few other constructs that are also pertinent but this definition will suffice for now.

Frames have a sequence of statements implementing their functionality. They can also have optional "exception handlers" that specify the response when exceptions are "raised" by those statements. These exceptions could be raised directly within the statements, or indirectly via calls to other procedures and functions.

For example, the frame below is a procedure including three exceptions handlers:

Listing 1: p.adb

```
1  procedure P is
2  begin
3     Statements_That_Might_Raise_Exceptions;
4  exception
5     when A =>
6        Handle_A;
7     when B =>
8        Handle_B;
9     when C =>
10       Handle_C;
11 end P;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Exceptions
MD5: bf7a8740dfca9f3da993f054e22ca97d
```

The three exception handlers each start with the word **when** (lines 5, 7, and 9). Next comes one or more exception identifiers, followed by the so-called "arrow." In Ada, the arrow always associates something on the left side with something on the right side. In this case, the left side is the exception name and the right side is the handler's code for that exception.

Each handler's code consists of an arbitrary sequence of statements, in this case specific procedures called in response to those specific exceptions. If exception A is raised we call procedure `Handle_A` (line 6), dedicated to doing the actual work of handling that exception. The other two exceptions are dealt with similarly, on lines 8 and 10.

Structurally, the exception handlers are grouped together and textually separated from the rest of the code in a frame. As a result, the sequence of statements representing the normal flow of execution is distinct from the section representing the error handling. The reserved word **`exception`** separates these two sections (line 4 above). This separation helps simplify the overall flow, increasing understandability. In particular, status result codes are not required so there is no mixture of error checking and normal processing. If no exception is raised the exception handler section is automatically skipped when the frame exits.

Note how the syntactic structure of the exception handling section resembles that of an Ada case statement. The resemblance is intentional, to suggest similar behavior. When something in the statements of the normal execution raises an exception, the corresponding exception handler for that specific exception is executed. After that, the routine completes. The handlers do not "fall through" to the handlers below. For example, if exception B is raised, procedure `Handle_B` is called but `Handle_C` is not called. There's no need for a **`break`** statement, just as there is no need for it in a case statement. (There's no break statement in Ada anyway.)

So far, we've seen a frame with three specific exceptions handled. What happens if a frame has no handler for the actual exception raised? In that case the run-time library code goes "looking" for one.

Specifically, the active exception is propagated up the dynamic call chain. At each point in the chain, normal execution in that caller is abandoned and the handlers are examined. If that caller has a handler for the exception, the handler is executed. That caller then returns normally to its caller and execution continues from there. Otherwise, propagation goes up one level in the call chain and the process repeats. The search continues until a matching handler is found or no callers remain. If a handler is never found the application terminates abnormally. If the search reaches the main procedure and it has a matching handler it will execute the handler, but, as always, the routine completes so once again the application terminates.

For a concrete example, consider the following:

Listing 2: arrays.ads

```
1  package Arrays is
2
3     type List is array (Natural range <>) of Integer;
4
5     function Value (A : List; X, Y : Integer) return Integer;
6
7  end Arrays;
```

Code block metadata

```

```

Listing 3: arrays.adb

```
1  package body Arrays is
2
3     function Value (A : List; X, Y : Integer) return Integer is
4     begin
5        return A (X + Y * 10);
```

(continues on next page)

(continued from previous page)

```
6     end Value;
7
8  end Arrays;
```

Listing 4: some_process.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2  with Arrays;      use Arrays;
3
4  procedure Some_Process is
5     L : constant List (1 .. 100) := (others => 42);
6  begin
7     Put_Line (Integer'Image (Value (L, 1, 10)));
8  exception
9     when Constraint_Error =>
10       Put_Line ("Constraint_Error caught in Some_Process");
11       Put_Line ("Some_Process completes normally");
12 end Some_Process;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Exceptions
MD5: 7733854601db37eb53f4c4094fe5ca0d
```

Listing 5: main.adb

```
1  with Some_Process;
2  with Ada.Text_IO; use Ada.Text_IO;
3
4  procedure Main is
5  begin
6     Some_Process;
7     Put_Line ("Main completes normally");
8  end Main;
```

Procedure Main calls Some_Process, which in turn calls function Value (line 7). Some_Process declares the array object L of type List on line 5, with bounds 1 through 100. The call to Value has arguments, including variable L, leading to an attempt to access an array component via an out-of-bounds index (1 + 10 * 10 = 101, beyond the last index of L). This attempt will trigger an exception in Value prior to actually accessing the array object's memory. Function Value doesn't have any exception handlers so the exception is propagated up to the caller Some_Process. Procedure Some_Process has an exception handler for Constraint_Error and it so happens that Constraint_Error is the exception raised in this case. As a result, the code for that handler will be executed, printing some messages on the screen. Then procedure Some_Process will return to Main normally. Main then continues to execute normally after the call to Some_Process and prints its completion message.

If procedure Some_Process had also not had a handler for Constraint_Error, that procedure call would also have returned abnormally and the exception would have been propagated further up the call chain to procedure Main. Normal execution in Main would likewise be abandoned in search of a handler. But Main does not have any handlers so Main would have completed abnormally, immediately, without printing its closing message.

This semantic model is the same as with many other programming languages, in which the execution of a frame's sequence of statements is unavoidably abandoned when an exception becomes active. The model is a direct reaction to the use of status codes returned from functions as in C, where it is all too easy to forget (intentionally or otherwise) to check the status values returned. With the exception model errors cannot be ignored.

However, full exception propagation as described above is not the norm for embedded applications when the highest levels of integrity are required. The run-time library code implementing exception propagation can be rather complex and expensive to certify. Those problems apply to the application code too, because exception propagation is a form of control flow without any explicit construct in the source. Instead of the full exception model, designers of high-integrity applications often take alternative approaches.

One alternative consists of deactivating exceptions altogether, or more precisely, deactivating language-defined checks, which means that the compiler will not generate code checking for conditions giving rise to exceptions. Of course, this makes the code vulnerable to attacks, such as buffer overflow, unless otherwise verified (e.g. through static analysis). Deactivation can be applied at the unit level, through the `-gnatp` compiler switch, or locally within a unit via the pragma `Suppress`. (Refer to the GNAT User's Guide for Native Platforms[335] for more details about the switch.)

For example, we can write the following. Note the pragma on line 4 of `arrays.adb` within function `Value`:

Listing 6: arrays.ads

```
1  package Arrays is
2
3     type List is array (Natural range <>) of Integer;
4
5     function Value (A : List; X, Y : Integer) return Integer;
6
7  end Arrays;
```

Listing 7: arrays.adb

```
1  package body Arrays is
2
3     function Value (A : List; X, Y : Integer) return Integer is
4        pragma Suppress (All_Checks);
5     begin
6        return A (X + Y * 10);
7     end Value;
8
9  end Arrays;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Exception_Suppress
MD5: 62c37774cbcd5f167858d3b5268006aa
```

Listing 8: some_process.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2  with Arrays;      use Arrays;
3
4  procedure Some_Process is
5     L : constant List (1 .. 100) := (others => 42);
6  begin
7     Put_Line (Integer'Image (Value (L, 1, 10)));
8  exception
9     when Constraint_Error =>
10       Put_Line ("FAILURE");
11 end Some_Process;
```

This placement of the pragma will only suppress checks in the function body. However,

[335] https://docs.adacore.com/gnat_ugn-docs/html/gnat_ugn/gnat_ugn/building_executable_programs_with_gnat.html

that is where the exception would otherwise have been raised, leading to incorrect and unpredictable execution. (Run the program more than once. If it prints the right answer (42), or even the same value each time, it's just a coincidence.) As you can see, suppressing checks negates the guarantee of errors being detected and addressed at run-time.

Another alternative is to leave checks enabled but not retain the dynamic call-chain propagation. There are a couple of approaches available in this alternative.

The first approach is for the run-time library to invoke a global "last chance handler" (LCH) when any exception is raised. Instead of the sequence of statements of an ordinary exception handler, the LCH is actually a procedure intended to perform "last-wishes" before the program terminates. No exception handlers are allowed. In this scheme "propagation" is simply a direct call to the LCH procedure. The default LCH implementation provided by GNAT does nothing other than loop infinitely. Users may define their own replacement implementation.

The availability of this approach depends on the run-time library. Typically, *Zero Footprint* and *Ravenscar SFP* run-times will provide this mechanism because they are intended for certification.

A user-defined LCH handler can be provided either in C or in Ada, with the following profiles:

[Ada]

```
procedure Last_Chance_Handler (Source_Location : System.Address; Line : Integer);
pragma Export (C,
               Last_Chance_Handler,
               "__gnat_last_chance_handler");
```

[C]

```
void __gnat_last_chance_handler (char *source_location,
                                 int line);
```

We'll go into the details of the pragma `Export` in a further section on language interfacing. For now, just know that the symbol `__gnat_last_chance_handler` is what the run-time uses to branch immediately to the last-chance handler. Pragma `Export` associates that symbol with this replacement procedure so it will be invoked instead of the default routine. As a consequence, the actual procedure name in Ada is immaterial.

Here is an example implementation that simply blinks an LED forever on the target:

```
procedure Last_Chance_Handler (Msg : System.Address; Line : Integer) is
   pragma Unreferenced (Msg, Line);

   Next_Release : Time := Clock;
   Period       : constant Time_Span := Milliseconds (500);
begin
   Initialize_LEDs;
   All_LEDs_Off;

   loop
      Toggle (LCH_LED);
      Next_Release := Next_Release + Period;
      delay until Next_Release;
   end loop;
end Last_Chance_Handler;
```

The `LCH_LED` is a constant referencing the LED used by the last-chance handler, declared elsewhere. The infinite loop is necessary because a last-chance handler must never return to the caller (hence the term "last-chance"). The LED changes state every half-second.

Unlike the approach in which there is only the last-chance handler routine, the other approach allows exception handlers, but in a specific, restricted manner. Whenever an ex-

ception is raised, the only handler that can apply is a matching handler located in the same frame in which the exception is raised. Propagation in this context is simply an immediate branch instruction issued by the compiler, going directly to the matching handler's sequence of statements. If there is no matching local handler the last chance handler is invoked. For example consider the body of function `Value` in the body of package `Arrays`:

Listing 9: arrays.ads

```
package Arrays is

   type List is array (Natural range <>) of Integer;

   function Value (A : List; X, Y : Integer) return Integer;

end Arrays;
```

Listing 10: arrays.adb

```
package body Arrays is

   function Value (A : List; X, Y : Integer) return Integer is
   begin
      return A (X + Y * 10);
   exception
      when Constraint_Error =>
         return 0;
   end Value;

end Arrays;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Exception_Return
MD5: 1f63b92739deb03529884ab0d25dadb8
```

Listing 11: some_process.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Arrays;      use Arrays;

procedure Some_Process is
   L : constant List (1 .. 100) := (others => 42);
begin
   Put_Line (Integer'Image (Value (L, 1, 10)));
exception
   when Constraint_Error =>
      Put_Line ("FAILURE");
end Some_Process;
```

In both procedure `Some_Process` and function `Value` we have an exception handler for `Constraint_Error`. In this example the exception is raised in `Value` because the index check fails there. A local handler for that exception is present so the handler applies and the function returns zero, normally. Because the call to the function returns normally, the execution of `Some_Process` prints zero and then completes normally.

Let's imagine, however, that function `Value` did *not* have a handler for `Constraint_Error`. In the context of full exception propagation, the function call would return to the caller, i.e., `Some_Process`, and would be handled in that procedure's handler. But only local handlers are allowed under the second alternative so the lack of a local handler in `Value` would result in the last-chance handler being invoked. The handler for `Constraint_Error` in `Some_Process` under this alternative approach.

So far we've only illustrated handling the `Constraint_Error` exception. It's possible to handle other language-defined and user-defined exceptions as well, of course. It is even possible to define a single handler for all other exceptions that might be encountered in the handled sequence of statements, beyond those explicitly named. The "name" for this otherwise anonymous exception is the Ada reserved word **`others`**. As in case statements, it covers all other choices not explicitly mentioned, and so must come last. For example:

Listing 12: arrays.ads

```
1  package Arrays is
2
3     type List is array (Natural range <>) of Integer;
4
5     function Value (A : List; X, Y : Integer) return Integer;
6
7  end Arrays;
```

Listing 13: arrays.adb

```
1  package body Arrays is
2
3     function Value (A : List; X, Y : Integer) return Integer is
4     begin
5        return A (X + Y * 10);
6     exception
7        when Constraint_Error =>
8           return 0;
9        when others =>
10          return -1;
11    end Value;
12
13 end Arrays;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Exception_Return_Others
MD5: 7c2ed7efa23242f502a6cf4767da0192
```

Listing 14: some_process.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2  with Arrays;      use Arrays;
3
4  procedure Some_Process is
5     L : constant List (1 .. 100) := (others => 42);
6  begin
7     Put_Line (Integer'Image (Value (L, 1, 10)));
8  exception
9     when Constraint_Error =>
10       Put_Line ("FAILURE");
11 end Some_Process;
```

In the code above, the `Value` function has a handler specifically for `Constraint_Error` as before, but also now has a handler for all other exceptions. For any exception other than `Constraint_Error`, function `Value` returns -1. If you remove the function's handler for `Constraint_Error` (lines 7 and 8) then the other "anonymous" handler will catch the exception and -1 will be returned instead of zero.

There are additional capabilities for exceptions, but for now you have a good basic understanding of how exceptions work, especially their dynamic nature at run-time.

70.2 Understanding Dynamic Checks versus Formal Proof

So far, we have discussed language-defined checks inserted by the compiler for verification at run-time, leading to exceptions being raised. We saw that these dynamic checks verified semantic conditions ensuring proper execution, such as preventing writing past the end of a buffer, or exceeding an application-specific integer range constraint, and so on. These checks are defined by the language because they apply generally and can be expressed in language-defined terms.

Developers can also define dynamic checks. These checks specify component-specific or application-specific conditions, expressed in terms defined by the component or application. We will refer to these checks as "user-defined" for convenience. (Be sure you understand that we are not talking about user-defined *exceptions* here.)

Like the language-defined checks, user-defined checks must be true at run-time. All checks consist of Boolean conditions, which is why we can refer to them as assertions: their conditions are asserted to be true by the compiler or developer.

Assertions come in several forms, some relatively low-level, such as a simple pragma `Assert`, and some high-level, such as type invariants and contracts. These forms will be presented in detail in a later section, but we will illustrate some of them here.

User-defined checks can be enabled at run-time in GNAT with the `-gnata` switch, as well as with pragma `Assertion_Policy`. The switch enables all forms of these assertions, whereas the pragma can be used to control specific forms. The switch is typically used but there are reasonable use-cases in which some user-defined checks are enabled, and others, although defined, are disabled.

By default in GNAT, language-defined checks are enabled but user-defined checks are disabled. Here's an example of a simple program employing a low-level assertion. We can use it to show the effects of the switches, including the defaults:

Listing 15: main.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Main is
4     X : Positive := 10;
5  begin
6     X := X * 5;
7     pragma Assert (X > 99);
8     X := X - 99;
9     Put_Line (Integer'Image (X));
10 end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Low_Level_Assertion
MD5: 2eb5e1879740cc3914acb8a362995b31
```

If we compiled this code we would get a warning about the assignment on line 8 after the pragma `Assert`, but not one about the `Assert` itself on line 7.

```
gprbuild -q -P main.gpr
main.adb:8:11: warning: value not in range of type "Standard.Positive"
main.adb:8:11: warning: "Constraint_Error" will be raised at run time
```

No code is generated for the user-defined check expressed via pragma `Assert` but the language-defined check is emitted. In this case the range constraint on X excludes zero and negative numbers, but `X * 5 = 50`, `X - 99 = -49`. As a result, the check for the last

assignment would fail, raising `Constraint_Error` when the program runs. These results are the expected behavior for the default switch settings.

But now let's enable user-defined checks and build it. Different compiler output will appear.

Listing 16: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   X : Positive := 10;
begin
   X := X * 5;
   pragma Assert (X > 99);
   X := X - 99;
   Put_Line (Integer'Image (X));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Assert
MD5: 2eb5e1879740cc3914acb8a362995b31
```

Build output

```
main.adb:7:19: warning: assertion will fail at run time [-gnatw.a]
main.adb:8:11: warning: value not in range of type "Standard.Positive" [enabled by␣
 ↪default]
main.adb:8:11: warning: Constraint_Error will be raised at run time [enabled by␣
 ↪default]
```

Runtime output

```

raised ADA.ASSERTIONS.ASSERTION_ERROR : main.adb:7
```

Now we also get the compiler warning about the pragma `Assert` condition. When run, the failure of pragma `Assert` on line 7 raises the exception `Ada.Assertions.Assertion_Error`. According to the expression in the assertion, X is expected (incorrectly) to be above 99 after the multiplication. (The exception name in the error message, SYSTEM.ASSERTIONS.ASSERT_FAILURE, is a GNAT-specific alias for `Ada.Assertions.Assertion_Error`.)

It's interesting to see in the output that the compiler can detect some violations at compile-time:

```
main.adb:7:19: warning: assertion will fail at run time
main.adb:7:21: warning: condition can only be True if invalid values present
main.adb:8:11: warning: value not in range of type "Standard.Positive"
```

Generally speaking, a complete analysis is beyond the scope of compilers and they may not find all errors prior to execution, even those we might detect ourselves by inspection. More errors can be found by tools dedicated to that purpose, known as static analyzers. But even an automated static analysis tool cannot guarantee it will find all potential problems.

A much more powerful alternative is formal proof, a form of static analysis that can (when possible) give strong guarantees about the checks, for all possible conditions and all possible inputs. Proof can be applied to both language-defined and user-defined checks.

Be sure you understand that formal proof, as a form of static analysis, verifies conditions prior to execution, even prior to compilation. That earliness provides significant cost benefits. Removing bugs earlier is far less expensive than doing so later because the cost to fix bugs increases exponentially over the phases of the project life cycle, especially after

deployment. Preventing bug introduction into the deployed system is the least expensive approach of all. Furthermore, cost savings during the initial development will be possible as well, for reasons specific to proof. We will revisit this topic later in this section.

Formal analysis for proof can be achieved through the SPARK subset of the Ada language combined with the **gnatprove** verification tool. SPARK is a subset encompassing most of the Ada language, except for features that preclude proof. As a disclaimer, this course is not aimed at providing a full introduction to proof and the SPARK language, but rather to present in a few examples what it is about and what it can do for us.

As it turns out, our procedure `Main` is already SPARK compliant so we can start verifying it.

Listing 17: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

 procedure Main is
    X : Positive := 10;
 begin
    X := X * 5;
    pragma Assert (X > 99);
    X := X - 99;
    Put_Line (Integer'Image (X));
 end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Assert
MD5: 98cad2c7e7b7a12740db013727f01d45
```

Build output

```
main.adb:7:20: warning: assertion will fail at run time [-gnatw.a]
main.adb:8:12: warning: value not in range of type "Standard.Positive" [enabled by␣
 ↪default]
main.adb:8:12: warning: Constraint_Error will be raised at run time [enabled by␣
 ↪default]
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
main.adb:7:20: medium: assertion might fail
gnatprove: unproved check messages considered as errors
```

Runtime output

```

raised ADA.ASSERTIONS.ASSERTION_ERROR : main.adb:7
```

The "Prove" button invokes **gnatprove** on `main.adb`. You can ignore the parameters to the invocation. For the purpose of this demonstration, the interesting output is this message:

```
main.adb:7:19: medium: assertion might fail, cannot prove X > 99 (e.g. when X = 50)
```

gnatprove can tell that the assertion `X > 99` may have a problem. There's indeed a bug here, and **gnatprove** even gives us the counterexample (when X is 50). As a result the code is not proven and we know we have an error to correct.

Notice that the message says the assertion "might fail" even though clearly **gnatprove** has an example for when failure is certain. That wording is a reflection of the fact that SPARK gives strong guarantees when the assertions are proven to hold, but does not guarantee that flagged problems are indeed problems. In other words, **gnatprove** does not give false

positives but false negatives are possible. The result is that if **gnatprove** does not indicate a problem for the code under analysis we can be sure there is no problem, but if **gnatprove** does indicate a problem the tool may be wrong.

70.3 Initialization and Correct Data Flow

An immediate benefit from having our code compatible with the SPARK subset is that we can ask **gnatprove** to verify initialization and correct data flow, as indicated by the absence of messages during SPARK "flow analysis." Flow analysis detects programming errors such as reading uninitialized data, problematic aliasing between formal parameters, and data races between concurrent tasks.

In addition, **gnatprove** checks unit specifications for the actual data read or written, and the flow of information from inputs to outputs. As you can imagine, this verification provides significant benefits, and it can be reached with comparatively low cost.

For example, the following illustrates an initialization failure:

Listing 18: main.adb

```
with Increment;
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   B : Integer;
begin
   Increment (B);
   Put_Line (B'Image);
end Main;
```

Listing 19: increment.adb

```
procedure Increment (Value : in out Integer) is
begin
    Value := Value + 1;
end Increment;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Contracts_0
MD5: 06d432a84d94635bb7bddafd9574a748
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
main.adb:7:15: warning: "B" may be referenced before it has a value [enabled by␣
 ↪default]
main.adb:7:15: high: "B" is not initialized
gnatprove: unproved check messages considered as errors
```

Granted, `Increment` is a silly procedure as-is, but imagine it did useful things, and, as part of that, incremented the argument. **gnatprove** tells us that the caller has not assigned a value to the argument passed to `Increment`.

Consider this next routine, which contains a serious coding error. Flow analysis will find it for us.

Listing 20: compute_offset.adb

```
with Ada.Numerics.Elementary_Functions;  use Ada.Numerics.Elementary_Functions;

procedure Compute_Offset (K : Float; Z : out Integer; Flag : out Boolean) is
   X : constant Float := Sin (K);
begin
   if X < 0.0 then
      Z := 0;
      Flag := True;
   elsif X > 0.0 then
      Z := 1;
      Flag := True;
   else
      Flag := False;
   end if;
end Compute_Offset;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Contracts_1
MD5: af7f16a9c83359c49fde44ed4796c8ec
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
compute_offset.adb:3:38: medium: "Z" might not be initialized in "Compute_Offset"␣
 ↪[reason for check: OUT parameter should be initialized on return] [possible fix:␣
 ↪initialize "Z" on all paths or make "Z" an IN OUT parameter]
gnatprove: unproved check messages considered as errors
```

gnatprove tells us that Z might not be initialized (assigned a value) in Compute_Offset, and indeed that is correct. Z is a mode **out** parameter so the routine should assign a value to it: Z is an output, after all. The fact that Compute_Offset does not do so is a significant and nasty bug. Why is it so nasty? In this case, formal parameter Z is of the scalar type **Integer**, and scalar parameters are always passed by copy in Ada and SPARK. That means that, when returning to the caller, an integer value is copied to the caller's argument passed to Z. But this procedure doesn't always assign the value to be copied back, and in that case an arbitrary value — whatever is on the stack — is copied to the caller's argument. The poor programmer must debug the code to find the problem, yet the effect could appear well downstream from the call to Compute_Offset. That's not only painful, it is expensive. Better to find the problem before we even compile the code.

70.4 Contract-Based Programming

So far, we've seen assertions in a routine's sequence of statements, either through implicit language-defined checks (is the index in the right range?) or explicit user-defined checks. These checks are already useful by themselves but they have an important limitation: the assertions are in the implementation, hidden from the callers of the routine. For example, a call's success or failure may depend upon certain input values but the caller doesn't have that information.

Generally speaking, Ada and SPARK put a lot of emphasis on strong, complete specifications for the sake of abstraction and analysis. Callers need not examine the implementations to determine whether the arguments passed to it are changed, for example. It is possible to go beyond that, however, to specify implementation constraints and functional requirements. We use contracts to do so.

At the language level, contracts are higher-level forms of assertions associated with specifications and declarations rather than sequences of statements. Like other assertions they can be activated or deactivated at run-time, and can be statically proven. We'll concentrate here on two kinds of contracts, both associated especially (but not exclusively) with procedures and functions:

- *Preconditions*, those Boolean conditions required to be true *prior* to a call of the corresponding subprogram
- *Postconditions*, those Boolean conditions required to be true *after* a call, as a result of the corresponding subprogram's execution

In particular, preconditions specify the initial conditions, if any, required for the called routine to correctly execute. Postconditions, on the other hand, specify what the called routine's execution must have done, at least, on normal completion. Therefore, preconditions are obligations on callers (referred to as "clients") and postconditions are obligations on implementers. By the same token, preconditions are guarantees to the implementers, and postconditions are guarantees to clients.

Contract-based programming, then, is the specification and rigorous enforcement of these obligations and guarantees. Enforcement is rigorous because it is not manual, but tool-based: dynamically at run-time with exceptions, or, with SPARK, statically, prior to build.

Preconditions are specified via the "Pre" aspect. Postconditions are specified via the "Post" aspect. Usually subprograms have separate declarations and these aspects appear with those declarations, even though they are *about* the bodies. Placement on the declarations allows the obligations and guarantees to be visible to all parties. For example:

Listing 21: mid.ads

```
1 function Mid (X, Y : Integer) return Integer with
2    Pre  => X + Y /= 0,
3    Post => Mid'Result > X;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Contracts_2
MD5: 0fb78847a167d9318b00667c59a7038d
```

The precondition on line 2 specifies that, for any given call, the sum of the values passed to parameters X and Y must not be zero. (Perhaps we're dividing by X + Y in the body.) The declaration also provides a guarantee about the function call's result, via the postcondition on line 3: for any given call, the value returned will be greater than the value passed to X.

Consider a client calling this function:

Listing 22: demo.adb

```
1  with Mid;
2  with Ada.Text_IO; use Ada.Text_IO;
3
4  procedure Demo is
5     A, B, C : Integer;
6  begin
7     A := Mid (1, 2);
8     B := Mid (1, -1);
9     C := Mid (A, B);
10    Put_Line (C'Image);
11 end Demo;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Contracts_2
MD5: 3e0617d4b1c14b37a81377456bf73eb5
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
demo.adb:8:09: medium: precondition might fail
gnatprove: unproved check messages considered as errors
```

gnatprove indicates that the assignment to B (line 8) might fail because of the precondition, i.e., the sum of the inputs shouldn't be 0, yet `-1 + 1 = 0`. (We will address the other output message elsewhere.)

Let's change the argument passed to Y in the second call (line 8). Instead of -1 we will pass -2:

Listing 23: demo.adb

```
1  with Mid;
2  with Ada.Text_IO; use Ada.Text_IO;
3
4  procedure Demo is
5     A, B, C : Integer;
6  begin
7     A := Mid (1, 2);
8     B := Mid (1, -2);
9     C := Mid (A, B);
10    Put_Line (C'Image);
11 end Demo;
```

Listing 24: mid.ads

```
1  function Mid (X, Y : Integer) return Integer with
2     Pre  => X + Y /= 0,
3     Post => Mid'Result > X;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Contracts_3
MD5: 496937d76e16ba524f98f5a94398e929
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
warning: no bodies have been analyzed by GNATprove
enable analysis of a non-generic body using SPARK_Mode
```

The second call will no longer be flagged for the precondition. In addition, **gnatprove** will know from the postcondition that A has to be greater than 1, as does B, because in both calls 1 was passed to X. Therefore, **gnatprove** can deduce that the precondition will hold for the third call `C := Mid (A, B);` because the sum of two numbers greater than 1 will never be zero.

Postconditions can also compare the state prior to a call with the state after a call, using the `'Old` attribute. For example:

Listing 25: increment.ads

```
procedure Increment (Value : in out Integer) with
  Pre  => Value < Integer'Last,
  Post => Value = Value'Old + 1;
```

Listing 26: increment.adb

```
procedure Increment (Value : in out Integer) is
begin
   Value := Value + 1;
end Increment;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Contracts_4
MD5: b879dcff91cb4fbce5501474b7f2e732
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
```

The postcondition specifies that, on return, the argument passed to the parameter `Value` will be one greater than it was immediately prior to the call (`Value'Old`).

70.5 Replacing Defensive Code

One typical benefit of contract-based programming is the removal of defensive code in subprogram implementations. For example, the *Push* operation for a stack type would need to ensure that the given stack is not already full. The body of the routine would first check that, explicitly, and perhaps raise an exception or set a status code. With preconditions we can make the requirement explicit and **gnatprove** will verify that the requirement holds at all call sites.

This reduction has a number of advantages:

- The implementation is simpler, removing validation code that is often difficult to test, makes the code more complex and leads to behaviors that are difficult to define.
- The precondition documents the conditions under which it's correct to call the subprogram, moving from an implementer responsibility to mitigate invalid input to a user responsibility to fulfill the expected interface.
- Provides the means to verify that this interface is properly respected, through code review, dynamic checking at run-time, or formal static proof.

As an example, consider a procedure Read that returns a component value from an array. Both the `Data` and `Index` are objects visible to the procedure so they are not formal parameters.

Listing 27: p.ads

```
package P is

   type List is array (Integer range <>) of Character;

   Data  : List (1 .. 100);
   Index : Integer := Data'First;

```

(continues on next page)

(continued from previous page)

```
8     procedure Read (V : out Character);
9
10 end P;
```

Listing 28: p.adb

```
1  package body P is
2
3     procedure Read (V : out Character) is
4     begin
5        if Index not in Data'Range then
6           V := Character'First;
7           return;
8        end if;
9
10       V := Data (Index);
11       Index := Index + 1;
12    end Read;
13 end P;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Defensive
MD5: 4b4767100079b228f4f3c630d267ec53
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
```

In addition to procedure Read we would also have a way to load the array components in the first place, but we can ignore that for the purpose of this discussion.

Procedure Read is responsible for reading an element of the array and then incrementing the index. What should it do in case of an invalid index? In this implementation there is defensive code that returns a value arbitrarily chosen. We could also redesign the code to return a status in this case, or — better — raise an exception.

An even more robust approach would be instead to ensure that this subprogram is only called when Index is within the indexing boundaries of Data. We can express that requirement with a precondition (line 9).

Listing 29: p.ads

```
1  package P is
2
3     type List is array (Integer range <>) of Character;
4
5     Data : List (1 .. 100);
6     Index : Integer := 1;
7
8     procedure Read (V : out Character)
9       with Pre => Index in Data'Range;
10
11 end P;
```

Listing 30: p.adb

```
1  package body P is
2
```

(continues on next page)

(continued from previous page)

```
3     procedure Read (V : out Character) is
4     begin
5        V := Data (Index);
6        Index := Index + 1;
7     end Read;
8
9  end P;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Defensive
MD5: 9646614c34d191be51b4522c972538aa
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
```

Now we don't need the defensive code in the procedure body. That's safe because SPARK will attempt to prove statically that the check will not fail at the point of each call.

Assuming that procedure Read is intended to be the only way to get values from the array, in a real application (where the principles of software engineering apply) we would take advantage of the compile-time visibility controls that packages offer. Specifically, we would move all the variables' declarations to the private part of the package, or even the package body, so that client code could not possibly access the array directly. Only procedure Read would remain visible to clients, thus remaining the only means of accessing the array. However, that change would entail others, and in this chapter we are only concerned with introducing the capabilities of SPARK. Therefore, we keep the examples as simple as possible.

70.6 Proving Absence of Run-Time Errors

Earlier we said that **gnatprove** will verify both language-defined and user-defined checks. Proving that the language-defined checks will not raise exceptions at run-time is known as proving "Absence of Run-Time Errors" or AoRTE for short. Successful proof of these checks is highly significant in itself.

One of the major resulting benefits is that we can deploy the final executable with checks disabled. That has obvious performance benefits, but it is also a safety issue. If we disable the checks we also disable the run-time library support for them, but in that case the language does not define what happens if indeed an exception is raised. Formally speaking, anything could happen. We must have good reason for thinking that exceptions cannot be raised.

This is such an important issue that proof of AoRTE can be used to comply with the objectives of certification standards in various high-integrity domains (for example, DO-178B/C in avionics, EN 50128 in railway, IEC 61508 in many safety-related industries, ECSS-Q-ST-80C in space, IEC 60880 in nuclear, IEC 62304 in medical, and ISO 26262 in automotive).

As a result, the quality of the program can be guaranteed to achieve higher levels of integrity than would be possible in other programming languages.

However, successful proof of AoRTE may require additional assertions, especially preconditions. We can see that with procedure `Increment`, the procedure that takes an Integer argument and increments it by one. But of course, if the incoming value of the argument is the largest possible positive value, the attempt to increment it would overflow, raising `Constraint_Error`. (As you have likely already concluded, `Constraint_Error` is the most

common exception you will have to deal with.) We added a precondition to allow only the integer values up to, but not including, the largest positive value:

Listing 31: increment.ads

```
procedure Increment (Value : in out Integer) with
  Pre  => Value < Integer'Last,
  Post => Value = Value'Old + 1;
```

Listing 32: increment.adb

```
procedure Increment (Value : in out Integer) is
begin
   Value := Value + 1;
end Increment;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.SPARK.Contracts_5
MD5: b879dcff91cb4fbce5501474b7f2e732
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
```

Prove it, then comment-out the precondition and try proving it again. Not only will **gnatprove** tell us what is wrong, it will suggest a solution as well.

Without the precondition the check it provides would have to be implemented as defensive code in the body. One or the other is critical here, but note that we should never need both.

70.7 Proving Abstract Properties

The postcondition on `Increment` expresses what is, in fact, a unit-level requirement. Successfully proving such requirements is another significant robustness and cost benefit. Together with the proofs for initialization and AoRTE, these proofs ensure program integrity, that is, the program executes within safe boundaries: the control flow of the program is correctly programmed and cannot be circumvented through run-time errors, and data cannot be corrupted.

We can go even further. We can use contracts to express arbitrary abstract properties when such exist. Safety and security properties, for instance, could be expressed as postconditions and then proven by **gnatprove**.

For example, imagine we have a procedure to move a train to a new position on the track, and we want to do so safely, without leading to a collision with another train. Procedure `Move`, therefore, takes two inputs: a train identifier specifying which train to move, and the intended new position. The procedure's output is a value indicating a motion command to be given to the train in order to go to that new position. If the train cannot go to that new position safely the output command is to stop the train. Otherwise the command is for the train to continue at an indicated speed:

```
type Move_Result is (Full_Speed, Slow_Down, Keep_Going, Stop);

procedure Move
   (Train        : in  Train_Id;
    New_Position : in  Train_Position;
    Result       : out Move_Result)
```

(continues on next page)

(continued from previous page)

```
with
   Pre  => Valid_Id (Train) and
           Valid_Move (Trains (Train), New_Position) and
           At_Most_One_Train_Per_Track and
           Safe_Signaling,
   Post => At_Most_One_Train_Per_Track and
           Safe_Signaling;

function At_Most_One_Train_Per_Track return Boolean;

function Safe_Signaling return Boolean;
```

The preconditions specify that, given a safe initial state and a valid move, the result of the call will also be a safe state: there will be at most one train per track section and the track signaling system will not allow any unsafe movements.

70.8 Final Comments

Make sure you understand that **gnatprove** does not attempt to prove the program correct as a whole. It attempts to prove language-defined and user-defined assertions about parts of the program, especially individual routines and calls to those routines. Furthermore, **gnatprove** proves the routines correct only to the extent that the user-defined assertions correctly and sufficiently describe and constrain the implementation of the corresponding routines.

Although we are not proving whole program correctness, as you will have seen — and done — we can prove properties than make our software far more robust and bug-free than is possible otherwise. But in addition, consider what proving the unit-level requirements for your procedures and functions would do for the cost of unit testing and system integration. The tests would pass the first time.

However, within the scope of what SPARK can do, not everything can be proven. In some cases that is because the software behavior is not amenable to expression as boolean conditions (for example, a mouse driver). In other cases the source code is beyond the capabilities of the analyzers that actually do the mathematical proof. In these cases the combination of proof and actual test is appropriate, and still less expensive that testing alone.

There is, of course, much more to be said about what can be done with SPARK and **gnatprove**. Those topics are reserved for the *Introduction to SPARK* (page 973) course.

CHAPTER

SEVENTYONE

C TO ADA TRANSLATION PATTERNS

71.1 Naming conventions and casing considerations

One question that may arise relatively soon when converting from C to Ada is the style of source code presentation. The Ada language doesn't impose any particular style and for many reasons, it may seem attractive to keep a C-like style — for example, camel casing — to the Ada program.

However, the code in the Ada language standard, most third-party code, and the libraries provided by GNAT follow a specific style for identifiers and reserved words. Using a different style for the rest of the program leads to inconsistencies, thereby decreasing readability and confusing automatic style checkers. For those reasons, it's usually advisable to adopt the Ada style — in which each identifier starts with an upper case letter, followed by lower case letters (or digits), with an underscore separating two "distinct" words within the identifier. Acronyms within identifiers are in upper case. For example, there is a language-defined package named `Ada.Text_IO`. Reserved words are all lower case.

Following this scheme doesn't preclude adding additional, project-specific rules.

71.2 Manually interfacing C and Ada

Before even considering translating code from C to Ada, it's worthwhile to evaluate the possibility of keeping a portion of the C code intact, and only translating selected modules to Ada. This is a necessary evil when introducing Ada to an existing large C codebase, where re-writing the entire code upfront is not practical nor cost-effective.

Fortunately, Ada has a dedicated set of features for interfacing with other languages. The `Interfaces` package hierarchy and the pragmas `Convention`, `Import`, and `Export` allow you to make inter-language calls while observing proper data representation for each language.

Let's start with the following C code:

[C]

Listing 1: call.c

```c
#include <stdio.h>

struct my_struct {
    int A, B;
};

void call (struct my_struct *p) {
    printf ("%d", p->A);
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.My_Struct_C
MD5: 67053ec329fa4dfcbd8d6125589b9fcb
```

To call that function from Ada, the Ada compiler requires a description of the data structure to pass as well as a description of the function itself. To capture how the C **struct my_struct** is represented, we can use the following record along with a **pragma** *Convention*. The pragma directs the compiler to lay out the data in memory the way a C compiler would.

[Ada]

Listing 2: use_my_struct.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with Interfaces.C;

procedure Use_My_Struct is

   type my_struct is record
     A : Interfaces.C.int;
     B : Interfaces.C.int;
   end record;
   pragma Convention (C, my_struct);

   V : my_struct := (A => 1, B => 2);
begin
   Put_Line ("V = ("
             & Interfaces.C.int'Image (V.A)
             & Interfaces.C.int'Image (V.B)
             & ")");
end Use_My_Struct;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.My_Struct_Ada
MD5: d19942018679df6fbab99f1c6bfdebc8
```

Runtime output

```
V = ( 1 2)
```

Describing a foreign subprogram call to Ada code is called *binding* and it is performed in two stages. First, an Ada subprogram specification equivalent to the C function is coded. A C function returning a value maps to an Ada function, and a void function maps to an Ada procedure. Then, rather than implementing the subprogram using Ada code, we use a **pragma** *Import*:

```
procedure Call (V : my_struct);
pragma Import (C, Call, "call"); -- Third argument optional
```

The `Import` pragma specifies that whenever `Call` is invoked by Ada code, it should invoke the `Call` function with the C calling convention.

And that's all that's necessary. Here's an example of a call to `Call`:

[Ada]

Listing 3: use_my_struct.adb

```
with Interfaces.C;

```

(continues on next page)

(continued from previous page)

```
procedure Use_My_Struct is

   type my_struct is record
     A : Interfaces.C.int;
     B : Interfaces.C.int;
   end record;
   pragma Convention (C, my_struct);

   procedure Call (V : my_struct);
   pragma Import (C, Call, "call"); -- Third argument optional

   V : my_struct := (A => 1, B => 2);
begin
   Call (V);
end Use_My_Struct;
```

Code block metadata

```

71.3 Building and Debugging mixed language code

The easiest way to build an application using mixed C / Ada code is to create a simple project file for **gprbuild** and specify C as an additional language. By default, when using **gprbuild** we only compile Ada source files. To compile C code files as well, we use the Languages attribute and specify c as an option, as in the following example of a project file named *default.gpr*:

```
project Default is

   for Languages use ("ada", "c");
   for Main use ("main.adb");

end Default;
```

Then, we use this project file to build the application by simply calling `gprbuild`. Alternatively, we can specify the project file on the command-line with the `-P` option — for example, `gprbuild -P default.gpr`. In both cases, `gprbuild` compiles all C source-code file found in the directory and links the corresponding object files to build the executable.

In order to include debug information, you can use `gprbuild -cargs -g`. This option adds debug information based on both C and Ada code to the executable. Alternatively, you can specify a `Builder` package in the project file and include global compilation switches for each language using the `Global_Compilation_Switches` attribute. For example:

```
project Default is

   for Languages use ("ada", "c");
   for Main use ("main.adb");

   package Builder is
      for Global_Compilation_Switches ("Ada") use ("-g");
      for Global_Compilation_Switches ("C") use ("-g");
   end Builder;

end Default;
```

In this case, you can simply run `gprbuild -P default.gpr` to build the executable.

To debug the executable, you can use programs such as **gdb** or **ddd**, which are suitable for debugging both C and Ada source-code. If you prefer a complete IDE, you may want to look into **GNAT Studio**, which supports building and debugging an application within a single environment, and remotely running applications loaded to various embedded devices. You can find more information about **gprbuild** and **GNAT Studio** in the *Introduction to GNAT Toolchain* (page 1681) course.

71.4 Automatic interfacing

It may be useful to start interfacing Ada and C by using automatic binding generators. These can be done either by invoking **gcc** `-fdump-ada-spec` option (to generate an Ada binding to a C header file) or `-gnatceg` option (to generate a C binding to an Ada specification file). For example:

```
gcc -c -fdump-ada-spec my_header.h
gcc -c -gnatceg spec.ads
```

The level of interfacing is very low level and typically requires either massaging (changing the generated files) or wrapping (calling the generated files from a higher level interface). For example, numbers bound from C to Ada are only standard numbers where user-defined types may be desirable. C uses a lot of by-pointer parameters which may be better replaced by other parameter modes, etc.

However, the automatic binding generator helps having a starting point which ensures compatibility of the Ada and the C code.

71.5 Using Arrays in C interfaces

It is relatively straightforward to pass an array from Ada to C. In particular, with the GNAT compiler, passing an array is equivalent to passing a pointer to its first element. Of course, as there's no notion of boundaries in C, the length of the array needs to be passed explicitly. For example:

[C]

Listing 4: p.h

```
1 void p (int * a, int length);
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Arr_1
MD5: 123353e301a3d43016d2799855e6732a
```

[Ada]

Listing 5: main.adb

```
1 procedure Main is
2    type Arr is array (Integer range <>) of Integer;
3
4    procedure P (V : Arr; Length : Integer);
5    pragma Import (C, P);
6
```

(continues on next page)

(continued from previous page)

```
   X : Arr (5 .. 15);
begin
   P (X, X'Length);
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Arr_1
MD5: 9bfbc0f31da4554a1e1dea1ba2b1d305
```

The other way around — that is, retrieving an array that has been creating on the C side — is more difficult. Because C doesn't explicitly carry boundaries, they need to be recreated in some way.

The first option is to actually create an Ada array without boundaries. This is the most flexible, but also the least safe option. It involves creating an array with indices over the full range of `Integer` without ever creating it from Ada, but instead retrieving it as an access from C. For example:

[C]

Listing 6: f.h

```
int * f ();
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Arr_2
MD5: 19e33efb6d7d46778b88baa2709111e5
```

[Ada]

Listing 7: main.adb

```
procedure Main is
   type Arr is array (Integer) of Integer;
   type Arr_A is access all Arr;

   function F return Arr_A;
   pragma Import (C, F);
begin
   null;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Arr_2
MD5: b52213bcdd8db5e8abfcb8effabb84df
```

Note that `Arr` is a constrained type (it doesn't have the `range <>` notation for indices). For that reason, as it would be for C, it's possible to iterate over the whole range of integer, beyond the memory actually allocated for the array.

A somewhat safer way is to overlay an Ada array over the C one. This requires having access to the length of the array. This time, let's consider two cases, one with an array and its size accessible through functions, another one on global variables. This time, as we're using an overlay, the function will be directly mapped to an Ada function returning an address:

[C]

Listing 8: fg.h

```c
int * f_arr (void);
int f_size (void);

int * g_arr;
int g_size;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Arr_3
MD5: b315ec2e5d9fdd297ba295ccbae910bc
```

[Ada]

Listing 9: fg.ads

```ada
with System;

package Fg is

   type Arr is array (Integer range <>) of Integer;

   function F_Arr return System.Address;
   pragma Import (C, F_Arr, "f_arr");

   function F_Size return Integer;
   pragma Import (C, F_Size, "f_size");

   F : Arr (0 .. F_Size - 1) with Address => F_Arr;

   G_Size : Integer;
   pragma Import (C, G_Size, "g_size");

   G_Arr : Arr (0 .. G_Size - 1);
   pragma Import (C, G_Arr, "g_arr");

end Fg;
```

Listing 10: main.adb

```
with Fg;

procedure Main is
begin
   null;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Arr_3
MD5: 5c74f9bca93520ecf85a2010760cc2f8
```

With all solutions though, importing an array from C is a relatively unsafe pattern, as there's only so much information on the array as there would be on the C side in the first place. These are good places for careful peer reviews.

71.6 By-value vs. by-reference types

When interfacing Ada and C, the rules of parameter passing are a bit different with regards to what's a reference and what's a copy. Scalar types and pointers are passed by value, whereas record and arrays are (almost) always passed by reference. However, there may be cases where the C interface also passes values and not pointers to objects. Here's a slightly modified version of a previous example to illustrate this point:

[C]

Listing 11: call.c

```
#include <stdio.h>

struct my_struct {
    int A, B;
};

void call (struct my_struct p) {
    printf ("%d", p.A);
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Param_By_Value_C
MD5: 42b6e329c5dbfcae368078ca7635341f
```

In Ada, a type can be modified so that parameters of this type can always be passed by copy.

[Ada]

Listing 12: main.adb

```
with Interfaces.C;

procedure Main is
   type my_struct is record
      A : Interfaces.C.int;
      B : Interfaces.C.int;
   end record
```

(continues on next page)

(continued from previous page)

```
     with Convention => C_Pass_By_Copy;

   procedure Call (V : my_struct);
   pragma Import (C, Call, "call");
begin
   null;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Param_By_Value_Ada
MD5: 16e97033bdffb2bacc0cf3322c019a94
```

Note that this cannot be done at the subprogram declaration level, so if there is a mix of by-copy and by-reference calls, two different types need to be used on the Ada side.

71.7 Naming and prefixes

Because of the absence of namespaces, any global name in C tends to be very long. And because of the absence of overloading, they can even encode type names in their type.

In Ada, the package is a namespace — two entities declared in two different packages are clearly identified and can always be specifically designated. The C names are usually a good indication of the names of the future packages and should be stripped — it is possible to use the full name if useful. For example, here's how the following declaration and call could be translated:

[C]

Listing 13: reg_interface.h

```
void registerInterface_Initialize (int size);
```

Listing 14: reg_interface_test.c

```
#include "reg_interface.h"

int main(int argc, const char * argv[])
{
    registerInterface_Initialize(15);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Namespaces
MD5: e8c25da648a2e8662d97a9a5b863a5bc
```

[Ada]

Listing 15: register_interface.ads

```
package Register_Interface is
   procedure Initialize (Size : Integer)
     with Import     => True,
          Convention => C,
          External_Name => "registerInterface_Initialize";
```

(continues on next page)

(continued from previous page)

```
6
7  end Register_Interface;
```

Listing 16: main.adb

```
1  with Register_Interface;
2
3  procedure Main is
4  begin
5     Register_Interface.Initialize (15);
6  end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Namespaces
MD5: 934edd7d3c74d058f862a786582a32c0
```

Note that in the above example, a **use** clause on Register_Interface could allow us to omit the prefix.

71.8 Pointers

The first thing to ask when translating pointers from C to Ada is: are they needed in the first place? In Ada, pointers (or access types) should only be used with complex structures that cannot be allocated at run-time — think of a linked list or a graph for example. There are many other situations that would need a pointer in C, but do not in Ada, in particular:

- Arrays, even when dynamically allocated
- Results of functions
- Passing large structures as parameters
- Access to registers
- ... others

This is not to say that pointers aren't used in these cases but, more often than not, the pointer is hidden from the user and automatically handled by the code generated by the compiler; thus avoiding possible mistakes from being made. Generally speaking, when looking at C code, it's good practice to start by analyzing how many pointers are used and to translate as many as possible into *pointerless* Ada structures.

Here are a few examples of such patterns — additional examples can be found throughout this document.

Dynamically allocated arrays can be directly allocated on the stack:

[C]

Listing 17: array_decl.c

```
1  #include <stdlib.h>
2
3  int main() {
4      int *a = malloc(sizeof(int) * 10);
5
6      return 0;
7  }
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Array_Stack_Alloc_C
MD5: a922c3e163494339d6773c6ab1256549
```

[Ada]

Listing 18: main.adb

```ada
procedure Main is
   type Arr is array (Integer range <>) of Integer;
   A : Arr (0 .. 9);
begin
   null;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Array_Stack_Alloc_Ada
MD5: 2e4196c2a2016244a48de153beaa2b49
```

Build output

```
main.adb:3:04: warning: variable "A" is never read and never assigned [-gnatwv]
```

It's even possible to create a such an array within a structure, provided that the size of the array is known when instantiating this object, using a type discriminant:

[C]

Listing 19: array_decl.c

```c
#include <stdlib.h>

typedef struct {
    int * a;
} S;

int main(int argc, const char * argv[])
{
    S v;

    v.a = malloc(sizeof(int) * 10);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Struct_Array_Stack_Alloc_C
MD5: f8e5a877977387986b3e2353834a2989
```

[Ada]

Listing 20: main.adb

```ada
procedure Main is
   type Arr is array (Integer range <>) of Integer;

   type S (Last : Integer) is record
      A : Arr (0 .. Last);
   end record;

   V : S (9);
```

(continues on next page)

(continued from previous page)

```
9  begin
10    null;
11 end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Struct_Array_Stack_Alloc_Ada
MD5: 955c704bdbe4b2b788e4a790ade12df7
```

Build output

```
main.adb:8:04: warning: variable "V" is never read and never assigned [-gnatwv]
```

With regards to parameter passing, usage mode (input / output) should be preferred to implementation mode (by copy or by reference). The Ada compiler will automatically pass a reference when needed. This works also for smaller objects, so that the compiler will copy in an out when needed. One of the advantages of this approach is that it clarifies the nature of the object: in particular, it differentiates between arrays and scalars. For example:

[C]

Listing 21: p.h

```
1 void p (int * a, int * b);
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Array_In_Out_C
MD5: c2c936dd3afc4850c5869e4db73bb36b
```

[Ada]

Listing 22: array_types.ads

```
1 package Array_Types is
2    type Arr is array (Integer range <>) of Integer;
3
4    procedure P (A : in out Integer; B : in out Arr);
5 end Array_Types;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Array_In_Out_Ada
MD5: cf8e51391c9fd8608183c9dae2aa2802
```

Most of the time, access to registers end up in some specific structures being mapped onto a specific location in memory. In Ada, this can be achieved through an **Address** clause associated to a variable, for example:

[C]

Listing 23: test_c.c

```
1 int main(int argc, const char * argv[])
2 {
3     int * r = (int *)0xFFFF00A0;
4
5     return 0;
6 }
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Address_C
MD5: e810538d72d835a04736fcaf732f1930
```

[Ada]

Listing 24: test.adb

```ada
with System;

procedure Test is
   R : Integer with Address => System'To_Address (16#FFFF00A0#);
begin
   null;
end Test;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Address_Ada
MD5: 1263f7289cec6673f19d88bffbeead48
```

These are some of the most common misuse of pointers in Ada. Previous sections of the document deal with specifically using access types if absolutely necessary.

71.9 Bitwise Operations

Bitwise operations such as masks and shifts in Ada should be relatively rarely needed, and, when translating C code, it's good practice to consider alternatives. In a lot of cases, these operations are used to insert several pieces of data into a larger structure. In Ada, this can be done by describing the structure layout at the type level through representation clauses, and then accessing this structure as any other.

Consider the case of using a C primitive type as a container for single bit boolean flags. In C, this would be done through masks, e.g.:

[C]

Listing 25: flags.c

```c
#define FLAG_1 0b0001
#define FLAG_2 0b0010
#define FLAG_3 0b0100
#define FLAG_4 0b1000

int main(int argc, const char * argv[])
{
    int value = 0;

    value |= FLAG_2 | FLAG_4;

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Flags_C
MD5: cf903dee1fb1d78d74dc42b66adcdbd5
```

In Ada, the above can be represented through a Boolean array of enumerate values:

[Ada]

Listing 26: main.adb

```
procedure Main is
   type Values is (Flag_1, Flag_2, Flag_3, Flag_4);
   type Value_Array is array (Values) of Boolean
     with Pack;

   Value : Value_Array :=
      (Flag_2 => True,
       Flag_4 => True,
       others => False);
begin
   null;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Flags_Ada
MD5: c92c8532763469f5e4d1027df2bd6a6b
```

Note the Pack directive for the array, which requests that the array takes as little space as possible.

It is also possible to map records on memory when additional control over the representation is needed or more complex data are used:

[C]

Listing 27: struct_map.c

```
int main(int argc, const char * argv[])
{
    int value = 0;

    value = (2 << 1) | 1;

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Rec_Map_C
MD5: 16606f11ab3e9c86d3e1d88ac9c3f37f
```

[Ada]

Listing 28: main.adb

```
procedure Main is
   type Value_Rec is record
     V1 : Boolean;
     V2 : Integer range 0 .. 3;
   end record;

   for Value_Rec use record
      V1 at 0 range 0 .. 0;
      V2 at 0 range 1 .. 2;
   end record;

   Value : Value_Rec := (V1 => True, V2 => 2);
begin
```

(continues on next page)

(continued from previous page)

```
14    null;
15 end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Rec_Map_Ada
MD5: 52078824814b0d83789dd837ac2e86bf
```

The benefit of using Ada structure instead of bitwise operations is threefold:

- The code is simpler to read / write and less error-prone
- Individual fields are named
- The compiler can run consistency checks (for example, check that the value indeed fit in the expected size).

Note that, in cases where bitwise operators are needed, Ada provides modular types with **and**, **or** and **xor** operators. Further shift operators can also be provided upon request through a **pragma**. So the above could also be literally translated to:

[Ada]

Listing 29: main.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Main is
4     type Value_Type is mod 2 ** 32;
5     pragma Provide_Shift_Operators (Value_Type);
6
7     Value : Value_Type;
8  begin
9     Value := Shift_Left (2, 1) or 1;
10    Put_Line ("Value = " & Value_Type'Image (Value));
11 end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Bitwise_Ops_Ada
MD5: 22cb824a0c99bd1a9092dc5f90e9d7fc
```

Runtime output

```
Value =  5
```

71.10 Mapping Structures to Bit-Fields

In the previous section, we've seen how to perform bitwise operations. In this section, we look at how to interpret a data type as a bit-field and perform low-level operations on it.

In general, you can create a bit-field from any arbitrary data type. First, we declare a bit-field type like this:

[Ada]

```
type Bit_Field is array (Natural range <>) of Boolean with Pack;
```

As we've seen previously, the Pack aspect declared at the end of the type declaration indicates that the compiler should optimize for size. We must use this aspect to be able to interpret data types as a bit-field.

Then, we can use the `Size` and the **`Address`** attributes of an object of any type to declare a bit-field for this object. We've discussed the `Size` attribute *earlier in this course* (page 1443).

The **`Address`** attribute indicates the address in memory of that object. For example, assuming we've declare a variable `V`, we can declare an actual bit-field object by referring to the **`Address`** attribute of `V` and using it in the declaration of the bit-field, as shown here:

[Ada]

```
B : Bit_Field (0 .. V'Size - 1) with Address => V'Address;
```

Note that, in this declaration, we're using the **`Address`** attribute of `V` for the **`Address`** aspect of `B`.

This technique is called overlays for serialization. Now, any operation that we perform on `B` will have a direct impact on `V`, since both are using the same memory location.

The approach that we use in this section relies on the **`Address`** aspect. Another approach would be to use unchecked conversions, which we'll discuss in the *next section* (page 1502).

We should add the `Volatile` aspect to the declaration to cover the case when both objects can still be changed independently — they need to be volatile, otherwise one change might be missed. This is the updated declaration:

[Ada]

```
B : Bit_Field (0 .. V'Size - 1) with Address => V'Address, Volatile;
```

Using the `Volatile` aspect is important at high level of optimizations. You can find further details about this aspect in the section about the *Volatile and Atomic aspects* (page 1439).

Another important aspect that should be added is `Import`. When used in the context of object declarations, it'll avoid default initialization which could overwrite the existing content while creating the overlay — see an example in the admonition below. The declaration now becomes:

```
B : Bit_Field (0 .. V'Size - 1)
  with
    Address => V'Address, Import, Volatile;
```

Let's look at a simple example:

[Ada]

Listing 30: simple_bitfield.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Simple_Bitfield is
   type Bit_Field is array (Natural range <>) of Boolean with Pack;

   V : Integer := 0;
   B : Bit_Field (0 .. V'Size - 1)
     with Address => V'Address, Import, Volatile;
begin
   B (2) := True;
   Put_Line ("V = " & Integer'Image (V));
end Simple_Bitfield;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Bitfield_Ada
MD5: 193a2db91619426a145cd267f873145f
```

Runtime output

```
V =  4
```

In this example, we first initialize V with zero. Then, we use the bit-field B and set the third element (B (2)) to **True**. This automatically sets bit #3 of V to 1. Therefore, as expected, the application displays the message V = 4, which corresponds to $2^2 = 4$.

Note that, in the declaration of the bit-field type above, we could also have used a positive range. For example:

```
type Bit_Field is array (Positive range <>) of Boolean with Pack;

B : Bit_Field (1 .. V'Size)
  with Address => V'Address, Import, Volatile;
```

The only difference in this case is that the first bit is B (1) instead of B (0).

In C, we would rely on bit-shifting and masking to set that specific bit:

[C]

Listing 31: bitfield.c

```
#include <stdio.h>

int main(int argc, const char * argv[])
{
    int v = 0;

    v = v | (1 << 2);

    printf("v = %d\n", v);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Bitfield_C
MD5: 98557f80ea3bc1b081ae2688f844cbe1
```

Runtime output

```
v = 4
```

Important

Ada has the concept of default initialization. For example, you may set the default value of record components:

[Ada]

Listing 32: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is

   type Rec is record
      X : Integer := 10;
      Y : Integer := 11;
   end record;
```

(continues on next page)

(continued from previous page)

```
9
10    R : Rec;
11 begin
12    Put_Line ("R.X = " & Integer'Image (R.X));
13    Put_Line ("R.Y = " & Integer'Image (R.Y));
14 end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Default_Record_Type
MD5: 010877f4d20302a1abcb9562c9e36a38
```

Runtime output

```
R.X =  10
R.Y =  11
```

In the code above, we don't explicitly initialize the components of R, so they still have the default values 10 and 11, which are displayed by the application.

Likewise, the `Default_Value` aspect can be used to specify the default value in other kinds of type declarations. For example:

[Ada]

Listing 33: main.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Main is
4
5     type Percentage is range 0 .. 100
6       with Default_Value => 10;
7
8     P : Percentage;
9  begin
10    Put_Line ("P = " & Percentage'Image (P));
11 end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Default_Value_Type
MD5: b3715f7cba0cbefa433bac529d95e395
```

Runtime output

```
P =  10
```

When declaring an object whose type has a default value, the object will automatically be initialized with the default value. In the example above, P is automatically initialized with 10, which is the default value of the `Percentage` type.

Some types have an implicit default value. For example, access types have a default value of **`null`**.

As we've just seen, when declaring objects for types with associated default values, automatic initialization will happen. This can also happens when creating an overlay with the **`Address`** aspect. The default value is then used to overwrite the content at the memory location indicated by the address. However, in most situations, this isn't the behavior we expect, since overlays are usually created to analyze and manipulate existing values. Let's look at an example where this happens:

[Ada]

Listing 34: p.ads

```
package P is

   type Unsigned_8 is mod 2 ** 8 with Default_Value => 0;

   type Byte_Field is array (Natural range <>) of Unsigned_8;

   procedure Display_Bytes_Increment (V : in out Integer);
end P;
```

Listing 35: p.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body P is

   procedure Display_Bytes_Increment (V : in out Integer) is
      BF  : Byte_Field (1 .. V'Size / 8)
        with Address => V'Address, Volatile;
   begin
      for B of BF loop
         Put_Line ("Byte = " & Unsigned_8'Image (B));
      end loop;
      Put_Line ("Now incrementing...");
      V := V + 1;
   end Display_Bytes_Increment;

end P;
```

Listing 36: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with P; use P;

procedure Main is
   V : Integer := 10;
begin
   Put_Line ("V = " & Integer'Image (V));
   Display_Bytes_Increment (V);
   Put_Line ("V = " & Integer'Image (V));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Overlay_Default_Init_Overwrite
MD5: 04994b2b4c98e9232a155515dc0c365a
```

Build output

```
p.adb:7:14: warning: default initialization of "Bf" may modify "V" [enabled by␣
 ↪default]
p.adb:7:14: warning: use pragma Import for "Bf" to suppress initialization (RM B.
 ↪1(24)) [enabled by default]
```

Runtime output

```
V =  10
Byte =  0
Byte =  0
```

(continues on next page)

(continued from previous page)

```
Byte =  0
Byte =  0
Now incrementing...
V =  1
```

In this example, we expect `Display_Bytes_Increment` to display each byte of the `V` parameter and then increment it by one. Initially, `V` is set to 10, and the call to `Display_Bytes_Increment` should change it to 11. However, due to the default value associated to the `Unsigned_8` type — which is set to 0 — the value of `V` is overwritten in the declaration of `BF` (in `Display_Bytes_Increment`). Therefore, the value of `V` is 1 after the call to `Display_Bytes_Increment`. Of course, this is not the behavior that we originally intended.

Using the `Import` aspect solves this problem. This aspect tells the compiler to not apply default initialization in the declaration because the object is imported. Let's look at the corrected example:

[Ada]

Listing 37: p.ads

```
package P is

   type Unsigned_8 is mod 2 ** 8 with Default_Value => 0;

   type Byte_Field is array (Natural range <>) of Unsigned_8;

   procedure Display_Bytes_Increment (V : in out Integer);
end P;
```

Listing 38: p.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body P is

   procedure Display_Bytes_Increment (V : in out Integer) is
      BF  : Byte_Field (1 .. V'Size / 8)
        with Address => V'Address, Import, Volatile;
   begin
      for B of BF loop
         Put_Line ("Byte = " & Unsigned_8'Image (B));
      end loop;
      Put_Line ("Now incrementing...");
      V := V + 1;
   end Display_Bytes_Increment;

end P;
```

Listing 39: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with P; use P;

procedure Main is
   V : Integer := 10;
begin
   Put_Line ("V = " & Integer'Image (V));
   Display_Bytes_Increment (V);
```

(continues on next page)

(continued from previous page)

```
10    Put_Line ("V = " & Integer'Image (V));
11 end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Overlay_Default_Init_Import
MD5: e269d9d3c06c0f6c69ead16e7d2ba70b
```

Runtime output

```
V =  10
Byte =  10
Byte =  0
Byte =  0
Byte =  0
Now incrementing...
V =  11
```

This unwanted side-effect of the initialization by the `Default_Value` aspect that we've just seen can also happen in these cases:

- when we set a default value for components of a record type declaration,
- when we use the `Default_Component_Value` aspect for array types, or
- when we set use the `Initialize_Scalars` pragma for a package.

Again, using the `Import` aspect when declaring the overlay eliminates this side-effect.

We can use this pattern for objects of more complex data types like arrays or records. For example:

[Ada]

Listing 40: int_array_bitfield.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  procedure Int_Array_Bitfield is
4     type Bit_Field is array (Natural range <>) of Boolean with Pack;
5
6     A : array (1 .. 2) of Integer := (others => 0);
7     B : Bit_Field (0 .. A'Size - 1)
8       with Address => A'Address, Import, Volatile;
9  begin
10    B (2) := True;
11    for I in A'Range loop
12       Put_Line ("A (" & Integer'Image (I)
13                 & ")= " & Integer'Image (A (I)));
14    end loop;
15 end Int_Array_Bitfield;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Bitfield_Int_Array_Ada
MD5: 478ba4ce4f5886566556bddb58245eb9
```

Runtime output

```
A ( 1)=  4
A ( 2)=  0
```

In the Ada example above, we're using the bit-field to set bit #3 of the first element of the array (`A (1)`). We could set bit #4 of the second element by using the size of the data type (in this case, `Integer'Size`):

[Ada]

```
B (Integer'Size + 3) := True;
```

In C, we would select the specific array position and, again, rely on bit-shifting and masking to set that specific bit:

[C]

Listing 41: bitfield_int_array.c

```
#include <stdio.h>

int main(int argc, const char * argv[])
{
    int i;
    int a[2] = {0, 0};

    a[0] = a[0] | (1 << 2);

    for (i = 0; i < 2; i++)
    {
        printf("a[%d] = %d\n", i, a[i]);
    }

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Bitfield_Int_Array_C
MD5: 4dc3fe77e8260ff3b449c8779745a63c
```

Runtime output

```
a[0] = 4
a[1] = 0
```

Since we can use this pattern for any arbitrary data type, this allows us to easily create a subprogram to serialize data types and, for example, transmit complex data structures as a bitstream. For example:

[Ada]

Listing 42: serializer.ads

```
package Serializer is

   type Bit_Field is array (Natural range <>) of Boolean with Pack;

   procedure Transmit (B : Bit_Field);

end Serializer;
```

Listing 43: serializer.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Serializer is
```

(continues on next page)

(continued from previous page)

```
4
5     procedure Transmit (B : Bit_Field) is
6
7        procedure Show_Bit (V : Boolean) is
8        begin
9           case V is
10             when False => Put ("0");
11             when True  => Put ("1");
12          end case;
13       end Show_Bit;
14
15    begin
16       Put ("Bits: ");
17       for E of B loop
18          Show_Bit (E);
19       end loop;
20       New_Line;
21    end Transmit;
22
23 end Serializer;
```

Listing 44: my_recs.ads

```
1  package My_Recs is
2
3     type Rec is record
4        V : Integer;
5        S : String (1 .. 3);
6     end record;
7
8  end My_Recs;
```

Listing 45: main.adb

```
1  with Serializer;  use Serializer;
2  with My_Recs;     use My_Recs;
3
4  procedure Main is
5     R : Rec := (5, "abc");
6     B : Bit_Field (0 .. R'Size - 1)
7       with Address => R'Address, Import, Volatile;
8  begin
9     Transmit (B);
10 end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Bitfield_Serialization_ada
MD5: 5c9c2d18bab7c78456d1d795c6334cd9
```

Build output

```
main.adb:9:14: warning: volatile actual passed by copy (RM C.6(19)) [enabled by␣
↪default]
```

Runtime output

Bits: 10100000000000000000000000000001000011001000110110001100000000
```

In this example, the `Transmit` procedure from `Serializer` package displays the individual bits of a bit-field. We could have used this strategy to actually transmit the information as

a bitstream. In the main application, we call `Transmit` for the object R of record type Rec. Since `Transmit` has the bit-field type as a parameter, we can use it for any type, as long as we have a corresponding bit-field representation.

In C, we interpret the input pointer as an array of bytes, and then use shifting and masking to access the bits of that byte. Here, we use the **`char`** type because it has a size of one byte in most platforms.

[C]

Listing 46: my_recs.h

```c
typedef struct {
    int v;
    char s[4];
} rec;
```

Listing 47: serializer.h

```c
void transmit (void *bits, int len);
```

Listing 48: serializer.c

```c
#include "serializer.h"

#include <stdio.h>
#include <assert.h>

void transmit (void *bits, int len)
{
    int i, j;
    char *c = (char *)bits;

    assert(sizeof(char) == 1);

    printf("Bits: ");
    for (i = 0; i < len / (sizeof(char) * 8); i++)
    {
        for (j = 0; j < sizeof(char) * 8; j++)
        {
            printf("%d", c[i] >> j & 1);
        }
    }
    printf("\n");
}
```

Listing 49: bitfield_serialization.c

```c
#include <stdio.h>

#include "my_recs.h"
#include "serializer.h"

int main(int argc, const char * argv[])
{
    rec r = {5, "abc"};

    transmit(&r, sizeof(r) * 8);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Bitfield_Serialization_C
MD5: 47f0a4efcbec9303f44d535064e5d6ce
```

Runtime output

```
Bits: 10100000000000000000000000000000100001100100011011000011000000000
```

Similarly, we can write a subprogram that converts a bit-field — which may have been received as a bitstream — to a specific type. We can add a To_Rec subprogram to the My_Recs package to convert a bit-field to the Rec type. This can be used to convert a bitstream that we received into the actual data type representation.

As you know, we may write the To_Rec subprogram as a procedure or as a function. Since we need to use slightly different strategies for the implementation, the following example has both versions of To_Rec.

This is the updated code for the My_Recs package and the Main procedure:

[Ada]

Listing 50: serializer.ads

```
package Serializer is

   type Bit_Field is array (Natural range <>) of Boolean with Pack;

   procedure Transmit (B : Bit_Field);

end Serializer;
```

Listing 51: serializer.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Serializer is

   procedure Transmit (B : Bit_Field) is

      procedure Show_Bit (V : Boolean) is
      begin
         case V is
            when False => Put ("0");
            when True  => Put ("1");
         end case;
```

(continues on next page)

(continued from previous page)

```
      end Show_Bit;

   begin
      Put ("Bits: ");
      for E of B loop
         Show_Bit (E);
      end loop;
      New_Line;
   end Transmit;

end Serializer;
```

Listing 52: my_recs.ads

```
with Serializer;  use Serializer;

package My_Recs is

   type Rec is record
      V : Integer;
      S : String (1 .. 3);
   end record;

   procedure To_Rec (B :     Bit_Field;
                     R : out Rec);

   function To_Rec (B : Bit_Field) return Rec;

   procedure Display (R : Rec);

end My_Recs;
```

Listing 53: my_recs.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body My_Recs is

   procedure To_Rec (B :     Bit_Field;
                     R : out Rec) is
      B_R : Rec
        with Address => B'Address, Import, Volatile;
   begin
      --  Assigning data from overlayed record B_R to output parameter R.
      R := B_R;
   end To_Rec;

   function To_Rec (B : Bit_Field) return Rec is
      R   : Rec;
      B_R : Rec
        with Address => B'Address, Import, Volatile;
   begin
      --  Assigning data from overlayed record B_R to local record R.
      R := B_R;

      return R;
   end To_Rec;

   procedure Display (R : Rec) is
   begin
```

(continues on next page)

(continued from previous page)

```
      Put ("("  & Integer'Image (R.V) & ", "
           & (R.S) & ")");
   end Display;

end My_Recs;
```

Listing 54: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Serializer;  use Serializer;
with My_Recs;     use My_Recs;

procedure Main is
   R1 : Rec := (5, "abc");
   R2 : Rec := (0, "zzz");

   B1 : Bit_Field (0 .. R1'Size - 1)
     with Address => R1'Address, Import, Volatile;
begin
   Put ("R2 = ");
   Display (R2);
   New_Line;

   --  Getting Rec type using data from B1, which is a bit-field
   --  representation of R1.
   To_Rec (B1, R2);

   --  We could use the function version of To_Rec:
   --  R2 := To_Rec (B1);

   Put_Line ("New bitstream received!");
   Put ("R2 = ");
   Display (R2);
   New_Line;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Bitfield_Deserialization_Ada
MD5: bf5cb5ef048ed1f95dba8e85275f6e32
```

Build output

```
main.adb:18:12: warning: volatile actual passed by copy (RM C.6(19)) [enabled by␣
↪default]
```

Runtime output

```
R2 = ( 0, zzz)
New bitstream received!
R2 = ( 5, abc)
```

In both versions of To_Rec, we declare the record object B_R as an overlay of the input bit-field. In the procedure version of To_Rec, we then simply copy the data from B_R to the output parameter R. In the function version of To_Rec, however, we need to declare a local record object R, which we return after the assignment.

In C, we can interpret the input pointer as an array of bytes, and copy the individual bytes. For example:

[C]

Listing 55: my_recs.h

```c
typedef struct {
    int v;
    char s[3];
} rec;

void to_r (void *bits, int len, rec *r);

void display_r (rec *r);
```

Listing 56: my_recs.c

```c
#include "my_recs.h"

#include <stdio.h>
#include <assert.h>

void to_r (void *bits, int len, rec *r)
{
    int i;
    char *c1 = (char *)bits;
    char *c2 = (char *)r;

    assert(len == sizeof(rec) * 8);

    for (i = 0; i < len / (sizeof(char) * 8); i++)
    {
        c2[i] = c1[i];
    }
}

void display_r (rec *r)
{
    printf("{%d, %c%c%c}", r->v, r->s[0], r->s[1], r->s[2]);
}
```

Listing 57: bitfield_serialization.c

```c
#include <stdio.h>
#include "my_recs.h"

int main(int argc, const char * argv[])
{
    rec r1 = {5, "abc"};
    rec r2 = {0, "zzz"};

    printf("r2 = ");
    display_r (&r2);
    printf("\n");

    to_r(&r1, sizeof(r1) * 8, &r2);

    printf("New bitstream received!\n");
    printf("r2 = ");
    display_r (&r2);
    printf("\n");

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Bitfield_Deserialization_C
MD5: 1c0fda773b0b681d0a4e9a57cf67d997
```

Runtime output

```
r2 = {0, zzz}
New bitstream received!
r2 = {5, abc}
```

Here, `to_r` casts both pointer parameters to pointers to **`char`** to get a byte-aligned pointer. Then, it simply copies the data byte-by-byte.

71.10.1 Overlays vs. Unchecked Conversions

Unchecked conversions are another way of converting between unrelated data types. This conversion is done by instantiating the generic `Unchecked_Conversions` function for the types you want to convert. Let's look at a simple example:

[Ada]

Listing 58: simple_unchecked_conversion.adb

```
with Ada.Text_IO;              use Ada.Text_IO;
with Ada.Unchecked_Conversion;

procedure Simple_Unchecked_Conversion is
   type State is (Off, State_1, State_2)
     with Size => Integer'Size;

   for State use (Off => 0, State_1 => 32, State_2 => 64);

   function As_Integer is new Ada.Unchecked_Conversion (Source => State,
                                                        Target => Integer);

   I : Integer;
begin
   I := As_Integer (State_2);
   Put_Line ("I = " & Integer'Image (I));
end Simple_Unchecked_Conversion;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Simple_Unchecked_Conversion
MD5: 1b6058ef1919879a7d2d86be41f3b269
```

Runtime output

```
I =  64
```

In this example, `As_Integer` is an instantiation of `Unchecked_Conversion` to convert between the `State` enumeration and the **`Integer`** type. Note that, in order to ensure safe conversion, we're declaring `State` to have the same size as the **`Integer`** type we want to convert to.

This is the corresponding implementation using overlays:

[Ada]

Listing 59: simple_overlay.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Simple_Overlay is
   type State is (Off, State_1, State_2)
     with Size => Integer'Size;

   for State use (Off => 0, State_1 => 32, State_2 => 64);

   S : State;
   I : Integer
     with Address => S'Address, Import, Volatile;
begin
   S := State_2;
   Put_Line ("I = " & Integer'Image (I));
end Simple_Overlay;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Simple_Overlay
MD5: 932135a47c36c406e70b22e075afeaf2
```

Runtime output

```
I =  64
```

Let's look at another example of converting between different numeric formats. In this case, we want to convert between a 16-bit fixed-point and a 16-bit integer data type. This is how we can do it using Unchecked_Conversion:

[Ada]

Listing 60: fixed_int_unchecked_conversion.adb

```
with Ada.Text_IO;              use Ada.Text_IO;
with Ada.Unchecked_Conversion;

procedure Fixed_Int_Unchecked_Conversion is
   Delta_16 : constant := 1.0 / 2.0 ** (16 - 1);
   Max_16   : constant := 2 ** 15;

   type Fixed_16 is delta Delta_16 range -1.0 .. 1.0 - Delta_16
     with Size => 16;
   type Int_16   is range -Max_16 .. Max_16 - 1
     with Size => 16;

   function As_Int_16 is new Ada.Unchecked_Conversion (Source => Fixed_16,
                                                       Target => Int_16);
   function As_Fixed_16 is new Ada.Unchecked_Conversion (Source => Int_16,
                                                         Target => Fixed_16);

   I : Int_16   := 0;
   F : Fixed_16 := 0.0;
begin
   F := Fixed_16'Last;
   I := As_Int_16 (F);

   Put_Line ("F = " & Fixed_16'Image (F));
   Put_Line ("I = " & Int_16'Image (I));
end Fixed_Int_Unchecked_Conversion;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Fixed_Int_Unchecked_Conversion
MD5: 53b59ca56a5c25408d8b6e5fcb06f37a
```

Runtime output

```
F =  0.99997
I =  32767
```

Here, we instantiate Unchecked_Conversion for the Int_16 and Fixed_16 types, and we call the instantiated functions explicitly. In this case, we call As_Int_16 to get the integer value corresponding to Fixed_16'Last.

This is how we can rewrite the implementation above using overlays:

[Ada]

Listing 61: fixed_int_overlay.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Fixed_Int_Overlay is
   Delta_16 : constant := 1.0 / 2.0 ** (16 - 1);
   Max_16   : constant := 2 ** 15;

   type Fixed_16 is delta Delta_16 range -1.0 .. 1.0 - Delta_16
     with Size => 16;
   type Int_16   is range -Max_16 .. Max_16 - 1
     with Size => 16;

   I : Int_16   := 0;
   F : Fixed_16
     with Address => I'Address, Import, Volatile;
begin
   F := Fixed_16'Last;

   Put_Line ("F = " & Fixed_16'Image (F));
   Put_Line ("I = " & Int_16'Image (I));
end Fixed_Int_Overlay;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Fixed_Int_Overlay
MD5: ee86e3d10266f8c8c96311595b6624ec
```

Runtime output

```
F =  0.99997
I =  32767
```

Here, the conversion to the integer value is implicit, so we don't need to call a conversion function.

Using Unchecked_Conversion has the advantage of making it clear that a conversion is happening, since the conversion is written explicitly in the code. With overlays, that conversion is automatic and therefore implicit. In that sense, using an unchecked conversion is a cleaner and safer approach. On the other hand, an unchecked conversion requires a copy, so it's less efficient than overlays, where no copy is performed — because one change in the source object is automatically reflected in the target object (and vice-versa). In the end, the choice between unchecked conversions and overlays depends on the level of performance that you want to achieve.

Also note that an unchecked conversion only has defined behavior when instantiated for constrained types. For example, we shouldn't use this kind of conversion:

```
Ada.Unchecked_Conversion (Source => String,
                          Target => Integer);
```

Although this compiles, the behavior will only be well-defined in those cases when `Source'Size = Target'Size`. Therefore, instead of using an unconstrained type for `Source`, we should use a subtype that matches this expectation:

```
subtype Integer_String is String (1 .. Integer'Size / Character'Size);

function As_Integer is new
  Ada.Unchecked_Conversion (Source => Integer_String,
                            Target => Integer);
```

Similarly, in order to rewrite the examples using bit-fields that we've seen in the previous section, we cannot simply instantiate `Unchecked_Conversion` with the `Target` indicating the *unconstrained* bit-field, such as:

```
Ada.Unchecked_Conversion (Source => Integer,
                          Target => Bit_Field);
```

Instead, we have to declare a subtype for the specific range we're interested in. This is how we can rewrite one of the previous examples:

[Ada]

Listing 62: simple_bitfield_conversion.adb

```
with Ada.Text_IO;              use Ada.Text_IO;
with Ada.Unchecked_Conversion;

procedure Simple_Bitfield_Conversion is
   type Bit_Field is array (Natural range <>) of Boolean with Pack;

   V : Integer := 4;

   --  Declaring subtype that takes the size of V into account.
   --
   subtype Integer_Bit_Field is Bit_Field (0 .. V'Size - 1);

   --  NOTE: we could also use the Integer type in the declaration:
   --
   --    subtype Integer_Bit_Field is Bit_Field (0 .. Integer'Size - 1);
   --

   --  Using the Integer_Bit_Field subtype as the target
   function As_Bit_Field is new
     Ada.Unchecked_Conversion (Source => Integer,
                               Target => Integer_Bit_Field);

   B : Integer_Bit_Field;
begin
   B := As_Bit_Field (V);

   Put_Line ("V = " & Integer'Image (V));
end Simple_Bitfield_Conversion;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Translation.Bitfield_Conversion
MD5: 46ead7e5f3da8f261770811d450453e7
```

Runtime output

```
V =  4
```

In this example, we first declare the subtype `Integer_Bit_Field` as a bit-field with a length that fits the `V` variable we want to convert to. Then, we can use that subtype in the instantiation of `Unchecked_Conversion`.

CHAPTER

SEVENTYTWO

HANDLING VARIABILITY AND RE-USABILITY

72.1 Understanding static and dynamic variability

It is common to see embedded software being used in a variety of configurations that require small changes to the code for each instance. For example, the same application may need to be portable between two different architectures (ARM and x86), or two different platforms with different set of devices available. Maybe the same application is used for two different generations of the product, so it needs to account for absence or presence of new features, or it's used for different projects which may select different components or configurations. All these cases, and many others, require variability in the software in order to ensure its reusability.

In C, variability is usually achieved through macros and function pointers, the former being tied to static variability (variability in different builds) the latter to dynamic variability (variability within the same build decided at run-time).

Ada offers many alternatives for both techniques, which aim at structuring possible variations of the software. When Ada isn't enough, the GNAT compilation system also provides a layer of capabilities, in particular selection of alternate bodies.

If you're familiar with object-oriented programming (OOP) — supported in languages such as C++ and Java —, you might also be interested in knowing that OOP is supported by Ada and can be used to implement variability. This should, however, be used with care, as OOP brings its own set of problems, such as loss of efficiency — dispatching calls can't be inlined and require one level of indirection — or loss of analyzability — the target of a dispatching call isn't known at run time. As a rule of thumb, OOP should be considered only for cases of dynamic variability, where several versions of the same object need to exist concurrently in the same application.

72.2 Handling variability & reusability statically

72.2.1 Genericity

One usage of C macros involves the creation of functions that works regardless of the type they're being called upon. For example, a swap macro may look like:

[C]

Listing 1: main.c

```
#include <stdio.h>
#include <stdlib.h>

#define SWAP(t, a, b) ({\
```

(continues on next page)

(continued from previous page)

```
                            t tmp = a; \
                            a = b; \
                            b = tmp; \
                        })

int main()
{
    int a = 10;
    int b = 42;

    printf("a = %d, b = %d\n", a, b);

    SWAP (int, a, b);

    printf("a = %d, b = %d\n", a, b);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Swap_C
MD5: 96d0e8ce9ae985e4de9ed64a0f0961f5
```

Runtime output

```
a = 10, b = 42
a = 42, b = 10
```

Ada offers a way to declare this kind of functions as a generic, that is, a function that is written after static arguments, such as a parameter:

[Ada]

Listing 2: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is

   generic
      type A_Type is private;
   procedure Swap (Left, Right : in out A_Type);

   procedure Swap (Left, Right : in out A_Type) is
      Temp : constant A_Type := Left;
   begin
      Left  := Right;
      Right := Temp;
   end Swap;

   procedure Swap_I is new Swap (Integer);

   A : Integer := 10;
   B : Integer := 42;

begin
   Put_Line ("A = "
             & Integer'Image (A)
             & ", B = "
             & Integer'Image (B));
```

(continues on next page)

(continued from previous page)

```
26
27    Swap_I (A, B);
28
29    Put_Line ("A = "
30              & Integer'Image (A)
31              & ", B = "
32              & Integer'Image (B));
33 end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Swap_Ada
MD5: 13f3527b4e3258ebd43be827ad0fcd14
```

Runtime output

```
A =  10, B =  42
A =  42, B =  10
```

There are a few key differences between the C and the Ada version here. In C, the macro can be used directly and essentially get expanded by the preprocessor without any kind of checks. In Ada, the generic will first be checked for internal consistency. It then needs to be explicitly instantiated for a concrete type. From there, it's exactly as if there was an actual version of this Swap function, which is going to be called as any other function. All rules for parameter modes and control will apply to this instance.

In many respects, an Ada generic is a way to provide a safe specification and implementation of such macros, through both the validation of the generic itself and its usage.

Subprograms aren't the only entities that can me made generic. As a matter of fact, it's much more common to render an entire package generic. In this case the instantiation creates a new version of all the entities present in the generic, including global variables. For example:

[Ada]

Listing 3: gen.ads

```
1 generic
2    type T is private;
3 package Gen is
4    type C is tagged record
5       V : T;
6    end record;
7
8    G : Integer;
9 end Gen;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Gen_Pkg_1
MD5: 721f9954561b7e0d2964ba0d226c748b
```

The above can be instantiated and used the following way:

Listing 4: main.adb

```
1 with Gen;
2
3 procedure Main is
4    package I1 is new Gen (Integer);
```

(continues on next page)

(continued from previous page)

```
   package I2 is new Gen (Integer);
   subtype Str10 is String (1 .. 10);
   package I3 is new Gen (Str10);
begin
   I1.G := 0;
   I2.G := 1;
   I3.G := 2;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Gen_Pkg_1
MD5: ab0e99dedf40fff1bced048a96a0fbb6
```

Here, `I1.G`, `I2.G` and `I3.G` are three distinct variables.

So far, we've only looked at generics with one kind of parameter: a so-called private type. There's actually much more that can be described in this section, such as variables, subprograms or package instantiations with certain properties. For example, the following provides a sort algorithm for any kind of structurally compatible array type:

[Ada]

Listing 5: sort.ads

```
generic
   type Component is private;
   type Index is (<>);
   with function "<" (Left, Right : Component) return Boolean;
   type Array_Type is array (Index range <>) of Component;
procedure Sort (A : in out Array_Type);
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Gen_Pkg_2
MD5: 5781f53f4fd4453ecc1313d05ab76f81
```

The declaration above states that we need a type (`Component`), a discrete type (`Index`), a comparison subprogram (`"<"`), and an array definition (`Array_Type`). Given these, it's possible to write an algorithm that can sort any `Array_Type`. Note the usage of the with reserved word in front of the function name: it exists to differentiate between the generic parameter and the beginning of the generic subprogram.

Here is a non-exhaustive overview of the kind of constraints that can be put on types:

```
type T is private; -- T is a constrained type, such as Integer
type T (<>) is private; -- T can be an unconstrained type e.g. String
type T is tagged private; -- T is a tagged type
type T is new T2 with private; -- T is an extension of T2
type T is (<>); -- T is a discrete type
type T is range <>; -- T is an integer type
type T is digits <>; -- T is a floating point type
type T is access T2; -- T is an access type to T2
```

For a more complete list please reference the Generic Formal Types in the *Appendix of the Introduction to Ada course* (page 269).

72.2.2 Simple derivation

Let's take a case where a codebase needs to handle small variations of a given device, or maybe different generations of a device, depending on the platform it's running on. In this example, we're assuming that each platform will lead to a different binary, so the code can statically resolve which set of services are available. However, we want an easy way to implement a new device based on a previous one, saying "this new device is the same as this previous device, with these new services and these changes in existing services".

We can implement such patterns using Ada's simple derivation — as opposed to tagged derivation, which is OOP-related and discussed in a later section.

Let's start from the following example:

[Ada]

Listing 6: drivers_1.ads

```ada
package Drivers_1 is

   type Device_1 is null record;
   procedure Startup (Device : Device_1);
   procedure Send (Device : Device_1; Data : Integer);
   procedure Send_Fast (Device : Device_1; Data : Integer);
   procedure Receive (Device : Device_1; Data : out Integer);

end Drivers_1;
```

Listing 7: drivers_1.adb

```ada
package body Drivers_1 is

   --  NOTE: unimplemented procedures: Startup, Send, Send_Fast
   --        mock-up implementation: Receive

   procedure Startup (Device : Device_1) is null;

   procedure Send (Device : Device_1; Data : Integer) is null;

   procedure Send_Fast (Device : Device_1; Data : Integer) is null;

   procedure Receive (Device : Device_1; Data : out Integer) is
   begin
      Data := 42;
   end Receive;

end Drivers_1;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Derived_Drivers
MD5: 4f9d7e29b64cda8664438a1d7eed9049
```

In the above example, `Device_1` is an empty record type. It may also have some fields if required, or be a different type such as a scalar. Then the four procedures `Startup`, `Send`, `Send_Fast` and `Receive` are primitives of this type. A primitive is essentially a subprogram that has a parameter or return type directly referencing this type and declared in the same scope. At this stage, there's nothing special with this type: we're using it as we would use any other type. For example:

[Ada]

Listing 8: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Drivers_1;   use Drivers_1;

procedure Main is
   D : Device_1;
   I : Integer;
begin
   Startup (D);
   Send_Fast (D, 999);
   Receive (D, I);
   Put_Line (Integer'Image (I));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Derived_Drivers
MD5: 1b28f2c8ca92498cbcda582f092b9912
```

Runtime output

```
 42
```

Let's now assume that we need to implement a new generation of device, `Device_2`. This new device works exactly like the first one, except for the startup code that has to be done differently. We can create a new type that operates exactly like the previous one, but modifies only the behavior of `Startup`:

[Ada]

Listing 9: drivers_2.ads

```
with Drivers_1; use Drivers_1;

package Drivers_2 is

   type Device_2 is new Device_1;

   overriding
   procedure Startup (Device : Device_2);

end Drivers_2;
```

Listing 10: drivers_2.adb

```
package body Drivers_2 is

   overriding
   procedure Startup (Device : Device_2) is null;

end Drivers_2;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Derived_Drivers
MD5: 276c9da0b7c9ad61d679531e16fdd9cb
```

Here, `Device_2` is derived from `Device_1`. It contains all the exact same properties and primitives, in particular, `Startup`, `Send`, `Send_Fast` and `Receive`. However, here, we decided to change the `Startup` function and to provide a different implementation. We over-

ride this function. The main subprogram doesn't change much, except for the fact that it now relies on a different type:

[Ada]

Listing 11: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Drivers_2;   use Drivers_2;

procedure Main is
   D : Device_2;
   I : Integer;
begin
   Startup (D);
   Send_Fast (D, 999);
   Receive (D, I);
   Put_Line (Integer'Image (I));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Derived_Drivers
MD5: 31e7105a99771ce6c1602af117e2e8a6
```

Runtime output

```
 42
```

We can continue with this approach and introduce a new generation of devices. This new device doesn't implement the Send_Fast service so we want to remove it from the list of available services. Furthermore, for the purpose of our example, let's assume that the hardware team went back to the Device_1 way of implementing Startup. We can write this new device the following way:

[Ada]

Listing 12: drivers_3.ads

```
with Drivers_1; use Drivers_1;

package Drivers_3 is

   type Device_3 is new Device_1;

   overriding
   procedure Startup (Device : Device_3);

   procedure Send_Fast (Device : Device_3; Data : Integer)
   is abstract;

end Drivers_3;
```

Listing 13: drivers_3.adb

```
package body Drivers_3 is

   overriding
   procedure Startup (Device : Device_3) is null;

end Drivers_3;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Derived_Drivers
MD5: 779579532c81b672d8a641c0b8594ed5
```

The `is abstract` definition makes illegal any call to a function, so calls to Send_Fast on Device_3 will be flagged as being illegal. To then implement Startup of Device_3 as being the same as the Startup of Device_1, we can convert the type in the implementation:

[Ada]

Listing 14: drivers_3.adb

```
package body Drivers_3 is

   overriding
   procedure Startup (Device : Device_3) is
   begin
      Drivers_1.Startup (Device_1 (Device));
   end Startup;

end Drivers_3;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Derived_Drivers
MD5: 5db9596c276a7a4521914f4108f61d28
```

Our Main now looks like:

[Ada]

Listing 15: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Drivers_3;   use Drivers_3;

procedure Main is
   D : Device_3;
   I : Integer;
begin
   Startup (D);
   Send_Fast (D, 999);
   Receive (D, I);
   Put_Line (Integer'Image (I));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Derived_Drivers
MD5: 8b6af16d21c2f8a1f0e4866e6ddffd1f
```

Build output

```
main.adb:9:04: error: cannot call abstract operation "Send_Fast" declared at␣
 ↪drivers_3.ads:10
gprbuild: *** compilation phase failed
```

Here, the call to Send_Fast will get flagged by the compiler.

Note that the fact that the code of Main has to be changed for every implementation isn't necessarily satisfactory. We may want to go one step further, and isolate the selection of the device kind to be used for the whole application in one unique file. One way to do this is to use the same name for all types, and use a renaming to select which package to use. Here's a simplified example to illustrate that:

[Ada]

Listing 16: drivers_1.ads

```
package Drivers_1 is

   type Transceiver is null record;
   procedure Send (Device : Transceiver; Data : Integer);
   procedure Receive (Device : Transceiver; Data : out Integer);

end Drivers_1;
```

Listing 17: drivers_1.adb

```
package body Drivers_1 is

   procedure Send (Device : Transceiver; Data : Integer) is null;

   procedure Receive (Device : Transceiver; Data : out Integer) is
      pragma Unreferenced (Device);
   begin
      Data := 42;
   end Receive;

end Drivers_1;
```

Listing 18: drivers_2.ads

```
with Drivers_1;

package Drivers_2 is

   type Transceiver is new Drivers_1.Transceiver;
   procedure Send (Device : Transceiver; Data : Integer);
   procedure Receive (Device : Transceiver; Data : out Integer);

end Drivers_2;
```

Listing 19: drivers_2.adb

```
package body Drivers_2 is

   procedure Send (Device : Transceiver; Data : Integer) is null;

   procedure Receive (Device : Transceiver; Data : out Integer) is
      pragma Unreferenced (Device);
   begin
      Data := 42;
   end Receive;

end Drivers_2;
```

Listing 20: drivers.ads

```
with Drivers_1;

package Drivers renames Drivers_1;
```

Listing 21: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Drivers;     use Drivers;

procedure Main is
   D : Transceiver;
   I : Integer;
begin
   Send (D, 999);
   Receive (D, I);
   Put_Line (Integer'Image (I));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Derived_Drivers
MD5: e92590e4b91fef33f4fec23362a52873
```

Runtime output

```
 42
```

In the above example, the whole code can rely on `drivers.ads`, instead of relying on the specific driver. Here, `Drivers` is another name for `Driver_1`. In order to switch to `Driver_2`, the project only has to replace that one `drivers.ads` file.

In the following section, we'll go one step further and demonstrate that this selection can be done through a configuration switch selected at build time instead of a manual code modification.

72.2.3 Configuration pragma files

Configuration pragmas are a set of pragmas that modify the compilation of source-code files. You may use them to either relax or strengthen requirements. For example:

```
pragma Suppress (Overflow_Check);
```

In this example, we're suppressing the overflow check, thereby relaxing a requirement. Normally, the following program would raise a constraint error due to a failed overflow check:

[Ada]

Listing 22: p.ads

```
package P is
   function Add_Max (A : Integer) return Integer;
end P;
```

Listing 23: p.adb

```
package body P is
   function Add_Max (A : Integer) return Integer is
   begin
      return A + Integer'Last;
   end Add_Max;
end P;
```

Listing 24: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with P;           use P;

procedure Main is
   I : Integer := Integer'Last;
begin
   I := Add_Max (I);
   Put_Line ("I = " & Integer'Image (I));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Constraint_Error_Detection
MD5: d6960fe8ae2af1d66b617bb92d3d47b6
```

Runtime output

```

raised CONSTRAINT_ERROR : p.adb:4 overflow check failed
```

When suppressing the overflow check, however, the program doesn't raise an exception, and the value that Add_Max returns is -2, which is a wraparound of the sum of the maximum integer values (`Integer'Last + Integer'Last`).

We could also strengthen requirements, as in this example:

```
pragma Restrictions (No_Floating_Point);
```

Here, the restriction forbids the use of floating-point types and objects. The following program would violate this restriction, so the compiler isn't able to compile the program when the restriction is used:

```
procedure Main is
   F : Float := 0.0;
   --  Declaration is not possible with No_Floating_Point restriction.
begin
   null;
end Main;
```

Restrictions are especially useful for high-integrity applications. In fact, the Ada Reference Manual has a separate section for them[336].

When creating a project, it is practical to list all configuration pragmas in a separate file. This is called a configuration pragma file, and it usually has an *.adc* file extension. If you use **GPRbuild** for building Ada applications, you can specify the configuration pragma file in the corresponding project file. For example, here we indicate that `gnat.adc` is the configuration pragma file for our project:

```
project Default is

   for Source_Dirs use ("src");
   for Object_Dir use "obj";
   for Main use ("main.adb");

   package Compiler is
      for Local_Configuration_Pragmas use "gnat.adc";
   end Compiler;
```

(continues on next page)

[336] http://www.ada-auth.org/standards/12rm/html/RM-H-4.html

(continued from previous page)

```
end Default;
```

72.2.4 Configuration packages

In C, preprocessing flags are used to create blocks of code that are only compiled under certain circumstances. For example, we could have a block that is only used for debugging:

[C]

Listing 25: main.c

```c
#include <stdio.h>
#include <stdlib.h>

int func(int x)
{
    return x % 4;
}

int main()
{
    int a, b;

    a = 10;
    b = func(a);

#ifdef DEBUG
    printf("func(%d) => %d\n", a, b);
#endif

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Debug_Code_C
MD5: 4daa8123f7112e7487ab54f16f80d34b
```

Here, the block indicated by the DEBUG flag is only included in the build if we define this preprocessing flag, which is what we expect for a debug version of the build. In the release version, however, we want to keep debug information out of the build, so we don't use this flag during the build process.

Ada doesn't define a preprocessor as part of the language. Some Ada toolchains — like the GNAT toolchain — do have a preprocessor that could create code similar to the one we've just seen. When programming in Ada, however, the recommendation is to use configuration packages to select code blocks that are meant to be included in the application.

When using a configuration package, the example above can be written as:

[Ada]

Listing 26: config.ads

```ada
package Config is

   Debug : constant Boolean := False;

end Config;
```

Listing 27: func.ads

```
function Func (X : Integer) return Integer;
```

Listing 28: func.adb

```
function Func (X : Integer) return Integer is
begin
    return X mod 4;
end Func;
```

Listing 29: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Config;
with Func;

procedure Main is
   A, B : Integer;
begin
   A := 10;
   B := Func (A);

   if Config.Debug then
      Put_Line ("Func(" & Integer'Image (A) & ") => "
                & Integer'Image (B));
   end if;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Debug_Code_Ada
MD5: b643b683098fa7ad5568a69c9f2c000f
```

In this example, `Config` is a configuration package. The version of `Config` we're seeing here is the release version. The debug version of the `Config` package looks like this:

```
package Config is

   Debug : constant Boolean := True;

end Config;
```

The compiler makes sure to remove dead code. In the case of the release version, since `Config.Debug` is constant and set to **`False`**, the compiler is smart enough to remove the call to `Put_Line` from the build.

As you can see, both versions of `Config` are very similar to each other. The general idea is to create packages that declare the same constants, but using different values.

In C, we differentiate between the debug and release versions by selecting the appropriate preprocessing flags, but in Ada, we select the appropriate configuration package during the build process. Since the file name is usually the same (`config.ads` for the example above), we may want to store them in distinct directories. For the example above, we could have:

- `src/debug/config.ads` for the debug version, and
- `src/release/config.ads` for the release version.

Then, we simply select the appropriate configuration package for each version of the build by indicating the correct path to it. When using **`GPRbuild`**, we can select the appropriate

directory where the `config.ads` file is located. We can use scenario variables in our project, which allow for creating different versions of a build. For example:

```
project Default is

   type Mode_Type is ("debug", "release");

   Mode : Mode_Type := external ("mode", "debug");

   for Source_Dirs use ("src", "src/" & Mode);
   for Object_Dir use "obj";
   for Main use ("main.adb");

end Default;
```

In this example, we're defining a scenario type called `Mode_Type`. Then, we're declaring the scenario variable `Mode` and using it in the `Source_Dirs` declaration to complete the path to the subdirectory containing the `config.ads` file. The expression `"src/" & Mode` concatenates the user-specified mode to select the appropriate subdirectory.

We can then set the mode on the command-line. For example:

```
gprbuild -P default.gpr -Xmode=release
```

In addition to selecting code blocks for the build, we could also specify values that depend on the target build. For our example above, we may want to create two versions of the application, each one having a different version of a `MOD_VALUE` that is used in the implementation of `func()`. In C, we can achieve this by using preprocessing flags and defining the corresponding version in `APP_VERSION`. Then, depending on the value of `APP_VERSION`, we define the corresponding value of `MOD_VALUE`.

[C]

Listing 30: defs.h

```
#ifndef APP_VERSION
#define APP_VERSION     1
#endif

#if APP_VERSION == 1
#define MOD_VALUE       4
#endif

#if APP_VERSION == 2
#define MOD_VALUE       5
#endif
```

Listing 31: main.c

```
#include <stdio.h>
#include <stdlib.h>

#include "defs.h"

int func(int x)
{
    return x % MOD_VALUE;
}

int main()
{
    int a, b;
```

(continues on next page)

(continued from previous page)

```
14
15      a = 10;
16      b = func(a);
17
18      return 0;
19  }
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.App_Version_C
MD5: 9f204dcc65b70618324c48be0dbdffbe
```

If not defined outside, the code above will compile version #1 of the application. We can change this by specifying a value for APP_VERSION during the build (e.g. as a Makefile switch).

For the Ada version of this code, we can create two configuration packages for each version of the application. For example:

[Ada]

Listing 32: app_defs.ads

```
1  --  ./src/app_1/app_defs.ads
2
3  package App_Defs is
4
5     Mod_Value : constant Integer := 4;
6
7  end App_Defs;
```

Listing 33: func.ads

```
1  function Func (X : Integer) return Integer;
```

Listing 34: func.adb

```
1  with App_Defs;
2
3  function Func (X : Integer) return Integer is
4  begin
5      return X mod App_Defs.Mod_Value;
6  end Func;
```

Listing 35: main.adb

```
1  with Func;
2
3  procedure Main is
4     A, B : Integer;
5  begin
6     A := 10;
7     B := Func (A);
8  end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.App_Version_Ada
MD5: 7c8e4280e74c04ab51073b25e8f53995
```

The code above shows the version #1 of the configuration package. The corresponding

implementation for version #2 looks like this:

```
--  ./src/app_2/app_defs.ads

package App_Defs is

   Mod_Value : constant Integer := 5;

end App_Defs;
```

Again, we just need to select the appropriate configuration package for each version of the build, which we can easily do when using **GPRbuild**.

72.3 Handling variability & reusability dynamically

72.3.1 Records with discriminants

In basic terms, records with discriminants are records that include "parameters" in their type definitions. This allows for adding more flexibility to the type definition. In the section about *pointers* (page 1483), we've seen this example:

[Ada]

Listing 36: main.adb

```
1  procedure Main is
2     type Arr is array (Integer range <>) of Integer;
3
4     type S (Last : Positive) is record
5        A : Arr (0 .. Last);
6     end record;
7
8     V : S (9);
9  begin
10    null;
11 end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Rec_Disc_Ada
MD5: 02fa8fa7832a262b99aee139a1b5b7a6
```

Build output

```
main.adb:8:04: warning: variable "V" is never read and never assigned [-gnatwv]
```

Here, `Last` is the discriminant for type S. When declaring the variable V as S (9), we specify the actual index of the last position of the array component A by setting the `Last` discriminant to 9.

We can create an equivalent implementation in C by declaring a **struct** with a pointer to an array:

[C]

Listing 37: main.c

```
1  #include <stdio.h>
2  #include <stdlib.h>
```

(continues on next page)

(continued from previous page)

```

typedef struct {
    int       * a;
    const int   last;
} S;

S init_s (int last)
{
    S v = { malloc (sizeof(int) * last + 1), last };
    return v;
}

int main(int argc, const char * argv[])
{
    S v = init_s (9);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Rec_Disc_C
MD5: 8f8b53c38c2ef8c1624208a2d8fd13ef
```

Here, we need to explicitly allocate the a array of the S struct via a call to `malloc()`, which allocates memory space on the heap. In the Ada version, in contrast, the array (`V.A`) is allocated on the stack and we don't need to explicitly allocate it.

Note that the information that we provide as the discriminant to the record type (in the Ada code) is constant, so we cannot assign a value to it. For example, we cannot write:

[Ada]

```
V.Last := 10;       --  COMPILATION ERROR!
```

In the C version, we declare the `last` field constant to get the same behavior.

[C]

```
v.last = 10;        //  COMPILATION ERROR!
```

Note that the information provided as discriminants is visible. In the example above, we could display `Last` by writing:

[Ada]

```
Put_Line ("Last : " & Integer'Image (V.Last));
```

Also note that, even if a type is private, we can still access the information of the discriminants if they are visible in the *public* part of the type declaration. Let's rewrite the example above:

[Ada]

Listing 38: array_definition.ads

```
package Array_Definition is
   type Arr is array (Integer range <>) of Integer;

   type S (Last : Integer) is private;

private
```

(continues on next page)

(continued from previous page)

```
   type S (Last : Integer) is record
      A : Arr (0 .. Last);
   end record;

end Array_Definition;
```

Listing 39: main.adb

```
with Ada.Text_IO;       use Ada.Text_IO;
with Array_Definition; use Array_Definition;

procedure Main is
   V : S (9);
begin
   Put_Line ("Last : " & Integer'Image (V.Last));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Rec_Disc_Ada_Private
MD5: fa0158c3c61dd9ec7e4000416672f9e9
```

Build output

```
main.adb:5:04: warning: variable "V" is read but never assigned [-gnatwv]
```

Runtime output

```
Last :  9
```

Even though the S type is now private, we can still display `Last` because this discriminant is visible in the *non-private* part of package `Array_Definition`.

72.3.2 Variant records

In simple terms, a variant record is a record with discriminants that allows for changing its structure. Basically, it's a record containing a **`case`**. This is the general structure:

[Ada]

```
type Var_Rec (V : F) is record

   case V is
     when Opt_1 => F1 : Type_1;
     when Opt_2 => F2 : Type_2;
   end case;

end record;
```

Let's look at this example:

[Ada]

Listing 40: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is

```

(continues on next page)

(continued from previous page)

```
   type Float_Int (Use_Float : Boolean) is record
      case Use_Float is
        when True  => F : Float;
        when False => I : Integer;
      end case;
   end record;

   procedure Display (V : Float_Int) is
   begin
      if V.Use_Float then
         Put_Line ("Float value:   " & Float'Image (V.F));
      else
         Put_Line ("Integer value: " & Integer'Image (V.I));
      end if;
   end Display;

   F : constant Float_Int := (Use_Float => True,  F => 10.0);
   I : constant Float_Int := (Use_Float => False, I => 9);

begin
   Display (F);
   Display (I);
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Var_Rec_Ada
MD5: 72dd64c22d65fc527af0c3de73ff7966
```

Runtime output

```
Float value:    1.00000E+01
Integer value:  9
```

Here, we declare F containing a floating-point value, and I containing an integer value. In the Display procedure, we present the correct information to the user according to the Use_Float discriminant of the Float_Int type.

We can implement this example in C by using unions:

[C]

Listing 41: main.c

```
#include <stdio.h>
#include <stdlib.h>

typedef struct {
    int use_float;
    union {
        float f;
        int   i;
    };
} float_int;

float_int init_float (float f)
{
    float_int v;

    v.use_float = 1;
    v.f         = f;
    return v;
```

(continues on next page)

(continued from previous page)

```
}

float_int init_int (int i)
{
    float_int v;

    v.use_float = 0;
    v.i         = i;
    return v;
}

void display (float_int v)
{
    if (v.use_float) {
        printf("Float value   : %f\n", v.f);
    }
    else {
        printf("Integer value : %d\n", v.i);
    }
}

int main(int argc, const char * argv[])
{
    float_int f = init_float (10.0);
    float_int i = init_int (9);

    display (f);
    display (i);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Var_Rec_C
MD5: ac0ad1e6ff7f2154e9dbb6838999a62e
```

Runtime output

```
Float value   : 10.000000
Integer value : 9
```

Similar to the Ada code, we declare `f` containing a floating-point value, and `i` containing an integer value. One difference is that we use the `init_float()` and `init_int()` functions to initialize the `float_int` struct. These functions initialize the correct field of the union and set the `use_float` field accordingly.

Variant records and unions

There is, however, a difference in accessibility between variant records in Ada and unions in C. In C, we're allowed to access any field of the union regardless of the initialization:

[C]

```
float_int v = init_float (10.0);

printf("Integer value : %d\n", v.i);
```

This feature is useful to create overlays. In this specific example, however, the information displayed to the user doesn't make sense, since the union was initialized with a floating-

point value (`v.f`) and, by accessing the integer field (`v.i`), we're displaying it as if it was an integer value.

In Ada, accessing the wrong component would raise an exception at run-time ("discriminant check failed"), since the component is checked before being accessed:

[Ada]

```
   V : constant Float_Int := (Use_Float => True,  F => 10.0);
begin
   Put_Line ("Integer value: " & Integer'Image (V.I));
   --                                          ^ Constraint_Error is raised!
```

Using this method prevents wrong information being used in other parts of the program.

To get the same behavior in Ada as we do in C, we need to explicitly use the `Unchecked_Union` aspect in the type declaration. This is the modified example:

[Ada]

Listing 42: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is

   type Float_Int_Union (Use_Float : Boolean) is record
      case Use_Float is
        when True  => F : Float;
        when False => I : Integer;
      end case;
   end record
     with Unchecked_Union;

   V : constant Float_Int_Union := (Use_Float => True,  F => 10.0);

begin
   Put_Line ("Integer value: " & Integer'Image (V.I));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Unchecked_Union_Ada
MD5: f6c5eacbd96c23531d02bb47a9668ac5
```

Runtime output

```
Integer value:  1092616192
```

Now, we can display the integer component (`V.I`) even though we initialized the floating-point component (`V.F`). As expected, the information displayed by the test application in this case doesn't make sense.

Note that, when using the `Unchecked_Union` aspect in the declaration of a variant record, the reference discriminant is not available anymore, since it isn't stored as part of the record. Therefore, we cannot access the `Use_Float` discriminant as in the following code:

[Ada]

```
   V : constant Float_Int_Union := (Use_Float => True,  F => 10.0);
begin
   if V.Use_Float then       --  COMPILATION ERROR!
      --  Do something...
   end if;
```

Unchecked unions are particularly useful in Ada when creating bindings for C code.

Optional components

We can also use variant records to specify optional components of a record. For example:

[Ada]

Listing 43: main.adb

```ada
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   type Arr is array (Integer range <>) of Integer;

   type Extra_Info is (No, Yes);

   type S_Var (Last : Integer; Has_Extra_Info : Extra_Info) is record
      A : Arr (0 .. Last);

      case Has_Extra_Info is
        when No   => null;
        when Yes  => B : Arr (0 .. Last);
      end case;
   end record;

   V1 : S_Var (Last => 9, Has_Extra_Info => Yes);
   V2 : S_Var (Last => 9, Has_Extra_Info => No);
begin
   Put_Line ("Size of V1 is: " & Integer'Image (V1'Size));
   Put_Line ("Size of V2 is: " & Integer'Image (V2'Size));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Var_Rec_Null_Ada
MD5: 548235fa8458302ba025c8fa49e61777
```

Build output

```
main.adb:17:04: warning: variable "V1" is read but never assigned [-gnatwv]
main.adb:18:04: warning: variable "V2" is read but never assigned [-gnatwv]
```

Runtime output

```
Size of V1 is:  704
Size of V2 is:  384
```

Here, in the declaration of `S_Var`, we don't have any component in case `Has_Extra_Info` is false. The component is simply set to **`null`** in this case.

When running the example above, we see that the size of V1 is greater than the size of V2 due to the extra B component — which is only included when `Has_Extra_Info` is true.

Optional output information

We can use optional components to prevent subprograms from generating invalid information that could be misused by the caller. Consider the following example:

[C]

Listing 44: main.c

```c
#include <stdio.h>
#include <stdlib.h>

float calculate (float  f1,
                 float  f2,
                 int   *success)
{
    if (f1 < f2) {
        *success = 1;
        return f2 - f1;
    }
    else {
        *success = 0;
        return 0.0;
    }
}

void display (float v,
              int   success)
{
    if (success) {
        printf("Value = %f\n", v);
    }
    else {
        printf("Calculation error!\n");
    }
}

int main(int argc, const char * argv[])
{
    float f;
    int success;

    f = calculate (1.0, 0.5, &success);
    display (f, success);

    f = calculate (0.5, 1.0, &success);
    display (f, success);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Non_Opt_C
MD5: 56f8a72782c4a54d8a6026aa39ce421a
```

Runtime output

```
Calculation error!
Value = 0.500000
```

In this code, we're using the output parameter `success` of the `calculate()` function to indicate whether the calculation was successful or not. This approach has a major problem:

there's no way to prevent that the invalid value returned by `calculate()` in case of an error is misused in another computation. For example:

[C]

```c
int main(int argc, const char * argv[])
{
    float f;
    int success;

    f = calculate (1.0, 0.5, &success);

    f = f * 0.25;   // Using f in another computation even though
                    // calculate() returned a dummy value due to error!
                    // We should have evaluated "success", but we didn't.

    return 0;
}
```

We cannot prevent access to the returned value or, at least, force the caller to evaluate `success` before using the returned value.

This is the corresponding code in Ada:

[Ada]

Listing 45: main.adb

```ada
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is

   function Calculate (F1, F2  : Float;
                       Success : out Boolean) return Float is
   begin
      if F1 < F2 then
         Success := True;
         return F2 - F1;
      else
        Success := False;
        return 0.0;
      end if;
   end Calculate;

   procedure Display (V : Float; Success : Boolean) is
   begin
      if Success then
         Put_Line ("Value = " & Float'Image (V));
      else
         Put_Line ("Calculation error!");
      end if;
   end Display;

   F       : Float;
   Success : Boolean;
begin
   F := Calculate (1.0, 0.5, Success);
   Display (F, Success);

   F := Calculate (0.5, 1.0, Success);
   Display (F, Success);
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Non_Opt_Ada
MD5: bb27fd31660ad604487f908934a3d3cb
```

Runtime output

```
Calculation error!
Value =  5.00000E-01
```

The Ada code above suffers from the same drawbacks as the C code. Again, there's no way to prevent misuse of the invalid value returned by `Calculate` in case of errors.

However, in Ada, we can use variant records to make the component unavailable and therefore prevent misuse of this information. Let's rewrite the original example and *wrap* the returned value in a variant record:

[Ada]

Listing 46: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is

   type Opt_Float (Success : Boolean) is record
      case Success is
        when False => null;
        when True  => F : Float;
      end case;
   end record;

   function Calculate (F1, F2 : Float) return Opt_Float is
   begin
      if F1 < F2 then
         return (Success => True, F => F2 - F1);
      else
         return (Success => False);
      end if;
   end Calculate;

   procedure Display (V : Opt_Float) is
   begin
      if V.Success then
         Put_Line ("Value = " & Float'Image (V.F));
      else
         Put_Line ("Calculation error!");
      end if;
   end Display;

begin
   Display (Calculate (1.0, 0.5));
   Display (Calculate (0.5, 1.0));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Opt_Ada
MD5: 8b70cd16d5ff13611567fa71059d6891
```

Runtime output

```
Calculation error!
Value =  5.00000E-01
```

In this example, we can determine whether the calculation was successful or not by evaluating the `Success` component of the `Opt_Float`. If the calculation wasn't successful, we won't be able to access the F component of the `Opt_Float`. As mentioned before, trying to access the component in this case would raise an exception. Therefore, in case of errors, we can ensure that no information is misused after the call to `Calculate`.

72.3.3 Object orientation

In the *previous section* (page 1522), we've seen that we can add variability to records by using discriminants. Another approach is to use *tagged* records, which are the base for object-oriented programming in Ada.

Type extension

A tagged record type is declared by adding the **`tagged`** keyword. For example:

[Ada]

Listing 47: main.adb

```
procedure Main is

   type Rec is record
      V : Integer;
   end record;

   type Tagged_Rec is tagged record
      V : Integer;
   end record;

   R1 : Rec;
   R2 : Tagged_Rec;

   pragma Unreferenced (R1, R2);
begin
   R1 := (V => 0);
   R2 := (V => 0);
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Tagged_Type_Decl
MD5: 53810d3bb5aa7e7b1483270d974eb025
```

In this simple example, there isn't much difference between the Rec and Tagged_Rec type. However, tagged types can be derived and extended. For example:

[Ada]

Listing 48: main.adb

```
procedure Main is

   type Rec is record
      V : Integer;
   end record;

   --  We cannot declare this:
   --
```

(continues on next page)

(continued from previous page)

```
   --  type Ext_Rec is new Rec with record
   --     V : Integer;
   --  end record;

   type Tagged_Rec is tagged record
      V : Integer;
   end record;

   --  But we can declare this:
   --
   type Ext_Tagged_Rec is new Tagged_Rec with record
      V2 : Integer;
   end record;

   R1 : Rec;
   R2 : Tagged_Rec;
   R3 : Ext_Tagged_Rec;

   pragma Unreferenced (R1, R2, R3);
begin
   R1 := (V => 0);
   R2 := (V => 0);
   R3 := (V => 0, V2 => 0);
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Tagged_Type_Extension_Decl
MD5: 707a3e6b220357f50f6792190b000c91
```

As indicated in the example, a type derived from an untagged type cannot have an extension. The compiler indicates this error if you uncomment the declaration of the Ext_Rec type above. In contrast, we can extend a tagged type, as we did in the declaration of Ext_Tagged_Rec. In this case, Ext_Tagged_Rec has all the components of the Tagged_Rec type (V, in this case) plus the additional components from its own type declaration (V2, in this case).

Overriding subprograms

Previously, we've seen that subprograms can be overriden. For example, if we had implemented a Reset and a Display procedure for the Rec type that we declared above, these procedures would be available for an Ext_Rec type derived from Rec. Also, we could override these procedures for the Ext_Rec type. In Ada, we don't need object-oriented programming features to do that: simple (untagged) records can be used to derive types, inherit operations and override them. However, in applications where the actual subprogram to be called is determined dynamically at run-time, we need dispatching calls. In this case, we must use tagged types to implement this.

Comparing untagged and tagged types

Let's discuss the similarities and differences between untagged and tagged types based on this example:

[Ada]

Listing 49: p.ads

```
package P is

   type Rec is record
      V : Integer;
   end record;

   procedure Display (R : Rec);
   procedure Reset (R : out Rec);

   type New_Rec is new Rec;

   overriding procedure Display (R : New_Rec);
   not overriding procedure New_Op (R : in out New_Rec);

   type Tagged_Rec is tagged record
      V : Integer;
   end record;

   procedure Display (R : Tagged_Rec);
   procedure Reset (R : out Tagged_Rec);

   type Ext_Tagged_Rec is new Tagged_Rec with record
      V2 : Integer;
   end record;

   overriding procedure Display (R : Ext_Tagged_Rec);
   overriding procedure Reset (R : out Ext_Tagged_Rec);
   not overriding procedure New_Op (R : in out Ext_Tagged_Rec);

end P;
```

Listing 50: p.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body P is

   procedure Display (R : Rec) is
   begin
      Put_Line ("TYPE: REC");
      Put_Line ("Rec.V = " & Integer'Image (R.V));
      New_Line;
   end Display;

   procedure Reset (R : out Rec) is
   begin
      R.V := 0;
   end Reset;

   procedure Display (R : New_Rec) is
   begin
      Put_Line ("TYPE: NEW_REC");
      Put_Line ("New_Rec.V = " & Integer'Image (R.V));
```

(continues on next page)

(continued from previous page)

```
      New_Line;
   end Display;

   procedure New_Op (R : in out New_Rec) is
   begin
      R.V := R.V + 1;
   end New_Op;

   procedure Display (R : Tagged_Rec) is
   begin
      --  Using External_Tag attribute to retrieve the tag as a string
      Put_Line ("TYPE: " & Tagged_Rec'External_Tag);
      Put_Line ("Tagged_Rec.V = " & Integer'Image (R.V));
      New_Line;
   end Display;

   procedure Reset (R : out Tagged_Rec) is
   begin
      R.V := 0;
   end Reset;

   procedure Display (R : Ext_Tagged_Rec) is
   begin
      --  Using External_Tag attribute to retrieve the tag as a string
      Put_Line ("TYPE: " & Ext_Tagged_Rec'External_Tag);
      Put_Line ("Ext_Tagged_Rec.V  = " & Integer'Image (R.V));
      Put_Line ("Ext_Tagged_Rec.V2 = " & Integer'Image (R.V2));
      New_Line;
   end Display;

   procedure Reset (R : out Ext_Tagged_Rec) is
   begin
      Tagged_Rec (R).Reset;
      R.V2 := 0;
   end Reset;

   procedure New_Op (R : in out Ext_Tagged_Rec) is
   begin
      R.V := R.V + 1;
   end New_Op;

end P;
```

Listing 51: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with P;           use P;

procedure Main is
   X_Rec              : Rec;
   X_New_Rec          : New_Rec;

   X_Tagged_Rec       : aliased Tagged_Rec;
   X_Ext_Tagged_Rec   : aliased Ext_Tagged_Rec;

   X_Tagged_Rec_Array : constant array (1 .. 2) of access Tagged_Rec'Class
                         := (X_Tagged_Rec'Access, X_Ext_Tagged_Rec'Access);
begin
   --
   --  Reset all objects
   --
```

(continues on next page)

(continued from previous page)

```
   Reset (X_Rec);
   Reset (X_New_Rec);
   X_Tagged_Rec.Reset;    --  we could write "Reset (X_Tagged_Rec)" as well
   X_Ext_Tagged_Rec.Reset;

   --
   --  Use new operations when available
   --
   New_Op (X_New_Rec);
   X_Ext_Tagged_Rec.New_Op;

   --
   --  Display all objects
   --
   Display (X_Rec);
   Display (X_New_Rec);
   X_Tagged_Rec.Display;  --  we could write "Display (X_Tagged_Rec)" as well
   X_Ext_Tagged_Rec.Display;

   --
   --  Resetting and display objects of Tagged_Rec'Class
   --
   Put_Line ("Operations on Tagged_Rec'Class");
   Put_Line ("------------------------------");
   for E of X_Tagged_Rec_Array loop
      E.Reset;
      E.Display;
   end loop;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Tagged_Type_Extension_Decl

```

Runtime output

```
TYPE: REC
Rec.V =  0

TYPE: NEW_REC
New_Rec.V =  1

TYPE: P.TAGGED_REC
Tagged_Rec.V =  0

TYPE: P.EXT_TAGGED_REC
Ext_Tagged_Rec.V  =  1
Ext_Tagged_Rec.V2 =  0

Operations on Tagged_Rec'Class
------------------------------
TYPE: P.TAGGED_REC
Tagged_Rec.V =  0

TYPE: P.EXT_TAGGED_REC
Ext_Tagged_Rec.V  =  0
Ext_Tagged_Rec.V2 =  0
```

These are the similarities between untagged and tagged types:

- We can derive types and inherit operations in both cases.
  - Both `X_New_Rec` and `X_Ext_Tagged_Rec` inherit the `Display` and `Reset` procedures from their respective ancestors.
- We can override operations in both cases.
- We can implement new operations in both cases.
  - Both `X_New_Rec` and `X_Ext_Tagged_Rec` implement a procedure called `New_Op`, which is not available for their respective ancestors.

Now, let's look at the differences between untagged and tagged types:

- We can dispatch calls for a given type class.
  - This is what we do when we iterate over objects of the `Tagged_Rec` class — in the loop over `X_Tagged_Rec_Array` at the last part of the `Main` procedure.
- We can use the dot notation.
  - We can write both `E.Reset` or `Reset (E)` forms: they're equivalent.

Dispatching calls

Let's look more closely at the dispatching calls implemented above. First, we declare the `X_Tagged_Rec_Array` array and initialize it with the access to objects of both parent and derived tagged types:

[Ada]

```
X_Tagged_Rec       : aliased Tagged_Rec;
X_Ext_Tagged_Rec   : aliased Ext_Tagged_Rec;

X_Tagged_Rec_Array : constant array (1 .. 2) of access Tagged_Rec'Class
                       := (X_Tagged_Rec'Access, X_Ext_Tagged_Rec'Access);
```

Here, we use the **`aliased`** keyword to be able to get access to the objects (via the `'Access` attribute).

Then, we loop over this array and call the `Reset` and `Display` procedures:

[Ada]

```
for E of X_Tagged_Rec_Array loop
   E.Reset;
   E.Display;
end loop;
```

Since we're using dispatching calls, the actual procedure that is selected depends on the type of the object. For the first element (`X_Tagged_Rec_Array (1)`), this is `Tagged_Rec`, while for the second element (`X_Tagged_Rec_Array (2)`), this is `Ext_Tagged_Rec`.

Dispatching calls are only possible for a type class — for example, the `Tagged_Rec'Class`. When the type of an object is known at compile time, the calls won't dispatch at runtime. For example, the call to the `Reset` procedure of the `X_Ext_Tagged_Rec` object (`X_Ext_Tagged_Rec.Reset`) will always take the overriden `Reset` procedure of the `Ext_Tagged_Rec` type. Similarly, if we perform a view conversion by writing `Tagged_Rec (A_Ext_Tagged_Rec).Display`, we're instructing the compiler to interpret `A_Ext_Tagged_Rec` as an object of type `Tagged_Rec`, so that the compiler selects the `Display` procedure of the `Tagged_Rec` type.

Interfaces

Another useful feature of object-oriented programming is the use of interfaces. In this case, we can define abstract operations, and implement them in the derived tagged types. We declare an interface by simply writing **type T is interface**. For example:

[Ada]

```
type My_Interface is interface;

procedure Op (Obj : My_Interface) is abstract;

--  We cannot declare actual objects of an interface:
--
--  Obj : My_Interface;  --   ERROR!
```

All operations on an interface type are abstract, so we need to write **is abstract** in the signature — as we did in the declaration of Op above. Also, since interfaces are abstract types and don't have an actual implementation, we cannot declare objects for it.

We can derive tagged types from an interface and implement the actual operations of that interface:

[Ada]

```
type My_Derived is new My_Interface with null record;

procedure Op (Obj : My_Derived);
```

Note that we're not using the **tagged** keyword in the declaration because any type derived from an interface is automatically tagged.

Let's look at an example with an interface and two derived tagged types:

[Ada]

Listing 52: p.ads

```
1  package P is
2
3     type Display_Interface is interface;
4     procedure Display (D : Display_Interface) is abstract;
5
6     type Small_Display_Type is new Display_Interface with null record;
7     procedure Display (D : Small_Display_Type);
8
9     type Big_Display_Type is new Display_Interface with null record;
10    procedure Display (D : Big_Display_Type);
11
12 end P;
```

Listing 53: p.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body P is
4
5     procedure Display (D : Small_Display_Type) is
6        pragma Unreferenced (D);
7     begin
8        Put_Line ("Using Small_Display_Type");
9     end Display;
10
```

(continues on next page)

(continued from previous page)

```
   procedure Display (D : Big_Display_Type) is
      pragma Unreferenced (D);
   begin
      Put_Line ("Using Big_Display_Type");
   end Display;

end P;
```

Listing 54: main.adb

```
with P; use P;

procedure Main is
   D_Small : Small_Display_Type;
   D_Big   : Big_Display_Type;

   procedure Dispatching_Display (D : Display_Interface'Class) is
   begin
      D.Display;
   end Dispatching_Display;

begin
   Dispatching_Display (D_Small);
   Dispatching_Display (D_Big);
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Interfaces_1
MD5: 564eba158b2f8fc3efea9e892a21caa9
```

Runtime output

```
Using Small_Display_Type
Using Big_Display_Type
```

In this example, we have an interface type `Display_Interface` and two tagged types that are derived from `Display_Interface`: `Small_Display_Type` and `Big_Display_Type`.

Both types (`Small_Display_Type` and `Big_Display_Type`) implement the interface by overriding the `Display` procedure. Then, in the inner procedure `Dispatching_Display` of the `Main` procedure, we perform a dispatching call depending on the actual type of `D`.

Deriving from multiple interfaces

We may derive a type from multiple interfaces by simply writing **`type Derived_T is new`** T1 **`and`** T2 **`with null record`**. For example:

[Ada]

Listing 55: transceivers.ads

```
package Transceivers is

   type Send_Interface is interface;

   procedure Send (Obj : in out Send_Interface) is abstract;

   type Receive_Interface is interface;
```

(continues on next page)

(continued from previous page)

```
8
9     procedure Receive (Obj : in out Receive_Interface) is abstract;
10
11    type Transceiver is new Send_Interface and Receive_Interface
12      with null record;
13
14    procedure Send (D : in out Transceiver);
15    procedure Receive (D : in out Transceiver);
16
17 end Transceivers;
```

Listing 56: transceivers.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Transceivers is
4
5     procedure Send (D : in out Transceiver) is
6        pragma Unreferenced (D);
7     begin
8        Put_Line ("Sending data...");
9     end Send;
10
11    procedure Receive (D : in out Transceiver) is
12       pragma Unreferenced (D);
13    begin
14       Put_Line ("Receiving data...");
15    end Receive;
16
17 end Transceivers;
```

Listing 57: main.adb

```
1  with Transceivers; use Transceivers;
2
3  procedure Main is
4     D : Transceiver;
5  begin
6     D.Send;
7     D.Receive;
8  end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Multiple_Interfaces
MD5: c81813941bd3458eaf7b1fd39b010a03
```

Runtime output

```
Sending data...
Receiving data...
```

In this example, we're declaring two interfaces (`Send_Interface` and `Receive_Interface`) and the tagged type `Transceiver` that derives from both interfaces. Since we need to implement the interfaces, we implement both Send and Receive for `Transceiver`.

Abstract tagged types

We may also declare abstract tagged types. Note that, because the type is abstract, we cannot use it to declare objects for it — this is the same as for interfaces. We can only use it to derive other types. Let's look at the abstract tagged type declared in the `Abstract_Transceivers` package:

[Ada]

Listing 58: abstract_transceivers.ads

```
with Transceivers; use Transceivers;

 package Abstract_Transceivers is

    type Abstract_Transceiver is abstract new Send_Interface and
      Receive_Interface with null record;

    procedure Send (D : in out Abstract_Transceiver);
    --  We don't implement Receive for Abstract_Transceiver!

 end Abstract_Transceivers;
```

Listing 59: abstract_transceivers.adb

```
with Ada.Text_IO; use Ada.Text_IO;

 package body Abstract_Transceivers is

    procedure Send (D : in out Abstract_Transceiver) is
       pragma Unreferenced (D);
    begin
       Put_Line ("Sending data...");
    end Send;

 end Abstract_Transceivers;
```

Listing 60: main.adb

```
with Abstract_Transceivers; use Abstract_Transceivers;

 procedure Main is
    D : Abstract_Transceiver;
 begin
    D.Send;
    D.Receive;
 end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Multiple_Interfaces
MD5: c2b0b3aab1ffc9c3b9a0749bf6721088
```

Build output

```
main.adb:4:09: error: type of object cannot be abstract
main.adb:7:06: error: call to abstract procedure must be dispatching
gprbuild: *** compilation phase failed
```

In this example, we declare the abstract tagged type `Abstract_Transceiver`. Here, we're only partially implementing the interfaces from which this type is derived: we're implementing Send, but we're skipping the implementation of `Receive`. Therefore, `Receive` is

an abstract operation of `Abstract_Transceiver`. Since any tagged type that has abstract operations is abstract, we must indicate this by adding the **`abstract`** keyword in type declaration.

Also, when compiling this example, we get an error because we're trying to declare an object of `Abstract_Transceiver` (in the `Main` procedure), which is not possible. Naturally, if we derive another type from `Abstract_Transceiver` and implement `Receive` as well, then we can declare objects of this derived type. This is what we do in the `Full_Transceivers` below:

[Ada]

Listing 61: full_transceivers.ads

```
with Abstract_Transceivers; use Abstract_Transceivers;

package Full_Transceivers is

   type Full_Transceiver is new Abstract_Transceiver with null record;
   procedure Receive (D : in out Full_Transceiver);

end Full_Transceivers;
```

Listing 62: full_transceivers.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Full_Transceivers is

   procedure Receive (D : in out Full_Transceiver) is
      pragma Unreferenced (D);
   begin
      Put_Line ("Receiving data...");
   end Receive;

end Full_Transceivers;
```

Listing 63: main.adb

```
with Full_Transceivers; use Full_Transceivers;

procedure Main is
   D : Full_Transceiver;
begin
   D.Send;
   D.Receive;
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Multiple_Interfaces
MD5: 77a86a6d917547d306a89422e7522111
```

Runtime output

```
Sending data...
Receiving data...
```

Here, we implement the `Receive` procedure for the `Full_Transceiver`. Therefore, the type doesn't have any abstract operation, so we can use it to declare objects.

From simple derivation to OOP

In the *section about simple derivation* (page 1511), we've seen an example where the actual selection was done at *implementation* time by renaming one of the packages:

[Ada]

```
with Drivers_1;

package Drivers renames Drivers_1;
```

Although this approach is useful in many cases, there might be situations where we need to select the actual driver dynamically at runtime. Let's look at how we could rewrite that example using interfaces, tagged types and dispatching calls:

[Ada]

Listing 64: drivers_base.ads

```
package Drivers_Base is

   type Transceiver is interface;

   procedure Send (Device : Transceiver; Data : Integer) is abstract;
   procedure Receive (Device : Transceiver; Data : out Integer) is abstract;
   procedure Display (Device : Transceiver) is abstract;

end Drivers_Base;
```

Listing 65: drivers_1.ads

```
with Drivers_Base;

package Drivers_1 is

   type Transceiver is new Drivers_Base.Transceiver with null record;

   procedure Send (Device : Transceiver; Data : Integer);
   procedure Receive (Device : Transceiver; Data : out Integer);
   procedure Display (Device : Transceiver);

end Drivers_1;
```

Listing 66: drivers_1.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Drivers_1 is

   procedure Send (Device : Transceiver; Data : Integer) is null;

   procedure Receive (Device : Transceiver; Data : out Integer) is
      pragma Unreferenced (Device);
   begin
      Data := 42;
   end Receive;

   procedure Display (Device : Transceiver) is
      pragma Unreferenced (Device);
   begin
      Put_Line ("Using Drivers_1");
   end Display;
```

(continues on next page)

(continued from previous page)

```
18
19 end Drivers_1;
```

Listing 67: drivers_2.ads

```
1  with Drivers_Base;
2
3  package Drivers_2 is
4
5     type Transceiver is new Drivers_Base.Transceiver with null record;
6
7     procedure Send (Device : Transceiver; Data : Integer);
8     procedure Receive (Device : Transceiver; Data : out Integer);
9     procedure Display (Device : Transceiver);
10
11 end Drivers_2;
```

Listing 68: drivers_2.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Drivers_2 is
4
5     procedure Send (Device : Transceiver; Data : Integer) is null;
6
7     procedure Receive (Device : Transceiver; Data : out Integer) is
8        pragma Unreferenced (Device);
9     begin
10       Data := 7;
11    end Receive;
12
13    procedure Display (Device : Transceiver) is
14       pragma Unreferenced (Device);
15    begin
16       Put_Line ("Using Drivers_2");
17    end Display;
18
19 end Drivers_2;
```

Listing 69: main.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  with Drivers_Base;
4  with Drivers_1;
5  with Drivers_2;
6
7  procedure Main is
8     D1 : aliased Drivers_1.Transceiver;
9     D2 : aliased Drivers_2.Transceiver;
10    D  : access Drivers_Base.Transceiver'Class;
11
12    I  : Integer;
13
14    type Driver_Number is range 1 .. 2;
15
16    procedure Select_Driver (N : Driver_Number) is
17    begin
18       if N = 1 then
19          D := D1'Access;
```

(continues on next page)

(continued from previous page)

```
      else
         D := D2'Access;
      end if;
      D.Display;
   end Select_Driver;

begin
   Select_Driver (1);
   D.Send (999);
   D.Receive (I);
   Put_Line (Integer'Image (I));

   Select_Driver (2);
   D.Send (999);
   D.Receive (I);
   Put_Line (Integer'Image (I));
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Tagged_Drivers
MD5: d823b7231f1adf003fb6f545cb482308
```

Runtime output

```
Using Drivers_1
 42
Using Drivers_2
 7
```

In this example, we declare the `Transceiver` interface in the `Drivers_Base` package. This interface is then used to derive the tagged types `Transceiver` from both `Drivers_1` and `Drivers_2` packages.

In the `Main` procedure, we use the access to `Transceiver'Class` — from the interface declared in the `Drivers_Base` package — to declare `D`. This object `D` contains the access to the actual driver loaded at any specific time. We select the driver at runtime in the inner `Select_Driver` procedure, which initializes `D` (with the access to the selected driver). Then, any operation on `D` triggers a dispatching call to the selected driver.

Further resources

In the appendices, we have a step-by-step *hands-on overview of object-oriented programming* (page 1577) that discusses how to translate a simple system written in C to an equivalent system in Ada using object-oriented programming.

72.3.4 Pointer to subprograms

Pointers to subprograms allow us to dynamically select an appropriate subprogram at runtime. This selection might be triggered by an external event, or simply by the user. This can be useful when multiple versions of a routine exist, and the decision about which one to use cannot be made at compilation time.

This is an example on how to declare and use pointers to functions in C:

[C]

Listing 70: main.c

```c
#include <stdio.h>
#include <stdlib.h>

void show_msg_v1 (char *msg)
{
    printf("Using version #1: %s\n", msg);
}

void show_msg_v2 (char *msg)
{
    printf("Using version #2:\n %s\n", msg);
}

int main()
{
    int selection = 1;
    void (*current_show_msg) (char *);

    switch (selection)
    {
        case 1:  current_show_msg = &show_msg_v1;    break;
        case 2:  current_show_msg = &show_msg_v2;    break;
        default: current_show_msg = NULL;            break;
    }

    if (current_show_msg != NULL)
    {
        current_show_msg ("Hello there!");
    }
    else
    {
        printf("ERROR: no version of show_msg() selected!\n");
    }

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Selecting_Subprogram_C
MD5: 414c99fca2490611d20d031f8549ff59
```

Runtime output

```
Using version #1: Hello there!
```

The example above contains two versions of the `show_msg()` function: `show_msg_v1()` and `show_msg_v2()`. The function is selected depending on the value of `selection`, which initializes the function pointer `current_show_msg`. If there's no corresponding value, `current_show_msg` is set to `null` — alternatively, we could have selected a default version of `show_msg()` function. By calling `current_show_msg ("Hello there!")`, we're calling the function that `current_show_msg` is pointing to.

This is the corresponding implementation in Ada:

[Ada]

Listing 71: show_subprogram_selection.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Subprogram_Selection is

   procedure Show_Msg_V1 (Msg : String) is
   begin
      Put_Line ("Using version #1: " & Msg);
   end Show_Msg_V1;

   procedure Show_Msg_V2 (Msg : String) is
   begin
      Put_Line ("Using version #2: ");
      Put_Line (Msg);
   end Show_Msg_V2;

   type Show_Msg_Proc is access procedure (Msg : String);

   Current_Show_Msg : Show_Msg_Proc;
   Selection        : Natural;

begin
   Selection := 1;

   case Selection is
      when 1      => Current_Show_Msg := Show_Msg_V1'Access;
      when 2      => Current_Show_Msg := Show_Msg_V2'Access;
      when others => Current_Show_Msg := null;
   end case;

   if Current_Show_Msg /= null then
      Current_Show_Msg ("Hello there!");
   else
      Put_Line ("ERROR: no version of Show_Msg selected!");
   end if;

end Show_Subprogram_Selection;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Selecting_Subprogram_Ada
MD5: ee41e042e3b879b4a2671bfe6d8072aa
```

Runtime output

```
Using version #1: Hello there!
```

The structure of the code above is very similar to the one used in the C code. Again, we have two version of Show_Msg: Show_Msg_V1 and Show_Msg_V2. We set `Current_Show_Msg` according to the value of `Selection`. Here, we use `'Access` to get access to the corresponding procedure. If no version of Show_Msg is available, we set `Current_Show_Msg` to **`null`**.

Pointers to subprograms are also typically used as callback functions. This approach is extensively used in systems that process events, for example. Here, we could have a two-layered system:

- A layer of the system (an event manager) triggers events depending on information from sensors.
  - For each event, callback functions can be registered.

  - The event manager calls registered callback functions when an event is triggered.
- Another layer of the system registers callback functions for specific events and decides what to do when those events are triggered.

This approach promotes information hiding and component decoupling because:

- the layer of the system responsible for managing events doesn't need to know what the callback function actually does, while
- the layer of the system that implements callback functions remains agnostic to implementation details of the event manager — for example, how events are implemented in the event manager.

Let's see an example in C where we have a `process_values()` function that calls a callback function (`process_one`) to process a list of values:

[C]

Listing 72: process_values.h

```
typedef int (*process_one_callback) (int);

void process_values (int                  *values,
                     int                   len,
                     process_one_callback  process_one);
```

Listing 73: process_values.c

```
#include "process_values.h"

#include <assert.h>
#include <stdio.h>

void process_values (int                  *values,
                     int                   len,
                     process_one_callback  process_one)
{
    int i;

    assert (process_one != NULL);

    for (i = 0; i < len; i++)
    {
        values[i] = process_one (values[i]);
    }
}
```

Listing 74: main.c

```
#include <stdio.h>
#include <stdlib.h>

#include "process_values.h"

int proc_10 (int val)
{
    return val + 10;
}

# define LEN_VALUES     5

int main()
```

(continues on next page)

(continued from previous page)

```
{

    int values[LEN_VALUES] = { 1, 2, 3, 4, 5 };
    int i;

    process_values (values, LEN_VALUES, &proc_10);

    for (i = 0; i < LEN_VALUES; i++)
    {
        printf("Value [%d] = %d\n", i, values[i]);
    }

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Callback_C
MD5: ff5c8611d0901f40b6c4a9effeb0a323
```

Runtime output

```
Value [0] = 11
Value [1] = 12
Value [2] = 13
Value [3] = 14
Value [4] = 15
```

As mentioned previously, `process_values()` doesn't have any knowledge about what `process_one()` does with the integer value it receives as a parameter. Also, we could replace `proc_10()` by another function without having to change the implementation of `process_values()`.

Note that `process_values()` calls an `assert()` for the function pointer to compare it against `null`. Here, instead of checking the validity of the function pointer, we're expecting the caller of `process_values()` to provide a valid pointer.

This is the corresponding implementation in Ada:

[Ada]

Listing 75: values_processing.ads

```
package Values_Processing is

   type Integer_Array is array (Positive range <>) of Integer;

   type Process_One_Callback is not null access
     function (Value : Integer) return Integer;

   procedure Process_Values (Values      : in out Integer_Array;
                             Process_One :        Process_One_Callback);

end Values_Processing;
```

Listing 76: values_processing.adb

```
package body Values_Processing is

   procedure Process_Values (Values      : in out Integer_Array;
                             Process_One :        Process_One_Callback) is
```

(continues on next page)

(continued from previous page)

```
   begin
      for I in Values'Range loop
         Values (I) := Process_One (Values (I));
      end loop;
   end Process_Values;

end Values_Processing;
```

Listing 77: proc_10.ads

```
function Proc_10 (Value : Integer) return Integer;
```

Listing 78: proc_10.adb

```
function Proc_10 (Value : Integer) return Integer is
begin
   return Value + 10;
end Proc_10;
```

Listing 79: show_callback.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Values_Processing; use Values_Processing;
with Proc_10;

procedure Show_Callback is
   Values : Integer_Array := (1, 2, 3, 4, 5);
begin
   Process_Values (Values, Proc_10'Access);

   for I in Values'Range loop
      Put_Line ("Value ["
                & Positive'Image (I)
                & "] = "
                & Integer'Image (Values (I)));
   end loop;
end Show_Callback;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.Callback_Ada
MD5: f49c54f0d14193d305c0e962a392ab67
```

Runtime output

```
Value [ 1] =  11
Value [ 2] =  12
Value [ 3] =  13
Value [ 4] =  14
Value [ 5] =  15
```

Similar to the implementation in C, the `Process_Values` procedure receives the access to a callback routine, which is then called for each value of the `Values` array.

Note that the declaration of `Process_One_Callback` makes use of the **`not null access`** declaration. By using this approach, we ensure that any parameter of this type has a valid value, so we can always call the callback routine.

72.4 Design by components using dynamic libraries

In the previous sections, we have shown how to use packages to create separate components of a system. As we know, when designing a complex system, it is advisable to separate concerns into distinct units, so we can use Ada packages to represent each unit of a system. In this section, we go one step further and create separate dynamic libraries for each component, which we'll then link to the main application.

Let's suppose we have a main system (`Main_System`) and a component *A* (`Component_A`) that we want to use in the main system. For example:

[Ada]

Listing 80: component_a.ads

```
--
--  File: component_a.ads
--
package Component_A is

   type Float_Array is array (Positive range <>) of Float;

   function Average (Data : Float_Array) return Float;

end Component_A;
```

Listing 81: component_a.adb

```
--
--  File: component_a.adb
--
package body Component_A is

   function Average (Data : Float_Array) return Float is
      Total : Float := 0.0;
   begin
      for Value of Data loop
         Total := Total + Value;
      end loop;
      return Total / Float (Data'Length);
   end Average;

end Component_A;
```

Listing 82: main_system.adb

```
--
--  File: main_system.adb
--
with Ada.Text_IO; use Ada.Text_IO;

with Component_A; use Component_A;

procedure Main_System is
   Values        : constant Float_Array := (10.0, 11.0, 12.0, 13.0);
   Average_Value : Float;
begin
   Average_Value := Average (Values);
   Put_Line ("Average = " & Float'Image (Average_Value));
end Main_System;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Reusability.System_For_Dyn_Lib
MD5: d759132b787e636d4bcd5f8cd6393f2a
```

Runtime output

```
Average =  1.15000E+01
```

Note that, in the source-code example above, we're indicating the name of each file. We'll now see how to organize those files in a structure that is suitable for the GNAT build system (**GPRbuild**).

In order to discuss how to create dynamic libraries, we need to dig into some details about the build system. With GNAT, we can use project files for **GPRbuild** to easily design dynamic libraries. Let's say we use the following directory structure for the code above:

```
|- component_a
|    | component_a.gpr
|    |- src
|    |    | component_a.adb
|    |    | component_a.ads
|- main_system
|    | main_system.gpr
|    |- src
|    |    | main_system.adb
```

Here, we have two directories: *component_a* and *main_system*. Each directory contains a project file (with the *.gpr* file extension) and a source-code directory (*src*).

In the source-code example above, we've seen the content of files `component_a.ads`, `component_a.adb` and `main_system.adb`. Now, let's discuss how to write the project file for `Component_A` (`component_a.gpr`), which will build the dynamic library for this component:

```
library project Component_A is

   for Source_Dirs use ("src");
   for Object_Dir use "obj";
   for Create_Missing_Dirs use "True";
   for Library_Name use "component_a";
   for Library_Kind use "dynamic";
   for Library_Dir use "lib";

end Component_A;
```

The project is defined as a *library project* instead of *project*. This tells **GPRbuild** to build a library instead of an executable binary. We then specify the library name using the *Library_Name* attribute, which is required, so it must appear in a library project. The next two library-related attributes are optional, but important for our use-case. We use:

- *Library_Kind* to specify that we want to create a dynamic library — by default, this attribute is set to *static*;
- *Library_Dir* to specify the directory where the library is stored.

In the project file of our main system (`main_system.gpr`), we just need to reference the project of `Component_A` using a *with* clause and indicating the correct path to that project file:

```
with "../component_a/component_a.gpr";

project Main_System is
    for Source_Dirs use ("src");
    for Object_Dir use "obj";
```

(continues on next page)

(continued from previous page)

```
    for Create_Missing_Dirs use "True";
    for Main use ("main_system.adb");
end Main_System;
```

GPRbuild takes care of selecting the correct settings to link the dynamic library created for `Component_A` with the main application (`Main_System`) and build an executable.

We can use the same strategy to create a `Component_B` and dynamically link to it in the `Main_System`. We just need to create the separate structure for this component — with the appropriate Ada packages and project file — and include it in the project file of the main system using a *with* clause:

```
with "../component_a/component_a.gpr";
with "../component_b/component_b.gpr";

...
```

Again, **GPRbuild** takes care of selecting the correct settings to link both dynamic libraries together with the main application.

You can find more details and special setting for library projects in the GPRbuild documentation[337].

In the GNAT toolchain

The GNAT toolchain includes a more advanced example focusing on how to load dynamic libraries at runtime. You can find it in the `share/examples/gnat/plugins` directory of the GNAT toolchain installation. As described in the README file from that directory, this example "comprises a main program which probes regularly for the existence of shared libraries in a known location. If such libraries are present, it uses them to implement features initially not present in the main program."

---

CHAPTER

SEVENTYTHREE

PERFORMANCE CONSIDERATIONS

73.1 Overall expectations

All in all, there should not be significant performance differences between code written in Ada and code written in C, provided that they are semantically equivalent. Taking the current GNAT implementation and its GCC C counterpart for example, most of the code generation and optimization phases are shared between C and Ada — so there's not one compiler more efficient than the other. Furthermore, the two languages are fairly similar in the way they implement imperative semantics, in particular with regards to memory management or control flow. They should be equivalent on average.

When comparing the performance of C and Ada code, differences might be observed. This usually comes from the fact that, while the two piece *appear* semantically equivalent, they happen to be actually quite different; C code semantics do not implicitly apply the same run-time checks that Ada does. This section will present common ways for improving Ada code performance.

73.2 Switches and optimizations

Clever use of compilation switches might optimize the performance of an application significantly. In this section, we'll briefly look into some of the switches available in the GNAT toolchain.

73.2.1 Optimizations levels

Optimization levels can be found in many compilers for multiple languages. On the lowest level, the GNAT compiler doesn't optimize the code at all, while at the higher levels, the compiler analyses the code and optimizes it by removing unnecessary operations and making the most use of the target processor's capabilities.

By being part of GCC, GNAT offers the same `-0_` switches as GCC:

Switc	Description
`-00`	No optimization: the generated code is completely unoptimized. This is the default optimization level.
`-01`	Moderate optimization.
`-02`	Full optimization.
`-03`	Same optimization level as for `-02`. In addition, further optimization strategies, such as aggressive automatic inlining and vectorization.

Note that the higher the level, the longer the compilation time. For fast compilation during development phase, unless you're working on benchmarking algorithms, using `-O0` is probably a good idea.

In addition to the levels presented above, GNAT also has the `-Os` switch, which allows for optimizing code and data usage.

73.2.2 Inlining

As we've seen in the previous section, automatic inlining depends on the optimization level. The highest optimization level (`-O3`), for example, performs aggressive automatic inlining. This could mean that this level inlines too much rather than not enough. As a result, the cache may become an issue and the overall performance may be worse than the one we would achieve by compiling the same code with optimization level 2 (`-O2`). Therefore, the general recommendation is to not *just* select `-O3` for the optimized version of an application, but instead compare it the optimized version built with `-O2`.

In some cases, it's better to reduce the optimization level and perform manual inlining instead of automatic inlining. We do that by using the `Inline` aspect. Let's reuse an example from a previous chapter and inline the `Average` function:

[Ada]

Listing 1: float_arrays.ads

```
package Float_Arrays is

   type Float_Array is array (Positive range <>) of Float;

   function Average (Data : Float_Array) return Float
     with Inline;

end Float_Arrays;
```

Listing 2: float_arrays.adb

```
package body Float_Arrays is

   function Average (Data : Float_Array) return Float is
      Total : Float := 0.0;
   begin
      for Value of Data loop
         Total := Total + Value;
      end loop;
      return Total / Float (Data'Length);
   end Average;

end Float_Arrays;
```

Listing 3: compute_average.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Float_Arrays; use Float_Arrays;

procedure Compute_Average is
   Values        : constant Float_Array := (10.0, 11.0, 12.0, 13.0);
   Average_Value : Float;
begin
   Average_Value := Average (Values);
```

(continues on next page)

(continued from previous page)

```
10    Put_Line ("Average = " & Float'Image (Average_Value));
11 end Compute_Average;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Performance.Inlining
MD5: faf9d0d8cd5aefd7a48bcd950b1256fa
```

Runtime output

```
Average =  1.15000E+01
```

When compiling this example, GNAT will inline `Average` in the `Compute_Average` procedure.

In order to effectively use this aspect, however, we need to set the optimization level to at least `-O1` and use the `-gnatn` switch, which instructs the compiler to take the `Inline` aspect into account.

Note, however, that the `Inline` aspect is just a *recommendation* to the compiler. Sometimes, the compiler might not be able to follow this recommendation, so it won't inline the subprogram. In this case, we get a compilation warning from GNAT.

These are some examples of situations where the compiler might not be able to inline a subprogram:

- when the code is too large,
- when it's too complicated — for example, when it involves exception handling —, or
- when it contains tasks, etc.

In addition to the `Inline` aspect, we also have the `Inline_Always` aspect. In contrast to the former aspect, however, the `Inline_Always` aspect isn't primarily related to performance. Instead, it should be used when the functionality would be incorrect if inlining was not performed by the compiler. Examples of this are procedures that insert Assembly instructions that only make sense when the procedure is inlined, such as memory barriers.

Similar to the `Inline` aspect, there might be situations where a subprogram has the `Inline_Always` aspect, but the compiler is unable to inline it. In this case, we get a compilation error from GNAT.

73.3 Checks and assertions

73.3.1 Checks

Ada provides many runtime checks to ensure that the implementation is working as expected. For example, when accessing an array, we would like to make sure that we're not accessing a memory position that is not allocated for that array. This is achieved by an index check.

Another example of runtime check is the verification of valid ranges. For example, when adding two integer numbers, we would like to ensure that the result is still in the valid range — that the value is neither too large nor too small. This is achieved by an range check. Likewise, arithmetic operations shouldn't overflow or underflow. This is achieved by an overflow check.

Although runtime checks are very useful and should be used as much as possible, they can also increase the overhead of implementations at certain hot-spots. For example, checking the index of an array in a sorting algorithm may significantly decrease its performance. In

those cases, suppressing the check may be an option. We can achieve this suppression by using `pragma Suppress (Index_Check)`. For example:

[Ada]

```
procedure Sort (A : in out Integer_Array) is
   pragma Suppress (Index_Check);
begin
   --  (implementation removed...)
   null;
end Sort;
```

In case of overflow checks, we can use `pragma Suppress (Overflow_Check)` to suppress them:

```
function Some_Computation (A, B : Int32) return Int32 is
   pragma Suppress (Overflow_Check);
begin
   --  (implementation removed...)
   null;
end Sort;
```

We can also deactivate overflow checks for integer types using the `-gnato` switch when compiling a source-code file with GNAT. In this case, overflow checks in the whole file are deactivated.

It is also possible to suppress all checks at once using `pragma Suppress (All_Checks)`. In addition, GNAT offers a compilation switch called `-gnatp`, which has the same effect on the whole file.

Note, however, that this kind of suppression is just a recommendation to the compiler. There's no guarantee that the compiler will actually suppress any of the checks because the compiler may not be able to do so — typically because the hardware happens to do it. For example, if the machine traps on any access via address zero, requesting the removal of null access value checks in the generated code won't prevent the checks from happening.

It is important to differentiate between required and redundant checks. Let's consider the following example in C:

[C]

Listing 4: main.c

```
#include <stdio.h>

int main(int argc, const char * argv[])
{
    int a = 8, b = 0, res;

    res = a / b;

    // printing the result
    printf("res = %d\n", res);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Performance.Division_By_Zero_C
MD5: c8d95cbdd76618108119886c27ce7eb6
```

Because C doesn't have language-defined checks, as soon as the application tries to divide a value by zero in `res = a / b`, it'll break — on Linux, for example, you may get the

following error message by the operating system: `Floating point exception (core dumped)`. Therefore, we need to manually introduce a check for zero before this operation. For example:

[C]

Listing 5: main.c

```c
#include <stdio.h>

int main(int argc, const char * argv[])
{
    int a = 8, b = 0, res;

    if (b != 0) {
        res = a / b;

        // printing the result
        printf("res = %d\n", res);
    }
    else
    {
        // printing error message
        printf("Error: cannot calculate value (division by zero)\n");
    }

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Performance.Division_By_Zero_Check_C
MD5: 67ea0140d8248674b4aac06825c7cdbe
```

Runtime output

```
Error: cannot calculate value (division by zero)
```

This is the corresponding code in Ada:

[Ada]

Listing 6: show_division_by_zero.adb

```ada
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Division_By_Zero is
   A   : Integer := 8;
   B   : Integer := 0;
   Res : Integer;
begin
   Res := A / B;

   Put_Line ("Res = " & Integer'Image (Res));
end Show_Division_By_Zero;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Performance.Division_By_Zero_Ada
MD5: 2af6690eb977203ef7ce2178d15255af
```

Build output

```
show_division_by_zero.adb:8:15: warning: division by zero [enabled by default]
show_division_by_zero.adb:8:15: warning: Constraint_Error will be raised at run␣
 ↪time [enabled by default]
```

Runtime output

```

raised CONSTRAINT_ERROR : show_division_by_zero.adb:8 divide by zero
```

Similar to the first version of the C code, we're not explicitly checking for a potential division by zero here. In Ada, however, this check is *automatically inserted* by the language itself. When running the application above, an exception is raised when the application tries to divide the value in A by zero. We could introduce exception handling in our example, so that we get the same message as we did in the second version of the C code:

[Ada]

Listing 7: show_division_by_zero.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Show_Division_By_Zero is
   A   : Integer := 8;
   B   : Integer := 0;
   Res : Integer;
begin
   Res := A / B;

   Put_Line ("Res = " & Integer'Image (Res));
exception
   when Constraint_Error =>
      Put_Line ("Error: cannot calculate value (division by zero)");
   when others =>
      null;
end Show_Division_By_Zero;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Performance.Division_By_Zero_Check_Ada
MD5: a96a94c15fda5f6c5feb232d615b1ea3
```

Build output

```
show_division_by_zero.adb:8:15: warning: division by zero [enabled by default]
show_division_by_zero.adb:8:15: warning: Constraint_Error will be raised at run␣
 ↪time [enabled by default]
```

Runtime output

```
Error: cannot calculate value (division by zero)
```

This example demonstrates that the division check for `Res := A / B` is required and shouldn't be suppressed. In contrast, a check is redundant — and therefore not required — when we know that the condition that leads to a failure can never happen. In many cases, the compiler itself detects redundant checks and eliminates them (for higher optimization levels). Therefore, when improving the performance of your application, you should:

1. keep all checks active for most parts of the application;
2. identify the hot-spots of your application;
3. identify which checks haven't been eliminated by the optimizer on these hot-spots;
4. identify which of those checks are redundant;

5. only suppress those checks that are redundant, and keep the required ones.

73.3.2 Assertions

We've already discussed assertions in *this section of the SPARK chapter* (page 1462). Assertions are user-defined checks that you can add to your code using the **pragma** *Assert*. For example:

[Ada]

```
function Some_Computation (A, B : Int32) return Int32 is
   Res : Int32;
begin
   --  (implementation removed...)

   pragma Assert (Res >= 0);

   return Res;
end Sort;
```

Assertions that are specified with **pragma** *Assert* are not enabled by default. You can enable them by setting the assertion policy to *check* — using **pragma** *Assertion_Policy* (Check) — or by using the `-gnata` switch when compiling with GNAT.

Similar to the checks discussed previously, assertions can generate significant overhead when used at hot-spots. Restricting those assertions to development (e.g. debug version) and turning them off on the release version may be an option. In this case, formal proof — as discussed in the *SPARK chapter* (page 1455) — can help you. By formally proving that assertions will never fail at run-time, you can safely deactivate them.

73.4 Dynamic vs. static structures

Ada generally speaking provides more ways than C or C++ to write simple dynamic structures, that is to say structures that have constraints computed after variables. For example, it's quite typical to have initial values in record types:

[Ada]

```
type R is record
   F : Some_Field := Call_To_Some_Function;
end record;
```

However, the consequences of the above is that any declaration of a instance of this type without an explicit value for F will issue a call to `Call_To_Some_Function`. More subtle issue may arise with elaboration. For example, it's possible to write:

Listing 8: some_functions.ads

```
1  package Some_Functions is
2
3     function Some_Function_Call return Integer is (2);
4
5     function Some_Other_Function_Call return Integer is (10);
6
7  end Some_Functions;
```

Listing 9: values.ads

```
with Some_Functions; use Some_Functions;

package Values is
   A_Start : Integer := Some_Function_Call;
   A_End   : Integer := Some_Other_Function_Call;
end Values;
```

Listing 10: arr_def.ads

```
with Values; use Values;

package Arr_Def is
   type Arr is array (Integer range A_Start .. A_End) of Integer;
end Arr_Def;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Performance.Dynamic_Array
MD5: 0c97cecb64d27e935724c8b5f941fb4f
```

It may indeed be appealing to be able to change the values of `A_Start` and `A_End` at startup so as to align a series of arrays dynamically. The consequence, however, is that these values will not be known statically, so any code that needs to access to boundaries of the array will need to read data from memory. While it's perfectly fine most of the time, there may be situations where performances are so critical that static values for array boundaries must be enforced.

Here's a last case which may also be surprising:

[Ada]

Listing 11: arr_def.ads

```
package Arr_Def is
   type Arr is array (Integer range <>) of Integer;

   type R (D1, D2 : Integer) is record
      F1 : Arr (1 .. D1);
      F2 : Arr (1 .. D2);
   end record;
end Arr_Def;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Performance.Record_With_Arrays
MD5: e7b2656433279d36db87506276b68398
```

In the code above, R contains two arrays, F1 and F2, respectively constrained by the discriminant D1 and D2. The consequence is, however, that to access F2, the run-time needs to know how large F1 is, which is dynamically constrained when creating an instance. Therefore, accessing to F2 requires a computation involving D1 which is slower than, let's say, two pointers in an C array that would point to two different arrays.

Generally speaking, when values are used in data structures, it's useful to always consider where they're coming from, and if their value is static (computed by the compiler) or dynamic (only known at run-time). There's nothing fundamentally wrong with dynamically constrained types, unless they appear in performance-critical pieces of the application.

73.5 Pointers vs. data copies

In the section about *pointers* (page 1483), we mentioned that the Ada compiler will automatically pass parameters by reference when needed. Let's look into what "when needed" means. The fundamental point to understand is that the parameter types determine how the parameters are passed in and/or out. The parameter modes do not control how parameters are passed.

Specifically, the language standards specifies that scalar types are always passed by value, and that some other types are always passed by reference. It would not make sense to make a copy of a task when passing it as a parameter, for example. So parameters that can be passed reasonably by value will be, and those that must be passed by reference will be. That's the safest approach.

But the language also specifies that when the parameter is an array type or a record type, and the record/array components are all by-value types, then the compiler decides: it can pass the parameter using either mechanism. The critical case is when such a parameter is large, e.g., a large matrix. We don't want the compiler to pass it by value because that would entail a large copy, and indeed the compiler will not do so. But if the array or record parameter is small, say the same size as an address, then it doesn't matter how it is passed and by copy is just as fast as by reference. That's why the language gives the choice to the compiler. Although the language does not mandate that large parameters be passed by reference, any reasonable compiler will do the right thing.

The modes do have an effect, but not in determining how the parameters are passed. Their effect, for parameters passed by value, is to determine how many times the value is copied. For `mode in` and `mode out` there is just one copy. For `mode in out` there will be two copies, one in each direction.

Therefore, unlike C, you don't have to use access types in Ada to get better performance when passing arrays or records to subprograms. The compiler will almost certainly do the right thing for you.

Let's look at this example:

[C]

Listing 12: main.c

```c
#include <stdio.h>

struct Data {
    int prev, curr;
};

void update(struct Data *d,
            int          v)
{
    d->prev = d->curr;
    d->curr = v;
}

void display(const struct Data *d)
{
    printf("Prev : %d\n", d->prev);
    printf("Curr : %d\n", d->curr);
}

int main(int argc, const char * argv[])
{
    struct Data D1 = { 0, 1 };

```

(continues on next page)

(continued from previous page)

```
    update (&D1, 3);
    display (&D1);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Performance.Passing_Rec_By_Reference_C
MD5: 9087e26168e49d095b5e0776d6330d69
```

Runtime output

```
Prev : 1
Curr : 3
```

In this C code example, we're using pointers to pass D1 as a reference to update and display. In contrast, the equivalent code in Ada simply uses the parameter modes to specify the data flow directions. The mechanisms used to pass the values do not appear in the source code.

[Ada]

Listing 13: update_record.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Update_Record is

   type Data is record
      Prev : Integer;
      Curr : Integer;
   end record;

   procedure Update (D : in out Data;
                     V :        Integer) is
   begin
      D.Prev := D.Curr;
      D.Curr := V;
   end Update;

   procedure Display (D : Data) is
   begin
      Put_Line ("Prev: " & Integer'Image (D.Prev));
      Put_Line ("Curr: " & Integer'Image (D.Curr));
   end Display;

   D1 : Data := (0, 1);

begin
   Update (D1, 3);
   Display (D1);
end Update_Record;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Performance.Passing_Rec_By_Reference_Ada
MD5: 6c64fb73e2cf490c0a129f0cd73c190b
```

Runtime output

```
Prev:  1
Curr:  3
```

In the calls to `Update` and `Display`, `D1` is always be passed by reference. Because no extra copy takes place, we get a performance that is equivalent to the C version. If we had used arrays in the example above, `D1` would have been passed by reference as well:

[Ada]

Listing 14: update_array.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Update_Array is

   type Data_State is (Prev, Curr);
   type Data is array (Data_State) of Integer;

   procedure Update (D : in out Data;
                     V :        Integer) is
   begin
      D (Prev) := D (Curr);
      D (Curr) := V;
   end Update;

   procedure Display (D : Data) is
   begin
      Put_Line ("Prev: " & Integer'Image (D (Prev)));
      Put_Line ("Curr: " & Integer'Image (D (Curr)));
   end Display;

   D1 : Data := (0, 1);

begin
   Update (D1, 3);
   Display (D1);
end Update_Array;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Performance.Passing_Array_By_Reference_Ada
MD5: 5fb27811f34543fc4150eb4fddbe7034
```

Runtime output

```
Prev:  1
Curr:  3
```

Again, no extra copy is performed in the calls to `Update` and `Display`, which gives us optimal performance when dealing with arrays and avoids the need to use access types to optimize the code.

73.5.1 Function returns

Previously, we've discussed the cost of passing complex records as arguments to subprograms. We've seen that we don't have to use explicit access type parameters to get better performance in Ada. In this section, we'll briefly discuss the cost of function returns.

In general, we can use either procedures or functions to initialize a data structure. Let's look at this example in C:

[C]

Listing 15: main.c

```c
#include <stdio.h>

struct Data {
    int prev, curr;
};

void init_data(struct Data *d)
{
    d->prev = 0;
    d->curr = 1;
}

struct Data get_init_data()
{
    struct Data d  = { 0, 1 };

    return d;
}

int main(int argc, const char * argv[])
{
    struct Data D1;

    D1 = get_init_data();

    init_data(&D1);

    return 0;
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Performance.Init_Rec_Proc_And_Func_C
MD5: 0586636d5e25c0d6bec2257af75ae998
```

This code example contains two subprograms that initialize the `Data` structure:

- `init_data()`, which receives the data structure as a reference (using a pointer) and initializes it, and
- `get_init_data()`, which returns the initialized structure.

In C, we generally avoid implementing functions such as `get_init_data()` because of the extra copy that is needed for the function return.

This is the corresponding implementation in Ada:

[Ada]

Listing 16: init_record.adb

```
procedure Init_Record is

   type Data is record
      Prev : Integer;
      Curr : Integer;
   end record;

   procedure Init (D : out Data) is
   begin
      D := (Prev => 0, Curr => 1);
   end Init;

   function Init return Data is
      D : constant Data := (Prev => 0, Curr => 1);
   begin
      return D;
   end Init;

   D1 : Data;

   pragma Unreferenced (D1);
begin
   D1 := Init;

   Init (D1);
end Init_Record;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Performance.Init_Rec_Proc_And_Func_Ada
MD5: 0f930eea432a82d78840b72c0714b283
```

Build output

```
init_record.adb:25:10: warning: pragma Unreferenced given for "D1" [enabled by␣
↪default]
```

In this example, we have two versions of `Init`: one using a procedural form, and the other one using a functional form. Note that, because of Ada's support for subprogram overloading, we can use the same name for both subprograms.

The issue is that assignment of a function result entails a copy, just as if we assigned one variable to another. For example, when assigning a function result to a constant, the function result is copied into the memory for the constant. That's what is happening in the above examples for the initialized variables.

Therefore, in terms of performance, the same recommendations apply: for large types we should avoid writing functions like the `Init` function above. Instead, we should use the procedural form of `Init`. The reason is that the compiler necessarily generates a copy for the `Init` function, while the `Init` procedure uses a reference for the output parameter, so that the actual record initialization is performed in place in the caller's argument.

An exception to this is when we use functions returning values of limited types, which by definition do not allow assignment. Here, to avoid allowing something that would otherwise look suspiciously like an assignment, the compiler generates the function body so that it builds the result directly into the object being assigned. No copy takes place.

We could, for example, rewrite the example above using limited types:

[Ada]

Listing 17: init_limited_record.adb

```
procedure Init_Limited_Record is

   type Data is limited record
      Prev : Integer;
      Curr : Integer;
   end record;

   function Init return Data is
   begin
      return D : Data do
         D.Prev := 0;
         D.Curr := 1;
      end return;
   end Init;

   D1 : Data := Init;

   pragma Unreferenced (D1);
begin
   null;
end Init_Limited_Record;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.Performance.Init_Lim_Rec_Proc_And_Func_Ada
MD5: 57fc1b3f69b42dd4633b0c67e252c2d2
```

In this example, `D1 : Data := Init;` has the same cost as the call to the procedural form — `Init (D1);` — that we've seen in the previous example. This is because the assignment is done in place.

Note that limited types require the use of the extended return statements (`return ... do ... end return`) in function implementations. Also note that, because the `Data` type is limited, we can only use the `Init` function in the declaration of `D1`; a statement in the code such as `D1 := Init;` is therefore forbidden.

CHAPTER

SEVENTYFOUR

ARGUMENTATION AND BUSINESS PERSPECTIVES

The technical benefits of a migration from C to Ada are usually relatively straightforward to demonstrate. Hopefully, this course provides a good basis for it. However, when faced with an actual business decision to make, additional considerations need to be taken into account, such as return on investment, perennity of the solution, tool support, etc. This section will cover a number of usual questions and provide elements of answers.

74.1 What's the expected ROI of a C to Ada transition?

Switching from one technology to another is a cost, may that be in terms of training, transition of the existing environment or acquisition of new tools. This investment needs to be matched with an expected return on investment, or ROI, to be consistent. Of course, it's incredibly difficult to provide a firm answer to how much money can be saved by transitioning, as this is highly dependent on specific project objectives and constraints. We're going to provide qualitative and quantitative arguments here, from the perspective of a project that has to reach a relatively high level of integrity, that is to say a system where the occurrence of a software failure is a relatively costly event.

From a qualitative standpoint, there are various times in the software development life cycle where defects can be found:

1. on the developer's desk
2. during component testing
3. during integration testing
4. after deployment
5. during maintenance

Numbers from studies vary greatly on the relative costs of defects found at each of these phases, but there's a clear ordering between them. For example, a defect found while developing is orders of magnitude less expensive to fix than a defect found e.g. at integration time, which may involve costly debugging sessions and slow down the entire system acceptance. The whole purpose of Ada and SPARK is to push defect detection to the developer's desk as much as possible; at least for all of these defects that can be identified at that level. While the strict act of writing software may be taking more effort because of all of the additional safeguards, this should have a significant and positive impact down the line and help to control costs overall. The exact value this may translate into is highly business dependent.

From a quantitative standpoint, two studies have been done almost 25 years apart and provide similar insights:

- Rational Software in 1995 found that the cost of developing software in Ada was overall half as much as the cost of developing software in C.

- VDC ran a study in 2018, finding that the cost savings of developing with Ada over C ranged from 6% to 38% in savings.

From a qualitative standpoint, in particular with regards to Ada and C from a formal proof perspective, an interesting presentation was made in 2017 by two researchers. They tried to apply formal proof on the same piece of code, developed in Ada/SPARK on one end and C/Frama-C on the other. Their results indicate that the Ada/SPARK technology is indeed more conducive to formal proof methodologies.

Although all of these studies have their own biases, they provide a good idea of what to expect in terms of savings once the initial investment in switching to Ada is made. This is assuming everything else is equal, in particular that the level of integrity is the same. In many situations, the migration to Ada is justified by an increase in terms of integrity expectations, in which case it's expected that development costs will rise (it's more expensive to develop better software) and Ada is viewed as a means to mitigate this rise in development costs.

That being said, the point of this argument is not to say that it's not possible to write very safe and secure software with languages different than Ada. With the right expertise, the right processes and the right tools, it's done every day. The point is that Ada overall reduces the level of processes, expertise and tools necessary and will allow to reach the same target at a lower cost.

74.2 Who is using Ada today?

Ada was initially born as a DoD project, and thus got its initial customer base in aerospace and defence (A&D). At the time these lines are written and from the perspective of AdaCore, A&D is still the largest consumer of Ada today and covers about 70% of the market. This creates a consistent and long lasting set of established users as these project last often for decades, using the same codebase migrating from platform to platform.

More recently however, there has been an emerging interest for Ada in new communities of users such as automotive, medical device, industrial automation and overall cyber-security. This can probably be explained by a rise of safety, reliability and cyber-security requirements. The market is moving relatively rapidly today and we're anticipating an increase of the Ada footprint in these domains, while still remaining a technology of choice for the development of mission critical software.

74.3 What is the future of the Ada technology?

The first piece of the answer lies in the user base of the Ada language, as seen in the previous question. Projects using Ada in the aerospace and defence domain maintain source code over decades, providing healthy funding foundation for Ada-based technologies.

AdaCore being the author of this course, it's difficult for us to be fair in our description of other Ada compilation technologies. We will leave to the readers the responsibility of forging their own opinion. If they present a credible alternative to the GNAT compiler, then this whole section can be considered as void.

Assuming GNAT is the only option available, and acknowledging that this is an argument that we're hearing from a number of Ada adopters, let's discuss the "sole source" issue.

First of all, it's worth noting that industries are using a lot of software that is provided by only one source, so while non-ideal, these situations are also quite common.

In the case of the GNAT compiler however, while AdaCore is the main maintainer, this maintenance is done as part of an open-source community. This means that nothing prevents

a third party to start selling a competing set of products based on the same compiler, provided that it too adopts the open-source approach. Our job is to be more cost-effective than the alternative, and indeed for the vast part this has prevented a competing offering to emerge. However, should AdaCore disappear or switch focus, Ada users would not be prevented from carrying on using its software (there is no lock) and a third party could take over maintenance. This is not a theoretical case, this has been done in the past either by companies looking at supporting their own version of GNAT, vendors occupying a specific niche that was left uncovered , or hobbyists developing their own builds.

With that in mind, it's clear that the "sole source" provider issue is a circumstantial — nothing is preventing other vendors from emerging if the conditions are met.

74.4 Is the Ada toolset complete?

A language by itself is of little use for the development of safety-critical software. Instead, a complete toolset is needed to accompany the development process, in particular tools for edition, testing, static analysis, etc.

AdaCore provides a number of these tools either in through its core or add-on package. These include (as of 2019):

- An IDE (GNAT Studio)
- An Eclipse plug-in (GNATbench)
- A debugger (GDB)
- A testing tool (GNATtest)
- A structural code coverage tool (GNATcoverage)
- A metric computation tool (GNATmetric)
- A coding standard checker (GNATcheck)
- Static analysis tools (CodePeer, SPARK Pro)
- A Simulink code generator (QGen)
- An Ada parser to develop custom tools (libadalang)

Ada is, however, an internationally standardized language, and many companies are providing third party solutions to complete the toolset. Overall, the language can be and is used with tools on par with their equivalent C counterparts.

74.5 Where can I find Ada or SPARK developers?

A common question from teams on the verge of selecting Ada and SPARK is how to manage the developer team growth and turnover. While Ada and SPARK are taught by a growing number of universities worldwide, it may still be challenging to hire new staff with prior Ada experience.

Fortunately, Ada's base semantics are very close to those of C/C++, so that a good embedded software developer should be able to learn it relatively easily. This course is definitely a resource available to get started. Online training material is also available, together with on-site in person training.

In general, getting an engineer operational in Ada and SPARK shouldn't take more than a few weeks worth of time.

74.6 How to introduce Ada and SPARK in an existing code base?

The most common scenario when introducing Ada and SPARK to a project or a team is to do it within a pre-existing C codebase, which can already spread over hundreds of thousands if not millions lines of code. Re-writing this software to Ada or SPARK is of course not practical and counterproductive.

Most teams select either a small piece of existing code which deserves particular attention, or new modules to develop, and concentrate on this. Developing this module or part of the application will also help in developing the coding patterns to be used for the particular project and company. This typically concentrates an effort of a few people on a few thousands lines of code. The resulting code can be linked to the rest of the C application. From there, the newly established practices and their benefit can slowly spread through the rest of the environment.

Establishing this initial core in Ada and SPARK is critical, and while learning the language isn't a particularly difficult task, applying it to its full capacity may require some expertise. One possibility to accelerate this initial process is to use AdaCore mentorship services.

CHAPTER

SEVENTYFIVE

CONCLUSION

Although Ada's syntax might seem peculiar to C developers at first glance, it was designed to increase readability and maintainability, rather than making it faster to write in a condensed manner — as it is often the case in C.

Especially in the embedded domain, C developers are used to working at a very low level, which includes mathematical operations on pointers, complex bit shifts, and logical bitwise operations. C is well designed for such operations because it was designed to replace Assembly language for faster, more efficient programming.

Ada can be used to describe high level semantics and architectures. The beauty of the language, however, is that it can be used all the way down to the lowest levels of the development, including embedded Assembly code or bit-level data management. However, although Ada supports bitwise operations such as masks and shifts, they should be relatively rarely needed. When translating C code to Ada, it's good practice to consider alternatives. In a lot of cases, these operations are used to insert several pieces of data into a larger structure. In Ada, this can be done by describing the structure layout at the type level through representation clauses, and then accessing this structure as any other. For example, we can interpret an arbitrary data type as a bit-field and perform low-level operations on it.

Because Ada is a strongly typed language, it doesn't define any implicit type conversions like C. If we try to compile Ada code that contains type mismatches, we'll get a compilation error. Because the compiler prevents mixing variables of different types without explicit type conversion, we can't accidentally end up in a situation where we assume something will happen implicitly when, in fact, our assumption is incorrect. In this sense, Ada's type system encourages programmers to think about data at a high level of abstraction. Ada supports overlays and unchecked conversions as a way of converting between unrelated data type, which are typically used for interfacing with low-level elements such as registers.

In Ada, arrays aren't interchangeable with operations on pointers like in C. Also, array types are considered first-class citizens and have dedicated semantics such as the availability of the array's boundaries at run-time. Therefore, unhandled array overflows are impossible unless checks are suppressed. Any discrete type can serve as an array index, and we can specify both the starting and ending bounds. In addition, Ada offers high-level operations for copying, slicing, and assigning values to arrays.

Although Ada supports pointers, most situations that would require a pointer in C do not in Ada. In the vast majority of the cases, indirect memory management can be hidden from the developer and thus prevent many potential errors. In C, pointers are typically used to pass references to subprograms, for example. In contrast, Ada parameter modes indicate the flow of information to the reader, leaving the means of passing that information to the compiler.

When translating pointers from C code to Ada, we need to assess whether they are needed in the first place. Ada pointers (access types) should only be used with complex structures that cannot be allocated at run-time. There are many situations that would require a pointer in C, but do not in Ada. For example, arrays — even when dynamically allocated —, results of functions, passing of large structures as parameters, access to registers, etc.

Because of the absence of namespaces, global names in C tend to be very long. Also, because of the absence of overloading, they can even encode type names in their name. In Ada, a package is a namespace. Also, we can use the private part of a package to declare private types and private subprograms. In fact, private types are useful for preventing the users of those types from depending on the implementation details. Another use-case is the prevention of package users from accessing the package state/data arbitrarily.

Ada has a dedicated set of features for interfacing with other languages, so we can easily interface with our existing C code before translating it to Ada. Also, GNAT includes automatic binding generators. Therefore, instead of re-writing the entire C code upfront, which isn't practical or cost-effective, we can selectively translate modules from C to Ada.

When it comes to implementing concurrency and real time, Ada offers several options. Ada provides high level constructs such as tasks and protected objects to express concurrency and synchronization, which can be used when running on top of an operating system such as Linux. On more constrained systems, such as bare metal or some real-time operating systems, a subset of the Ada tasking capabilities — known as the Ravenscar and Jorvik profiles — is available. Though restricted, this subset also has nice properties, in particular the absence of deadlock,the absence of priority inversion, schedulability and very small footprint. On bare metal systems, this also essentially means that Ada comes with its own real-time kernel. The advantage of using the full Ada tasking model or the restricted profiles is to enhance portability.

Ada includes many features typically used for embedded programming:

- Built-in support for handling interrupts, so we can process interrupts by attaching a handler — as a protected procedure — to it.
- Built-in support for handling both volatile and atomic data.
- Support for register overlays, which we can use to create a structure that facilitates manipulating bits from registers.
- Support for creating data streams for serialization of arbitrary information and transmission over a communication channel, such as a serial port.
- Built-in support for fixed-point arithmetic, which is an option when our target device doesn't have a floating-point unit or the result of calculations needs to be bit-exact.

Also, Ada compilers such as GNAT have built-in support for directly mixing Ada and Assembly code.

Ada also supports contracts, which can be associated with types and variables to refine values and define valid and invalid values. The most common kind of contract is a *range constraint* — using the **`range`** reserved word. Ada also supports contract-based programming in the form of preconditions and postconditions. One typical benefit of contract-based programming is the removal of defensive code in subprogram implementations.

It is common to see embedded software being used in a variety of configurations that require small changes to the code for each instance. In C, variability is usually achieved through macros and function pointers, the former being tied to static variability and the latter to dynamic variability. Ada offers many alternatives for both techniques, which aim at structuring possible variations of the software. Examples of static variability in Ada are: genericity, simple derivation, configuration pragma files, and configuration packages. Examples of dynamic variability in Ada are: records with discriminants, variant records — which may include the use of unions —, object orientation, pointers to subprograms, and design by components using dynamic libraries.

There shouldn't be significant performance differences between code written in Ada and code written in C — provided that they are semantically equivalent. One reason is that the two languages are fairly similar in the way they implement imperative semantics, in particular with regards to memory management or control flow. Therefore, they should be equivalent on average. However, when a piece of code in Ada is significantly slower than its counterpart in C, this usually comes from the fact that, while the two pieces of code appear

to be semantically equivalent, they happen to be actually quite different. Fortunately, there are strategies that we can use to improve the performance and make it equivalent to the C version. These are some examples:

- Clever use of compilation switches, which might optimize the performance of an application significantly.
- Suppression of checks at specific parts of the implementation.
  - Although runtime checks are very useful and should be used as much as possible, they can also increase the overhead of implementations at certain hot-spots.
- Restriction of assertions to development code.
  - For example, we may use assertions in the debug version of the code and turn them off in the release version.
  - Also, we may use formal proof to decide which assertions we turn off in the release version. By formally proving that assertions will never fail at run-time, we can safely deactivate them.

Formal proof — a form of static analysis — can give strong guarantees about checks, for all possible conditions and all possible inputs. It verifies conditions prior to execution, even prior to compilation, so we can remove bugs earlier in the development phase. This is far less expensive than doing so later because the cost to fix bugs increases exponentially over the phases of the project life cycle, especially after deployment. Preventing bug introduction into the deployed system is the least expensive approach of all.

Formal analysis for proof can be achieved through the SPARK subset of the Ada language combined with the **`gnatprove`** verification tool. SPARK is a subset encompassing most of the Ada language, except for features that preclude proof.

In Ada, several common programming errors that are not already detected at compile-time are detected instead at run-time, triggering *exceptions* that interrupt the normal flow of execution. However, we may be able to prove that the language-defined checks won't raise exceptions at run-time. This is known as proving *Absence of Run-Time Errors*. Successful proof of these checks is highly significant in itself. One of the major resulting benefits is that we can deploy the final executable with checks disabled.

In many situations, the migration of C code to Ada is justified by an increase in terms of integrity expectations, in which case it's expected that development costs will raise. However, Ada is a more expressive, powerful language, designed to reduce errors earlier in the life-cycle, thus reducing costs. Therefore, Ada makes it possible to write very safe and secure software at a lower cost than languages such as C.

CHAPTER

SEVENTYSIX

APPENDIX A: HANDS-ON OBJECT-ORIENTED PROGRAMMING

The goal of this appendix is to present a hands-on view on how to translate a system from C to Ada and improve it with object-oriented programming.

76.1 System Overview

Let's start with an overview of a simple system that we'll implement and use below. The main system is called AB and it combines two systems A and B. System AB is not supposed to do anything useful. However, it can serve as a good model for the hands-on we're about to start.

This is a list of requirements for the individual systems A and B, and the combined system AB:

- System A:
  - The system can be activated and deactivated.
    - During activation, the system's values are reset.
  - Its current value (in floating-point) can be retrieved.
    - This value is the average of the two internal floating-point values.
  - Its current state (activated or deactivated) can be retrieved.
- System B:
  - The system can be activated and deactivated.
    - During activation, the system's value is reset.
  - Its current value (in floating-point) can be retrieved.
  - Its current state (activated or deactivated) can be retrieved.
- System AB
  - The system contains an instance of system A and an instance of system B.
  - The system can be activated and deactivated.
    - System AB activates both systems A and B during its own activation.
    - System AB deactivates both systems A and B during its own deactivation.
  - Its current value (in floating-point) can be retrieved.
    - This value is the average of the current values of systems A and B.
  - Its current state (activated or deactivated) can be retrieved.
    - AB is only considered activated when both systems A and B are activated.

- The system's health can be checked.
  - This check consists in calculating the absolute difference D between the current values of systems A and B and checking whether D is below a threshold of 0.1.

The source-code in the following section contains an implementation of these requirements.

76.2 Non Object-Oriented Approach

In this section, we look into implementations (in both C and Ada) of system AB that don't make use of object-oriented programming.

76.2.1 Starting point in C

Let's start with an implementation in C for the system described above:

[C]

Listing 1: system_a.h

```c
typedef struct {
    float val[2];
    int   active;
} A;

void A_activate (A *a);

int A_is_active (A *a);

float A_value (A *a);

void A_deactivate (A *a);
```

Listing 2: system_a.c

```c
#include "system_a.h"

void A_activate (A *a)
{
    int i;

    for (i = 0; i < 2; i++)
    {
        a->val[i] = 0.0;
    }
    a->active = 1;
}

int A_is_active (A *a)
{
    return a->active == 1;
}

float A_value (A *a)
{
    return (a->val[0] + a->val[1]) / 2.0;
}
```

(continues on next page)

(continued from previous page)

```
23
24 void A_deactivate (A *a)
25 {
26     a->active = 0;
27 }
```

Listing 3: system_b.h

```
1  typedef struct {
2      float val;
3      int   active;
4  } B;
5
6  void B_activate (B *b);
7
8  int B_is_active (B *b);
9
10 float B_value (B *b);
11
12 void B_deactivate (B *b);
```

Listing 4: system_b.c

```
1  #include "system_b.h"
2
3  void B_activate (B *b)
4  {
5      b->val    = 0.0;
6      b->active = 1;
7  }
8
9  int B_is_active (B *b)
10 {
11     return b->active == 1;
12 }
13
14 float B_value (B *b)
15 {
16     return b->val;
17 }
18
19 void B_deactivate (B *b)
20 {
21     b->active = 0;
22 }
```

Listing 5: system_ab.h

```
1  #include "system_a.h"
2  #include "system_b.h"
3
4  typedef struct {
5      A a;
6      B b;
7  } AB;
8
9  void AB_activate (AB *ab);
10
11 int AB_is_active (AB *ab);
12
```

(continues on next page)

(continued from previous page)

```
float AB_value (AB *ab);

int AB_check (AB *ab);

void AB_deactivate (AB *ab);
```

Listing 6: system_ab.c

```
#include <math.h>
#include "system_ab.h"

void AB_activate (AB *ab)
{
    A_activate (&ab->a);
    B_activate (&ab->b);
}

int AB_is_active (AB *ab)
{
    return A_is_active(&ab->a) && B_is_active(&ab->b);
}

float AB_value (AB *ab)
{
    return (A_value (&ab->a) + B_value (&ab->b)) / 2;
}

int AB_check (AB *ab)
{
    const float threshold = 0.1;

    return fabs (A_value (&ab->a) - B_value (&ab->b)) < threshold;
}

void AB_deactivate (AB *ab)
{
    A_deactivate (&ab->a);
    B_deactivate (&ab->b);
}
```

Listing 7: main.c

```
#include <stdio.h>
#include "system_ab.h"

void display_active (AB *ab)
{
    if (AB_is_active (ab))
        printf ("System AB is active.\n");
    else
        printf ("System AB is not active.\n");
}

void display_check (AB *ab)
{
    if (AB_check (ab))
        printf ("System AB check: PASSED.\n");
    else
        printf ("System AB check: FAILED.\n");
}
```

(continues on next page)

(continued from previous page)

```c

int main()
{
    AB s;

    printf ("Activating system AB...\n");
    AB_activate (&s);

    display_active (&s);
    display_check (&s);

    printf ("Deactivating system AB...\n");
    AB_deactivate (&s);

    display_active (&s);
}
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.HandsOnOOP.System_AB_C
MD5: 649bcfe39504c853a0c3f43e1e048f34
```

Runtime output

```
Activating system AB...
System AB is active.
System AB check: PASSED.
Deactivating system AB...
System AB is not active.
```

Here, each system is implemented in a separate set of header and source-code files. For example, the API of system AB is in `system_ab.h` and its implementation in `system_ab.c`.

In the main application, we instantiate system AB and activate it. Then, we proceed to display the activation state and the result of the system's health check. Finally, we deactivate the system and display the activation state again.

76.2.2 Initial translation to Ada

The direct implementation in Ada is:

[Ada]

Listing 8: system_a.ads

```ada
package System_A is

   type Val_Array is array (Positive range <>) of Float;

   type A is record
      Val    : Val_Array (1 .. 2);
      Active : Boolean;
   end record;

   procedure A_Activate (E : in out A);

   function A_Is_Active (E : A) return Boolean;

   function A_Value (E : A) return Float;

```

(continues on next page)

(continued from previous page)

```
   procedure A_Deactivate (E : in out A);

end System_A;
```

Listing 9: system_a.adb

```
package body System_A is

   procedure A_Activate (E : in out A) is
   begin
      E.Val    := (others => 0.0);
      E.Active := True;
   end A_Activate;

   function A_Is_Active (E : A) return Boolean is
   begin
      return E.Active;
   end A_Is_Active;

   function A_Value (E : A) return Float is
   begin
      return (E.Val (1) + E.Val (2)) / 2.0;
   end A_Value;

   procedure A_Deactivate (E : in out A) is
   begin
      E.Active := False;
   end A_Deactivate;

end System_A;
```

Listing 10: system_b.ads

```
package System_B is

   type B is record
      Val    : Float;
      Active : Boolean;
   end record;

   procedure B_Activate (E : in out B);

   function B_Is_Active (E : B) return Boolean;

   function B_Value (E : B) return Float;

   procedure B_Deactivate (E : in out B);

end System_B;
```

Listing 11: system_b.adb

```
package body System_B is

   procedure B_Activate (E : in out B) is
   begin
      E.Val    := 0.0;
      E.Active := True;
   end B_Activate;

```

(continues on next page)

(continued from previous page)

```
   function B_Is_Active (E : B) return Boolean is
   begin
      return E.Active;
   end B_Is_Active;

   function B_Value (E : B) return Float is
   begin
      return E.Val;
   end B_Value;

   procedure B_Deactivate (E : in out B) is
   begin
      E.Active := False;
   end B_Deactivate;

end System_B;
```

Listing 12: system_ab.ads

```
with System_A; use System_A;
with System_B; use System_B;

package System_AB is

   type AB is record
      SA : A;
      SB : B;
   end record;

   procedure AB_Activate (E : in out AB);

   function AB_Is_Active (E : AB) return Boolean;

   function AB_Value (E : AB) return Float;

   function AB_Check (E : AB) return Boolean;

   procedure AB_Deactivate (E : in out AB);

end System_AB;
```

Listing 13: system_ab.adb

```
package body System_AB is

   procedure AB_Activate (E : in out AB) is
   begin
      A_Activate (E.SA);
      B_Activate (E.SB);
   end AB_Activate;

   function AB_Is_Active (E : AB) return Boolean is
   begin
      return A_Is_Active (E.SA) and B_Is_Active (E.SB);
   end AB_Is_Active;

   function AB_Value (E : AB) return Float is
   begin
      return (A_Value (E.SA) + B_Value (E.SB)) / 2.0;
   end AB_Value;
```

(continues on next page)

(continued from previous page)

```

   function AB_Check (E : AB) return Boolean is
      Threshold : constant := 0.1;
   begin
      return abs (A_Value (E.SA) - B_Value (E.SB)) < Threshold;
   end AB_Check;

   procedure AB_Deactivate (E : in out AB) is
   begin
      A_Deactivate (E.SA);
      B_Deactivate (E.SB);
   end AB_Deactivate;

end System_AB;
```

Listing 14: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with System_AB;   use System_AB;

procedure Main is

   procedure Display_Active (E : AB) is
   begin
      if AB_Is_Active (E) then
         Put_Line ("System AB is active");
      else
         Put_Line ("System AB is not active");
      end if;
   end Display_Active;

   procedure Display_Check (E : AB) is
   begin
      if AB_Check (E) then
         Put_Line ("System AB check: PASSED");
      else
         Put_Line ("System AB check: FAILED");
      end if;
   end Display_Check;

   S : AB;
begin
   Put_Line ("Activating system AB...");
   AB_Activate (S);

   Display_Active (S);
   Display_Check (S);

   Put_Line ("Deactivating system AB...");
   AB_Deactivate (S);

   Display_Active (S);
end Main;
```

Code block metadata

```
Project: Courses.Ada_For_Embedded_C_Dev.HandsOnOOP.System_AB_Ada
MD5: f2e3df0b3874e5edc5ea90c01961cf64
```

Runtime output

```
Activating system AB...
System AB is active
System AB check: PASSED
Deactivating system AB...
System AB is not active
```

As you can see, this is a direct translation that doesn't change much of the structure of the original C code. Here, the goal was to simply translate the system from one language to another and make sure that the behavior remains the same.

76.2.3 Improved Ada implementation

By analyzing this direct implementation, we may notice the following points:

- Packages `System_A`, `System_B` and `System_AB` are used to describe aspects of the same system. Instead of having three distinct packages, we could group them as child packages of a common parent package — let's call it `Simple`, since this system is supposed to be simple. This approach has the advantage of allowing us to later use the parent package to implement functionality that is common for all parts of the system.
- Since we have subprograms that operate on types `A`, `B` and `AB`, we should avoid exposing the record components by moving the type declarations to the private part of the corresponding packages.
- Since Ada supports subprogram overloading — as discussed in *this section from chapter 2* (page 1409) —, we don't need to have different names for subprograms with similar functionality. For example, instead of having `A_Is_Active` and `B_Is_Active`, we can simply name these functions `Is_Active` for both types `A` and `B`.
- Some of the functions — such as `A_Is_Active` and `A_Value` — are very simple, so we could simplify them with expression functions.

This is an update to the implementation that addresses all the points above:

[Ada]

Listing 15: simple.ads

```
package Simple
  with Pure
is
end Simple;
```

Listing 16: simple-system_a.ads

```
package Simple.System_A is

   type A is private;

   procedure Activate (E : in out A);

   function Is_Active (E : A) return Boolean;

System AB check: PASSED
Deactivating system AB...
System AB is not active
```

76.3 First Object-Oriented Approach

Until now, we haven't used any of the object-oriented programming features of the Ada language. So we can start by analyzing the API of systems A and B and deciding how to best abstract some of its elements using object-oriented programming.

76.3.1 Interfaces

The first thing we may notice is that we actually have two distinct sets of APIs there:

- one API for activating and deactivating the system.
- one API for retrieving the value of the system.

We can use this distinction to declare two interface types:

- `Activation_IF` for the `Activate` and `Deactivate` procedures and the `Is_Active` function;
- `Value_Retrieval_IF` for the `Value` function.

This is how the declaration could look like:

```
type Activation_IF is interface;

procedure Activate (E : in out Activation_IF) is abstract;
function Is_Active (E : Activation_IF) return Boolean is abstract;
procedure Deactivate (E : in out Activation_IF) is abstract;

type Value_Retrieval_IF is interface;

function Value (E : Value_Retrieval_IF) return Float is abstract;
```

Note that, because we are declaring interface types, all operations on those types must be abstract or, in the case of procedures, they can also be declared **`null`**. For example, we could change the declaration of the procedures above to this:

```
procedure Activate (E : in out Activation_IF) is null;
procedure Deactivate (E : in out Activation_IF) is null;
```

When an operation is declared abstract, we must override it for the type that derives from the interface. When a procedure is declared **`null`**, it acts as a do-nothing default. In this case, overriding the operation is optional for the type that derives from this interface.

76.3.2 Base type

Since the original system needs both interfaces we've just described, we have to declare another type that combines those interfaces. We can do this by declaring the interface type Sys_Base, which serves as the base type for systems A and B. This is the declaration:

```
type Sys_Base is interface and Activation_IF and Value_Retrieval_IF;
```

Since the system activation functionality is common for both systems A and B, we could implement it as part of Sys_Base. That would require changing the declaration from a simple interface to an abstract record:

```
type Sys_Base is abstract new Activation_IF and Value_Retrieval_IF
  with null record;
```

Now, we can add the Boolean component to the record (as a private component) and override the subprograms of the Activation_IF interface. This is the adapted declaration:

```
   type Sys_Base is abstract new Activation_IF and Value_Retrieval_IF with private;

   overriding procedure Activate (E : in out Sys_Base);
   overriding function Is_Active (E : Sys_Base) return Boolean;
   overriding procedure Deactivate (E : in out Sys_Base);

private

   type Sys_Base is abstract new Activation_IF and Value_Retrieval_IF with record
      Active : Boolean;
   end record;
```

76.3.3 Derived types

In the declaration of the Sys_Base type we've just seen, we're not overriding the Value function — from the Value_Retrieval_IF interface — for the Sys_Base type, so it remains an abstract function for Sys_Base. Therefore, the Sys_Base type itself remains abstract and needs be explicitly declared as such.

We use this strategy to ensure that all types derived from Sys_Base need to implement their own version of the Value function. For example:

```
type A is new Sys_Base with private;

overriding function Value (E : A) return Float;
```

Here, the A type is derived from the Sys_Base and it includes its own version of the Value function by overriding it. Therefore, A is not an abstract type anymore and can be used to declare objects:

```
procedure Main is
   Obj : A;
   V   : Float;
begin
   Obj.Activate;
   V := Obj.Value;
end Main;
```

Important

Note that the use of the **overriding** keyword in the subprogram declaration is not strictly necessary. In fact, we could leave this keyword out, and the code would still compile. However, if provided, the compiler will check whether the information is correct.

Using the **overriding** keyword can help to avoid bad surprises — when you *may think* that you're overriding a subprogram, but you're actually not. Similarly, you can also write **not overriding** to be explicit about subprograms that are new primitives of a derived type. For example:

```
not overriding function Check (E : AB) return Boolean;
```

We also need to declare the values that are used internally in systems A and B. For system A, this is the declaration:

```
   type A is new Sys_Base with private;

   overriding function Value (E : A) return Float;

private

   type Val_Array is array (Positive range <>) of Float;

   type A is new Sys_Base with record
      Val : Val_Array (1 .. 2);
   end record;
```

76.3.4 Subprograms from parent

In the previous implementation, we've seen that the `A_Activate` and `B_Activate` procedures perform the following steps:

- initialize internal values;
- indicate that the system is active (by setting the `Active` flag to **True**).

In the implementation of the `Activate` procedure for the `Sys_Base` type, however, we're only dealing with the second step. Therefore, we need to override the `Activate` procedure and make sure that we initialize internal values as well. First, we need to declare this procedure for type A:

```
type A is new Sys_Base with private;

overriding procedure Activate (E : in out A);
```

In the implementation of `Activate`, we should call the `Activate` procedure from the parent (`Sys_Base`) to ensure that whatever was performed for the parent will be performed in the derived type as well. For example:

```
overriding procedure Activate (E : in out A) is
begin
   E.Val := (others => 0.0);
   Sys_Base (E).Activate;     --  Calling Activate for Sys_Base type:
                              --  this call initializes the Active flag.
end;
```

Here, by writing `Sys_Base (E)`, we're performing a view conversion. Basically, we're telling the compiler to view `E` not as an object of type A, but of type `Sys_Base`. When we do this, any operation performed on this object will be done as if it was an object of `Sys_Base` type, which includes calling the `Activate` procedure of the `Sys_Base` type.

Important

If we write `T (Obj).Proc`, we're telling the compiler to call the `Proc` procedure of type T and apply it on `Obj`.

If we write `T'Class (Obj).Proc`, however, we're telling the compiler to dispatch the call. For example, if `Obj` is of derived type T2 and there's an overridden `Proc` procedure for type T2, then this procedure will be called instead of the `Proc` procedure for type T.

76.3.5 Type AB

While the implementation of systems A and B is almost straightforward, it gets more interesting in the case of system AB. Here, we have a similar API, but we don't need the activation mechanism implemented in the abstract type Sys_Base. Therefore, deriving from Sys_Base is not the best option. Instead, when declaring the AB type, we can simply use the same interfaces as we did for Sys_Base, but keep it independent from Sys_Base. For example:

```
   type AB is new Activation_IF and Value_Retrieval_IF with private;

private

   type AB is new Activation_IF and Value_Retrieval_IF with record
      SA : A;
      SB : B;
   end record;
```

Naturally, we still need to override all the subprograms that are part of the `Activation_IF` and `Value_Retrieval_IF` interfaces. Also, we need to implement the additional `Check` function that was originally only available on system AB. Therefore, we declare these subprograms:

```
overriding procedure Activate (E : in out AB);
overriding function Is_Active (E : AB) return Boolean;
overriding procedure Deactivate (E : in out AB);

overriding function Value (E : AB) return Float;

not overriding function Check (E : AB) return Boolean;
```

76.3.6 Updated source-code

Finally, this is the complete source-code example:

[Ada]

Listing 23: simple.ads

```
1  package Simple is
2
3     type Activation_IF is interface;
4
5     procedure Activate (E : in out Activation_IF) is abstract;
6     function Is_Active (E : Activation_IF) return Boolean is abstract;
7     procedure Deactivate (E : in out Activation_IF) is abstract;
8
```

(continues on next page)

(continued from previous page)

```
   type Value_Retrieval_IF is interface;

   function Value (E : Value_Retrieval_IF) return Float is abstract;

   type Sys_Base is abstract new Activation_IF and Value_Retrieval_IF
     with private;

   overriding procedure Activate (E : in out Sys_Base);
   overriding function Is_Active (E : Sys_Base) return Boolean;
   overriding procedure Deactivate (E : in out Sys_Base);

private

   type Sys_Base is abstract new Activation_IF and Value_Retrieval_IF
     with record
      Active : Boolean;
   end record;

end Simple;
```

Listing 24: simple.adb

```
package body Simple is

   overriding procedure Activate (E : in out Sys_Base) is
   begin
      E.Active := True;
   end Activate;

   overriding function Is_Active (E : Sys_Base) return Boolean is
      (E.Active);

   overriding procedure Deactivate (E : in out Sys_Base) is
   begin
      E.Active := False;
   end Deactivate;

end Simple;
```

Listing 25: simple-system_a.ads

```
package Simple.System_A is

   type A is new Sys_Base with private;

   overriding procedure Activate (E : in out A);

   overriding function Value (E : A) return Float;

private

   type Val_Array is array (Positive range <>) of Float;

   type A is new Sys_Base with record
      Val : Val_Array (1 .. 2);
   end record;

end Simple.System_A;
```

Listing 26: simple-system_a.adb

```
package body Simple.System_A is

   procedure Activate (E : in out A) is
   begin
      E.Val := (others => 0.0);
      Sys_Base (E).Activate;
   end Activate;

   function Value (E : A) return Float is
      pragma Assert (E.Val'Length = 2);
   begin
      return (E.Val (1) + E.Val (2)) / 2.0;
   end Value;

end Simple.System_A;
```

Listing 27: simple-system_b.ads

```
package Simple.System_B is

   type B is new Sys_Base with private;

```

Runtime output

```
Activating system AB...
System AB is active
System AB check: PASSED
Deactivating system AB...
System AB is not active
```

76.4 Further Improvements

When analyzing the complete source-code, we see that there are at least two areas that we could still improve.

76.4.1 Dispatching calls

The first issue concerns the implementation of the `Activate` procedure for types derived from `Sys_Base`. For those derived types, we're expecting that the `Activate` procedure of the parent must be called in the implementation of the overriding `Activate` procedure. For example:

```
package body Simple.System_A is

   procedure Activate (E : in out A) is
   begin
```

(continues on next page)

(continued from previous page)

```
      E.Val := (others => 0.0);
      Activate (Sys_Base (E));
   end;
```

If a developer forgets to call that specific `Activate` procedure, however, the system won't work as expected. A better strategy could be the following:

- Declare a new `Activation_Reset` procedure for `Sys_Base` type.
- Make a dispatching call to the `Activation_Reset` procedure in the body of the `Activate` procedure (of the `Sys_Base` type).
- Let the derived types implement their own version of the `Activation_Reset` procedure.

This is a simplified view of the implementation using the points described above:

```
package Simple is

   type Sys_Base is abstract new Activation_IF and Value_Retrieval_IF with
     private;

   not overriding procedure Activation_Reset (E : in out Sys_Base) is abstract;

end Simple;

package body Simple is

   procedure Activate (E : in out Sys_Base) is
   begin
      --  NOTE: calling "E.Activation_Reset" does NOT dispatch!
      --        We need to use the 'Class attribute here --- not using this
      --        attribute is an error that will be caught by the compiler.
      Sys_Base'Class (E).Activation_Reset;

      E.Active := True;
   end Activate;

end Simple;

package Simple.System_A is

   type A is new Sys_Base with private;

private

   type Val_Array is array (Positive range <>) of Float;

   type A is new Sys_Base with record
      Val : Val_Array (1 .. 2);
   end record;

   overriding procedure Activation_Reset (E : in out A);

end Simple.System_A;

package body Simple.System_A is

   procedure Activation_Reset (E : in out A) is
   begin
      E.Val    := (others => 0.0);
   end Activation_Reset;
```

(continues on next page)

(continued from previous page)

```
end Simple.System_A;
```

An important detail is that, in the implementation of Activate, we use Sys_Base'Class to ensure that the call to Activation_Reset will dispatch. If we had just written E.Activation_Reset instead, then we would be calling the Activation_Reset procedure of Sys_Base itself, which is not what we actually want here. The compiler will catch the error if you don't do the conversion to the class-wide type, because it would otherwise be a statically-bound call to an abstract procedure, which is illegal at compile-time.

76.4.2 Dynamic allocation

The next area that we could improve is in the declaration of the system AB. In the previous implementation, we were explicitly describing the two components of that system, namely a component of type A and a component of type B:

```
type AB is new Activation_IF and Value_Retrieval_IF with record
   SA : A;
   SB : B;
end record;
```

Of course, this declaration matches the system requirements that we presented in the beginning. However, we could use strategies that make it easier to incorporate requirement changes later on. For example, we could hide this information about systems A and B by simply declaring an array of components of type **access** Sys_Base'Class and allocate them dynamically in the body of the package. Naturally, this approach might not be suitable for certain platforms. However, the advantage would be that, if we wanted to replace the component of type B by a new component of type C, for example, we wouldn't need to change the interface. This is how the updated declaration could look like:

```
type Sys_Base_Class_Access is access Sys_Base'Class;
type Sys_Base_Array is array (Positive range <>) of Sys_Base_Class_Access;

type AB is limited new Activation_IF and Value_Retrieval_IF with record
   S_Array : Sys_Base_Array (1 .. 2);
end record;
```

Important

Note that we're now using the **limited** keyword in the declaration of type AB. That is necessary because we want to prevent objects of type AB being copied by assignment, which would lead to two objects having the same (dynamically allocated) subsystems A and B internally. This change requires that both Activation_IF and Value_Retrieval_IF are declared limited as well.

The body of Activate could then allocate those components:

```
procedure Activate (E : in out AB) is
begin
   E.S_Array := (new A, new B);
   for S of E.S_Array loop
      S.Activate;
   end loop;
end Activate;
```

And the body of Deactivate could deallocate them:

```
procedure Deactivate (E : in out AB) is
   procedure Free is
     new Ada.Unchecked_Deallocation (Sys_Base'Class, Sys_Base_Class_Access);
begin
   for S of E.S_Array loop
      S.Deactivate;
      Free (S);
   end loop;
end Deactivate;
```

76.4.3 Limited controlled types

Another approach that we could use to implement the dynamic allocation of systems A and B is to declare AB as a limited controlled type — based on the `Limited_Controlled` type of the `Ada.Finalization` package.

The `Limited_Controlled` type includes the following operations:

- `Initialize`, which is called when objects of a type derived from the `Limited_Controlled` type are being created — by declaring an object of the derived type, for example —, and
- `Finalize`, which is called when objects are being destroyed — for example, when an object gets out of scope at the end of a subprogram where it was created.

In this case, we must override those procedures, so we can use them for dynamic memory allocation. This is a simplified view of the update implementation:

```
package Simple.System_AB is

   type AB is limited new Ada.Finalization.Limited_Controlled and
     Activation_IF and Value_Retrieval_IF with private;

   overriding procedure Initialize (E : in out AB);
   overriding procedure Finalize   (E : in out AB);

end Simple.System_AB;

package body Simple.System_AB is

   overriding procedure Initialize (E : in out AB) is
   begin
      E.S_Array := (new A, new B);
   end Initialize;

   overriding procedure Finalize   (E : in out AB) is
      procedure Free is
        new Ada.Unchecked_Deallocation (Sys_Base'Class, Sys_Base_Class_Access);
   begin
      for S of E.S_Array loop
         Free (S);
      end loop;
   end Finalize;

end Simple.System_AB;
```

76.4.4 Updated source-code

Finally, this is the complete updated source-code example:

[Ada]

Listing 32: simple.ads

```ada
package Simple is

   type Activation_IF is limited interface;

   procedure Activate (E : in out Activation_IF) is abstract;
   function Is_Active (E : Activation_IF) return Boolean is abstract;
   procedure Deactivate (E : in out Activation_IF) is abstract;

   type Value_Retrieval_IF is limited interface;

   function Value (E : Value_Retrieval_IF) return Float is abstract;

   type Sys_Base is abstract new Activation_IF and Value_Retrieval_IF with
     private;

   overriding procedure Activate (E : in out Sys_Base);
   overriding function Is_Active (E : Sys_Base) return Boolean;
   overriding procedure Deactivate (E : in out Sys_Base);

   not overriding procedure Activation_Reset (E : in out Sys_Base) is abstract;

private

   type Sys_Base is abstract new Activation_IF and Value_Retrieval_IF with
      record
         Active : Boolean;
      end record;

end Simple;
```

Listing 33: simple.adb

```ada
package body Simple is

   procedure Activate (E : in out Sys_Base) is
   begin
      --  NOTE: calling "E.Activation_Reset" does NOT dispatch!
      --        We need to use the 'Class attribute:
      Sys_Base'Class (E).Activation_Reset;

      E.Active := True;
   end Activate;

   function Is_Active (E : Sys_Base) return Boolean is
      (E.Active);

   procedure Deactivate (E : in out Sys_Base) is
   begin
      E.Active := False;
   end Deactivate;

end Simple;
```

Listing 34: simple-system_a.ads

```

Project: Courses.Ada_For_Embedded_C_Dev.HandsOnOOP.System_AB_Ada_OOP_2
MD5: f8d0d4a07aaa045cb30bddc88db2215a
```

Runtime output

```
Activating system AB...
System AB is active
System AB check: PASSED
Deactivating system AB...
System AB is not active
```

Naturally, this is by no means the best possible implementation of system AB. By applying other software design strategies that we haven't covered here, we could most probably think of different ways to use object-oriented programming to improve this implementation. Also, in comparison to the *original implementation* (page 1581), we recognize that the amount of source-code has grown. On the other hand, we now have a system that is factored nicely, and also more extensible.

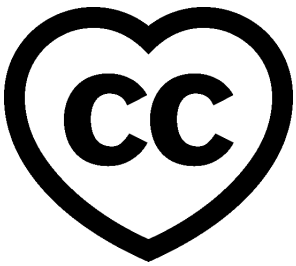
Copyright © 2018 – 2022, AdaCore

This book is published under a CC BY-SA license, which means that you can copy, redistribute, remix, transform, and build upon the content for any purpose, even commercially, as long as you give appropriate credit, provide a link to the license, and indicate if changes were made. If you remix, transform, or build upon the material, you must distribute your contributions under the same license as the original. You can find license details on this page[338]



This book presents the SPARK technology — the SPARK subset of Ada and its supporting static analysis tools — through an example-driven comparison with the rules in the widely known MISRA C subset of the C language.

This document was prepared by Yannick Moy, with contributions and review from Ben Brosgol.

Note: The code examples in this course use an 80-column limit, which is a typical limit for Ada code. Note that, on devices with a small screen size, some code examples might be difficult to read.

Note: Each code example from this book has an associated "code block metadata", which contains the name of the "project" and an MD5 hash value. This information is used to identify a single code example.

You can find all code examples in a zip file, which you can download from the learn website[339]. The directory structure in the zip file is based on the code block metadata. For example, if you're searching for a code example with this metadata:

- Project: Courses.Intro_To_Ada.Imperative_Language.Greet
- MD5: cba89a34b87c9dfa71533d982d05e6ab

you will find it in this directory:

```
projects/Courses/Intro_To_Ada/Imperative_Language/Greet/
cba89a34b87c9dfa71533d982d05e6ab/
```

In order to use this code example, just follow these steps:

1. Unpack the zip file;
2. Go to target directory;
3. Start GNAT Studio on this directory;
4. Build (or compile) the project;
5. Run the application (if a main procedure is available in the project).

CHAPTER

SEVENTYSEVEN

PREFACE

MISRA C appeared in 1998 as a coding standard for C; it focused on avoiding error-prone programming features of the C programming language rather than on enforcing a particular programming style. A study of coding standards for C by Les Hatton[340] found that, compared to ten typical coding standards for C, MISRA C was the only one to focus exclusively on error avoidance rather than style enforcement, and by a very large margin.

The popularity of the C programming language, as well as its many traps and pitfalls, have led to the huge success of MISRA C in domains where C is used for high-integrity sofware. This success has driven tool vendors to propose many competing implementations of MISRA C[341] checkers. Tools compete in particular on the coverage of MISRA C guidelines that they help enforce, as it is impossible to enforce the 16 directives and 143 rules (collectively referred to as guidelines) of MISRA C.

The 16 directives are broad guidelines, and it is not possible to define compliance in a unique and automated way. For example, "*all code should be traceable to documented requirements*" (Directive 3.1). Thus no tool is expected to enforce directives, as the MISRA C:2012 states in introduction to the guidelines: "*different tools may place widely different interpretations on what constitutes a non-compliance.*"

The 143 rules on the contrary are completely and precisely defined, and "*static analysis tools should be capable of checking compliance with rules*". But the same sentence continues with "*subject to the limitations described in Section 6.5*", which addresses "decidability of rules". It turns out that 27 rules out of 143 are not decidable, so no tool can always detect all violations of these rules without at the same time reporting "false alarms" on code that does not constitute a violation.

An example of an undecidable rule is rule 1.3: "*There shall be no occurrence of undefined or critical unspecified behaviour.*" Appendix H of MISRA:C 2012 lists hundreds of cases of undefined and critical unspecified behavior in the C programming language standard, a majority of which are not individually decidable. For the most part, MISRA C checkers ignore undecidable rules such as rule 1.3 and instead focus on the 116 rules for which detection of violations can be automated. It is telling in that respect that the MISRA C:2012 document and its accompanying set of examples (which can be downloaded from the MISRA website[342]) does not provide any example for rule 1.3.

However, violations of undecidable rules such as rule 1.3 are known to have dramatic impact on software quality. Violations of rule 1.3 in particular are commonly amplified by compilers using the permission in the C standard to optimize aggressively without looking at the consequences for programs with undefined or critical unspecified behavior. It would be valid to ignore these rules if violations did not occur in practice, but on the contrary even experienced programmers write C code with undefined or critical unspecified behavior. An example comes from the MISRA C Committee itself in its "Appendix I: Example deviation record" of the MISRA C:2012 document, repeated in "Appendix A: Example deviation record" of the MISRA C: Compliance 2016 document[343], where the following code is proposed as

[340] https://www.leshatton.org/Documents/MISRAC.pdf
[341] https://en.wikipedia.org/wiki/MISRA_C
[342] https://www.misra.org.uk
[343] https://www.misra.org.uk/LinkClick.aspx?fileticket=w_Syhpkf7xA%3d&tabid=57

a deviation of rule 10.6 "*The value of a composite expression shall not be assigned to an object with wider essential type*":

```
uint32_t prod = qty * time_step;
```

Here, the multiplication of two unsigned 16-bit values and assignment of the result to an unsigned 32-bit variable constitutes a violation of the aforementioned rule, which gets justified for efficiency reasons. What the authors seem to have missed is that the multiplication is then performed with the signed integer type **`int`** instead of the target unsigned type **`uint32_t`**. Thus the multiplication of two unsigned 16-bit values may lead to an overflow of the 32-bit intermediate signed result, which is an occurrence of an undefined behavior. In such a case, a compiler is free to assume that the value of `prod` cannot exceed 2^{31} - 1 (the maximal value of a signed 32-bit integer) as otherwise an undefined behavior would have been triggered. For example, the undefined behavior with values 65535 for `qty` and `time_step` is reported when running the code compiled by either the GCC or LLVM compiler with option `-fsanitize=undefined`.

The MISRA C checkers that detect violations of undecidable rules are either unsound tools that can detect only some of the violations, or sound tools that guarantee to detect all such violations at the cost of possibly many false reports of violations. This is a direct consequence of undecidability. However, static analysis technology is available that can achieve soundness without inundating users with false alarms. One example is the SPARK toolset developed by AdaCore, Altran and Inria, which is based on four principles:

- The base language Ada provides a solid foundation for static analysis through a well-defined language standard, strong typing and rich specification features.
- The SPARK subset of Ada restricts the base language in essential ways to support static analysis, by controlling sources of ambiguity such as side-effects and aliasing.
- The static analysis tools work mostly at the granularity of an individual function, making the analysis more precise and minimizing the possibility of false alarms.
- The static analysis tools are interactive, allowing users to guide the analysis if necessary or desired.

In this document, we show how SPARK can be used to achieve high code quality with guarantees that go beyond what would be feasible with MISRA C.

An on-line and interactive version of this document is available at AdaCore's learn.adacore.com site[344].

CHAPTER

SEVENTYEIGHT

ENFORCING BASIC PROGRAM CONSISTENCY

Many consistency properties that are taken for granted in other languages are not enforced in C. The basic property that all uses of a variable or function are consistent with its type is not enforced by the language and is also very difficult to enforce by a tool. Three features of C contribute to that situation:

- the textual-based inclusion of files means that every included declaration is subject to a possibly different reinterpretation depending on context.
- the lack of consistency requirements across translation units means that type inconsistencies can only be detected at link time, something linkers are ill-equipped to do.
- the default of making a declaration externally visible means that declarations that should be local will be visible to the rest of the program, increasing the chances for inconsistencies.

MISRA C contains guidelines on all three fronts to enforce basic program consistency.

78.1 Taming Text-Based Inclusion

The text-based inclusion of files is one of the dated idiosyncracies of the C programming language that was inherited by C++ and that is known to cause quality problems, especially during maintenance. Although multiple inclusion of a file in the same translation unit can be used to emulate template programming, it is generally undesirable. Indeed, MISRA C defines Directive 4.10 precisely to forbid it for header files: "*Precautions shall be taken in order to prevent the contents of a header file being included more than once*".

The subsequent section on "Preprocessing Directives" contains 14 rules restricting the use of text-based inclusion through preprocessing. Among other things these rules forbid the use of the *#undef* directive (which works around conflicts in macro definitions introduced by text-based inclusion) and enforces the well-known practice of enclosing macro arguments in parentheses (to avoid syntactic reinterpretations in the context of the macro use).

SPARK (and more generally Ada) does not suffer from these problems, as it relies on semantic inclusion of context instead of textual inclusion of content, using **with** clauses:

Listing 1: hello_world.adb

```
with Ada.Text_IO;

procedure Hello_World is
begin
   Ada.Text_IO.Put_Line ("hello, world!");
end Hello_World;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Program_Consistency.Hello_World
MD5: 5ed9609dd61bbcee252bb8529a6d3479
```

Runtime output

```
hello, world!
```

Note that **with** clauses are only allowed at the beginning of files; the compiler issues an error if they are used elsewhere:

Listing 2: hello_world.adb

```
procedure Hello_World is
   with Ada.Text_IO; -- Illegal
begin
   Ada.Text_IO.Put_Line ("hello, world!");
end Hello_World;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Program_Consistency.Hello_World
MD5: afa19e8e2c114a5832b49e9efcbe675e
```

Importing a unit (i.e., specifying it in a **with** clause) multiple times is harmless, as it is equivalent to importing it once, but a compiler warning lets us know about the redundancy:

Listing 3: hello_world.adb

```
with Ada.Text_IO;
with Ada.Text_IO; -- Legal but useless

procedure Hello_World is
begin
   Ada.Text_IO.Put_Line ("hello, world!");
end Hello_World;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Program_Consistency.Hello_World
MD5: 270928968d7beb4809af9e62df530722
```

Runtime output

```
hello, world!
```

The order in which units are imported is irrelevant. All orders are valid and have the same semantics.

No conflict arises from importing multiple units, even if the same name is defined in several, since each unit serves as namespace for the entities which it defines. So we can define our own version of `Put_Line` in some `Helper` unit and import it together with the standard version defined in `Ada.Text_IO`:

Listing 4: helper.ads

```
package Helper is
   procedure Put_Line (S : String);
end Helper;
```

Listing 5: helper.adb

```
with Ada.Text_IO;

package body Helper is
   procedure Put_Line (S : String) is
   begin
      Ada.Text_IO.Put_Line ("Start helper version");
      Ada.Text_IO.Put_Line (S);
      Ada.Text_IO.Put_Line ("End helper version");
   end Put_Line;
end Helper;
```

Listing 6: hello_world.adb

```
with Ada.Text_IO;
with Helper;

procedure Hello_World is
begin
   Ada.Text_IO.Put_Line ("hello, world!");
   Helper.Put_Line ("hello, world!");
end Hello_World;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Program_Consistency.Hello_World
MD5: 5fa012cc996e24e3b1f604e35bbba44f
```

Runtime output

```
hello, world!
Start helper version
hello, world!
End helper version
```

The only way a conflict can arise is if we want to be able to reference `Put_Line` directly, without using the qualified name `Ada.Text_IO.Put_Line` or `Helper.Put_Line`. The **use** clause makes public declarations from a unit available directly:

Listing 7: helper.ads

```
package Helper is
   procedure Put_Line (S : String);
end Helper;
```

Listing 8: helper.adb

```
with Ada.Text_IO;

package body Helper is
   procedure Put_Line (S : String) is
   begin
      Ada.Text_IO.Put_Line ("Start helper version");
      Ada.Text_IO.Put_Line (S);
      Ada.Text_IO.Put_Line ("End helper version");
   end Put_Line;
end Helper;
```

Listing 9: hello_world.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Helper; use Helper;

procedure Hello_World is
begin
   Ada.Text_IO.Put_Line ("hello, world!");
   Helper.Put_Line ("hello, world!");
   Put_Line ("hello, world!");  --  ERROR
end Hello_World;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Program_Consistency.Hello_World
MD5: 405e138d78e0dc869e8a340681d87e61
```

Build output

```
hello_world.adb:8:04: error: ambiguous expression (cannot resolve "Put_Line")
hello_world.adb:8:04: error: possible interpretation at helper.ads:2
hello_world.adb:8:04: error: possible interpretation at a-textio.ads:507
gprbuild: *** compilation phase failed
```

Here, both units `Ada.Text_IO` and `Helper` define a procedure `Put_Line` taking a `String` as argument, so the compiler cannot disambiguate the direct call to `Put_Line` and issues an error.

Note that it helpfully points to candidate declarations, so that the user can decide which qualified name to use as in the previous two calls.

Issues arising in C as a result of text-based inclusion of files are thus completely prevented in SPARK (and Ada) thanks to semantic import of units. Note that the C++ committee identified this weakness some time ago and has approved[345] the addition of *modules* to C++20, which provide a mechanism for semantic import of units.

78.2 Hardening Link-Time Checking

An issue related to text-based inclusion of files is that there is no single source for declaring the type of a variable or function. If a file `origin.c` defines a variable `var` and functions `fun` and `print`:

Listing 10: origin.c

```
#include <stdio.h>

int var = 0;
int fun() {
   return 1;
}
void print() {
   printf("var = %d\n", var);
}
```

Code block metadata

[345] http://www.open-std.org/jtc1/sc22/wg21/docs/papers/2018/n4720.pdf

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Program_Consistency.Origin
MD5: 3395f1e43408d5bc5c1e6b8431c959d6
```

and the corresponding header file `origin.h` declares `var`, `fun` and `print` as having external linkage:

Listing 11: origin.h

```
extern int var;
extern int fun();
extern void print();
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Program_Consistency.Origin
MD5: e8e880a16f5099dc1e0a75ffeeeb9468
```

then client code can include `origin.h` with declarations for `var` and `fun`:

Listing 12: main.c

```
#include "origin.h"

int main() {
   var = fun();
   print();
   return 0;
}
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Program_Consistency.Origin
MD5: 3d4582d3956897b657778ae355d0ef1b
```

Runtime output

```
var = 1
```

or, equivalently, repeat these declarations directly:

Listing 13: main.c

```
extern int var;
extern int fun();
extern void print();

int main() {
   var = fun();
   print();
   return 0;
}
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Program_Consistency.Origin
MD5: 4b25aa011b580f92f2831a48008fbef6
```

Runtime output

```
var = 1
```

Then, if an inconsistency is introduced in the type of `var` of `fun` between these alternative declarations and their actual type, the compiler cannot detect it. Only the linker, which has access to the set of object files for a program, can detect such inconsistencies. However, a linker's main task is to link, not to detect inconsistencies, and so inconsistencies in the type of variables and functions in most cases cannot be detected. For example, most linkers cannot detect if the type of `var` or the return type of `fun` is changed to **`float`** in the declarations above. With the declaration of `var` changed to **`float`**, the above program compiles and runs without errors, producing the erroneous output `var = 1065353216` instead of `var =1`. With the return type of `fun` changed to **`float`** instead, the program still compiles and runs without errors, producing this time the erroneous output `var = 0`.

The inconsistency just discussed is prevented by MISRA C Rule 8.3 "*All declarations of an object or function shall use the same names and type qualifiers*". This is a decidable rule, but it must be enforced at system level, looking at all translation units of the complete program. MISRA C Rule 8.6 also requires a unique definition for a given identifier across translation units, and Rule 8.5 requires that an external declaration shared between translation units comes from the same file. There is even a specific section on "Identifiers" containing 9 rules requiring uniqueness of various categories of identifiers.

SPARK (and more generally Ada) does not suffer from these problems, as it relies on semantic inclusion of context using **`with`** clauses to provide a unique declaration for each entity.

78.3 Going Towards Encapsulation

Many problems in C stem from the lack of encapsulation. There is no notion of namespace that would allow a file to make its declarations available without risking a conflict with other files. Thus MISRA C has a number of guidelines that discourage the use of external declarations:

- Directive 4.8 encourages hiding the definition of structures and unions in implementation files (`.c` files) when possible: "*If a pointer to a structure or union is never dereferenced within a translation unit, then the implementation of the object should be hidden.*"
- Rule 8.7 forbids the use of external declarations when not needed: "*Functions and objects should not be defined with external linkage if they are referenced in only one translation unit.*"
- Rule 8.8 forces the explicit use of keyword **`static`** when appropriate: "*The static storage class specifier shall be used in all declarations of objects and functions that have internal linkage.*"

The basic unit of modularization in SPARK, as in Ada, is the *package*. A package always has a spec (in an `.ads` file), which defines the interface to other units. It generally also has a body (in an `.adb` file), which completes the spec with an implementation. Only declarations from the package spec are visible from other units when they import (**`with`**) the package. In fact, only declarations from what is called the "visible part" of the spec (before the keyword **`private`**) are visible from units that **`with`** the package.

Listing 14: helper.ads

```
package Helper is
   procedure Public_Put_Line (S : String);
private
   procedure Private_Put_Line (S : String);
end Helper;
```

Listing 15: helper.adb

```
with Ada.Text_IO;

package body Helper is
   procedure Public_Put_Line (S : String) is
   begin
      Ada.Text_IO.Put_Line (S);
   end Public_Put_Line;

   procedure Private_Put_Line (S : String) is
   begin
      Ada.Text_IO.Put_Line (S);
   end Private_Put_Line;

   procedure Body_Put_Line (S : String) is
   begin
      Ada.Text_IO.Put_Line (S);
   end Body_Put_Line;
end Helper;
```

Listing 16: hello_world.adb

```
with Helper; use Helper;

procedure Hello_World is
begin
   Public_Put_Line ("hello, world!");
   Private_Put_Line ("hello, world!");  --  ERROR
   Body_Put_Line ("hello, world!");  --  ERROR
end Hello_World;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Program_Consistency.Hello_World
MD5: 148fd8101cc72413909675534f5e359c
```

Build output

```
hello_world.adb:6:04: error: "Private_Put_Line" is not visible
hello_world.adb:6:04: error: non-visible (private) declaration at helper.ads:4
hello_world.adb:7:04: error: "Body_Put_Line" is undefined
gprbuild: *** compilation phase failed
```

Note the different errors on the calls to the private and body versions of `Put_Line`. In the first case the compiler can locate the candidate procedure but it is illegal to call it from `Hello_World`, in the second case the compiler does not even know about any `Body_Put_Line` when compiling `Hello_World` since it only looks at the spec and not the body.

SPARK (and Ada) also allow defining a type in the private part of a package spec while simply declaring the type name in the public ("visible") part of the spec. This way, client code — i.e., code that **with**'s the package — can use the type, typically through a public API, but have no access to how the type is implemented:

Listing 17: vault.ads

```
package Vault is
   type Data is private;
   function Get (X : Data) return Integer;
   procedure Set (X : out Data; Value : Integer);
```

(continues on next page)

(continued from previous page)

```
private
   type Data is record
      Val : Integer;
   end record;
end Vault;
```

Listing 18: vault.adb

```
package body Vault is
   function Get (X : Data) return Integer is (X.Val);
   procedure Set (X : out Data; Value : Integer) is
   begin
      X.Val := Value;
   end Set;
end Vault;
```

Listing 19: information_system.ads

```
with Vault;

package Information_System is
   Archive : Vault.Data;
end Information_System;
```

Listing 20: hacker.adb

```
with Information_System;
with Vault;

procedure Hacker is
   V : Integer := Vault.Get (Information_System.Archive);
begin
   Vault.Set (Information_System.Archive, V + 1);
   Information_System.Archive.Val := 0;  --  ERROR
end Hacker;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Program_Consistency.Hacker
MD5: 065ed34dc727e2eb0bdc50a667cb1f78
```

Build output

```
hacker.adb:8:22: error: invalid prefix in selected component "Information_System.
 ↪Archive"
gprbuild: *** compilation phase failed
```

Note that it is possible to declare a variable of type `Vault.Data` in package `Information_System` and to get/set it through its API in procedure `Hacker`, but not to directly access its `Val` field.

CHAPTER

SEVENTYNINE

ENFORCING BASIC SYNTACTIC GUARANTEES

C's syntax is concise but also very permissive, which makes it easy to write programs whose effect is not what was intended. MISRA C contains guidelines to:

- clearly distinguish code from comments
- specially handle function parameters and result
- ensure that control structures are not abused

79.1 Distinguishing Code and Comments

The problem arises from block comments in C, starting with `/*` and ending with `*/`. These comments do not nest with other block comments or with line comments. For example, consider a block comment surrounding three lines that each increase variable a by one:

```
/*
++a;
++a;
++a; */
```

Now consider what happens if the first line is commented out using a block comment and the third line is commented out using a line comment (also known as a C++ style comment, allowed in C since C99):

```
/*
/* ++a; */
++a;
// ++a; */
```

The result of commenting out code that was already commented out is that the second line of code becomes live! Of course, the above example is simplified, but similar situations do arise in practice, which is the reason for MISRA C Directive 4.1 "*Sections of code should not be 'commented out'*". This is reinforced with Rules 3.1 and 3.2 from the section on "Comments" that forbid in particular the use of `/*` inside a comment like we did above.

These situations cannot arise in SPARK (or in Ada), as only line comments are permitted, using `--`:

```
--  A := A + 1;
--  A := A + 1;
--  A := A + 1;
```

So commenting again the first and third lines does not change the effect:

```
--  --  A := A + 1;
--  A := A + 1;
--  --  A := A + 1;
```

79.2 Specially Handling Function Parameters and Result

79.2.1 Handling the Result of Function Calls

It is possible in C to ignore the result of a function call, either implicitly or else explicitly by converting the result to **void**:

```
f();
(void)f();
```

This is particularly dangerous when the function returns an error status, as the caller is then ignoring the possibility of errors in the callee. Thus the MISRA C Directive 4.7: "*If a function returns error information, then that error information shall be tested*". In the general case of a function returning a result which is not an error status, MISRA C Rule 17.7 states that "*The value returned by a function having non-void return type shall be used*", where an explicit conversion to **void** counts as a use.

In SPARK, as in Ada, the result of a function call must be used, for example by assigning it to a variable or by passing it as a parameter, in contrast with procedures (which are equivalent to void-returning functions in C). SPARK analysis also checks that the result of the function is actually used to influence an output of the calling subprogram. For example, the first two calls to F in the following are detected as unused, even though the result of the function call is assigned to a variable, which is itself used in the second case:

Listing 1: fun.ads

```
1  package Fun is
2     function F return Integer is (1);
3  end Fun;
```

Listing 2: use_f.ads

```
1  procedure Use_F (Z : out Integer);
```

Listing 3: use_f.adb

```
1  with Fun; use Fun;
2
3  procedure Use_F (Z : out Integer) is
4     X, Y : Integer;
5  begin
6     X := F;
7
8     Y := F;
9     X := Y;
10
11    Z := F;
12 end Use_F;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Syntactic_Guarantees.Func_Return
MD5: 4fc78b4136677d6338984ab8ccfa5cd1
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
use_f.adb:6:06: warning: unused assignment
```

(continues on next page)

(continued from previous page)

```
use_f.adb:8:06: warning: unused assignment
use_f.adb:9:06: warning: unused assignment
```

Only the result of the third call is used to influence the value of an output of Use_F, here the output parameter Z of the procedure.

79.2.2 Handling Function Parameters

In C, function parameters are treated as local variables of the function. They can be modified, but these modifications won't be visible outside the function. This is an opportunity for mistakes. For example, the following code, which appears to swap the values of its parameters, has in reality no effect:

```
void swap (int x, int y) {
   int tmp = x;
   x = y;
   y = tmp;
}
```

MISRA C Rule 17.8 prevents such mistakes by stating that "*A function parameter should not be modified*".

No such rule is needed in SPARK, since function parameters are only inputs so cannot be modified, and procedure parameters have a *mode* defining whether they can be modified or not. Only parameters of mode **out** or ada:*in out* can be modified — and these are prohibited from functions in SPARK — and their modification is visible at the calling site. For example, assigning to a parameter of mode **in** (the default parameter mode if omitted) results in compilation errors:

Listing 4: swap.ads

```
1 procedure Swap (X, Y : Integer);
```

Listing 5: swap.adb

```
1 procedure Swap (X, Y : Integer) is
2    Tmp : Integer := X;
3 begin
4    X := Y;  --  ERROR
5    Y := Tmp;  --  ERROR
6 end Swap;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Syntactic_Guarantees.Swap
MD5: 187927c610e202f2e1eee6a602fda25e
```

Build output

```
swap.adb:4:04: error: assignment to "in" mode parameter not allowed
swap.adb:5:04: error: assignment to "in" mode parameter not allowed
gprbuild: *** compilation phase failed
```

Here is the output of AdaCore's GNAT compiler:

```
1.     procedure Swap (X, Y : Integer) is
2.        Tmp : Integer := X;
3.     begin
```

(continues on next page)

(continued from previous page)

```
4.         X := Y;  --  ERROR
           |
   >>> assignment to "in" mode parameter not allowed

5.         Y := Tmp;  --  ERROR
           |
   >>> assignment to "in" mode parameter not allowed

6.     end Swap;
```

The correct version of Swap in SPARK takes parameters of mode **in out**:

Listing 6: swap.ads

```
procedure Swap (X, Y : in out Integer);
```

Listing 7: swap.adb

```
procedure Swap (X, Y : in out Integer) is
   Tmp : constant Integer := X;
begin
   X := Y;
   Y := Tmp;
end Swap;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Syntactic_Guarantees.Swap
MD5: c983a229fc5a69db5dbb85f49a91b325
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
```

79.3 Ensuring Control Structures Are Not Abused

The previous issue (ignoring the result of a function call) is an example of a control structure being abused, due to the permissive syntax of C. There are many such examples, and MISRA C contains a number of guidelines to prevent such abuse.

79.3.1 Preventing the Semicolon Mistake

Because a semicolon can act as a statement, and because an if-statement and a loop accept a simple statement (possibly only a semicolon) as body, inserting a single semicolon can completely change the behavior of the code:

```
int func() {
   if (0)
      return 1;
   while (1)
      return 0;
   return 0;
}
```

As written, the code above returns with status 0. If a semicolon is added after the first line (`if (0);`), then the code returns with status 1. If a semicolon is added instead after the third line (`while (1);`), then the code does not return. To prevent such surprises, MISRA C Rule 15.6 states that "*The body of an iteration-statement or a selection-statement shall be a compound statement*" so that the code above must be written:

```
int func() {
   if (0) {
      return 1;
   }
   while (1) {
      return 0;
   }
   return 0;
}
```

Note that adding a semicolon after the test of the **if** or **while** statement has the same effect as before! But doing so would violate MISRA C Rule 15.6.

In SPARK, the semicolon is not a statement by itself, but rather a marker that terminates a statement. The null statement is an explicit **null**;, and all blocks of statements have explicit **begin** and **end** markers, which prevents mistakes that are possible in C. The SPARK (also Ada) version of the above C code is as follows:

Listing 8: func.ads

```
1  function Func return Integer;
```

Listing 9: func.adb

```
1  function Func return Integer is
2  begin
3     if False then
4        return 1;
5     end if;
6     while True loop
7        return 0;
8     end loop;
9     return 0;
10 end Func;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Syntactic_Guarantees.Semicolon
MD5: 34fc5967c41d337aada17429ee5f44e9
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
func.adb:3:04: warning: statement has no effect
func.adb:4:07: warning: this statement is never reached
```

79.3.2 Avoiding Complex Switch Statements

Switch statements are well-known for being easily misused. Control can jump to any case section in the body of the switch, which in C can be before any statement contained in the body of the switch. At the end of the sequence of statements associated with a case, execution continues with the code that follows unless a break is encountered. This is a recipe for mistakes, and MISRA C enforces a simpler *well-formed* syntax for switch statements defined in Rule 16.1: "*All switch statements shall be well-formed*".

The other rules in the section on "Switch statements" go on detailing individual consequences of Rule 16.1. For example Rule 16.3 forbids the fall-through from one case to the next: "*An unconditional break statement shall terminate every switch-clause*". As another example, Rule 16.4 mandates the presence of a default case to handle cases not taken into account explicitly: "*Every switch statement shall have a default label*".

The analog of the C switch statements in SPARK (and in Ada) is the case statement. This statement has a simpler and more robust structure than the C switch, with control automatically exiting after one of the case alternatives is executed, and the compiler checking that the alternatives are disjoint (like in C) and complete (unlike in C). So the following code is rejected by the compiler:

Listing 10: sign_domain.ads

```
package Sign_Domain is

   type Sign is (Negative, Zero, Positive);

   function Opposite (A : Sign) return Sign is
     (case A is  --  ERROR
         when Negative => Positive,
         when Positive => Negative);

   function Multiply (A, B : Sign) return Sign is
     (case A is
         when Negative        => Opposite (B),
         when Zero | Positive => Zero,
         when Positive        => B);  --  ERROR

   procedure Get_Sign (X : Integer; S : out Sign);

end Sign_Domain;
```

Listing 11: sign_domain.adb

```
package body Sign_Domain is

   procedure Get_Sign (X : Integer; S : out Sign) is
   begin
      case X is
         when 0 => S := Zero;
         when others => S := Negative;  --  ERROR
         when 1 .. Integer'Last => S := Positive;
      end case;
   end Get_Sign;

end Sign_Domain;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Syntactic_Guarantees.Case_Statement
MD5: d345a4d23b5b2402f8bd103e5e550a3b
```

Build output

```
sign_domain.adb:7:15: error: the choice "others" must appear alone and last
sign_domain.ads:6:07: error: missing case value: "Zero"
sign_domain.ads:14:15: error: duplication of choice value: "Positive" at line 13
gprbuild: *** compilation phase failed
```

The error in function `Opposite` is that the **`when`** choices do not cover all values of the target expression. Here, `A` is of the enumeration type `Sign`, so all three values of the enumeration must be covered.

The error in function `Multiply` is that **`Positive`** is covered twice, in the second and the third alternatives. This is not allowed.

The error in procedure `Get_Sign` is that the **`others`** choice (the equivalent of C **`default`** case) must come last. Note that an **`others`** choice would be useless in `Opposite` and `Multiply`, as all `Sign` values are covered.

Here is a correct version of the same code:

Listing 12: sign_domain.ads

```
1  package Sign_Domain is
2
3     type Sign is (Negative, Zero, Positive);
4
5     function Opposite (A : Sign) return Sign is
6       (case A is
7           when Negative => Positive,
8           when Zero     => Zero,
9           when Positive => Negative);
10
11    function Multiply (A, B : Sign) return Sign is
12      (case A is
13          when Negative => Opposite (B),
14          when Zero     => Zero,
15          when Positive => B);
16
17    procedure Get_Sign (X : Integer; S : out Sign);
18
19 end Sign_Domain;
```

Listing 13: sign_domain.adb

```
1  package body Sign_Domain is
2
3     procedure Get_Sign (X : Integer; S : out Sign) is
4     begin
5        case X is
6           when 0 => S := Zero;
7           when 1 .. Integer'Last => S := Positive;
8           when others => S := Negative;
9        end case;
10    end Get_Sign;
11
12 end Sign_Domain;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Syntactic_Guarantees.Case_Statement
MD5: 1c99fc53d2d2c0dddbea5e5b0a6c5746
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
sign_domain.ads:17:37: info: initialization of "S" proved
```

79.3.3 Avoiding Complex Loops

Similarly to C switches, for-loops in C can become unreadable. MISRA C thus enforces a simpler *well-formed* syntax for for-loops, defined in Rule 14.2: "*A for loop shall be well-formed*". The main effect of this simplification is that for-loops in C look like for-loops in SPARK (and in Ada), with a *loop counter* that is incremented or decremented at each iteration. Section 8.14 defines precisely what a loop counter is:

1. It has a scalar type;
2. Its value varies monotonically on each loop iteration; and
3. It is used in a decision to exit the loop.

In particular, Rule 14.2 forbids any modification of the loop counter inside the loop body. Here's the example used in MISRA C:2012 to illustrate this rule:

```
bool_t flag = false;

for ( int16_t i = 0; ( i < 5 ) && !flag; i++ )
{
  if ( C )
  {
    flag = true; /* Compliant - allows early termination of loop */
  }

  i = i + 3;     /* Non-compliant - altering the loop counter */
}
```

The equivalent SPARK (and Ada) code does not compile, because of the attempt to modify the value of the loop counter:

Listing 14: well_formed_loop.adb

```
1  procedure Well_Formed_Loop (C : Boolean) is
2     Flag : Boolean := False;
3  begin
4     for I in 0 .. 4 loop
5        exit when not Flag;
6
7        if C then
8           Flag := True;
9        end if;
10
11       I := I + 3;  --  ERROR
12    end loop;
13 end Well_Formed_Loop;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Syntactic_Guarantees.Well_Formed_Loop
MD5: 842564c961aa018e03e03f81439995ec
```

Build output

```
well_formed_loop.adb:11:07: error: assignment to loop parameter not allowed
gprbuild: *** compilation phase failed
```

Removing the problematic line leads to a valid program. Note that the additional condition being tested in the C for-loop has been moved to a separate exit statement at the start of the loop body.

SPARK (and Ada) loops can increase (or, with explicit syntax, decrease) the loop counter by 1 at each iteration.

```
for I in reverse 0 .. 4 loop
   ... -- Successive values of I are 4, 3, 2, 1, 0
end loop;
```

SPARK loops can iterate over any discrete type; i.e., integers as above or enumerations:

```
type Sign is (Negative, Zero, Positive);

for S in Sign loop
  ...
end loop;
```

79.3.4 Avoiding the Dangling Else Issue

C does not provide a closing symbol for an if-statement. This makes it possible to write the following code, which appears to try to return the absolute value of its argument, while it actually does the opposite:

Listing 15: main.c

```
#include <stdio.h>

int absval (int x) {
   int result = x;
   if (x >= 0)
      if (x == 0)
         result = 0;
   else
      result = -x;
   return result;
}

int main() {
   printf("absval(5) = %d\n", absval(5));
   printf("absval(0) = %d\n", absval(0));
   printf("absval(-10) = %d\n", absval(-10));
}
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Syntactic_Guarantees.Dangling_Else_C
MD5: c180a948dd8bed4e3b97efde1522214c
```

Runtime output

```
absval(5) = -5
absval(0) = 0
absval(-10) = -10
```

The warning issued by GCC or LLVM with option `-Wdangling-else` (implied by `-Wall`) gives a clue about the problem: although the **else** branch is written as though it completes the outer if-statement, in fact it completes the inner if-statement.

MISRA C Rule 15.6 avoids the problem: "*The body of an iteration-statement or a selection-statement shall be a compound statement*". That's the same rule as the one shown earlier for *Preventing the Semicolon Mistake* (page 1622). So the code for `absval` must be written:

Listing 16: main.c

```c
#include <stdio.h>

int absval (int x) {
   int result = x;
   if (x >= 0) {
      if (x == 0) {
         result = 0;
      }
   } else {
      result = -x;
   }
   return result;
}

int main() {
   printf("absval(5) = %d\n", absval(5));
   printf("absval(0) = %d\n", absval(0));
   printf("absval(-10) = %d\n", absval(-10));
}
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Syntactic_Guarantees.Dangling_Else_
 ↪MISRA_C
MD5: 2b76377aca52ff45ed6b19fa1f367473
```

Runtime output

```
absval(5) = 5
absval(0) = 0
absval(-10) = 10
```

which has the expected behavior.

In SPARK (as in Ada), each if-statement has a matching end marker end `if`; so the dangling-else problem cannot arise. The above C code is written as follows:

Listing 17: absval.ads

```
function Absval (X : Integer) return Integer;
```

Listing 18: absval.adb

```
function Absval (X : Integer) return Integer is
   Result : Integer := X;
begin
   if X >= 0 then
      if X = 0 then
         Result := 0;
      end if;
   else
      Result := -X;
   end if;
   return Result;
end Absval;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Syntactic_Guarantees.Dangling_Else_Ada
MD5: e867b6354ef7bdd89bae1673e888153a
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
absval.adb:9:17: medium: overflow check might fail, cannot prove upper bound for -
 ↪X [reason for check: result of negation must fit in a 32-bits machine integer]␣
 ↪[possible fix: add precondition (-X in Integer) to subprogram at absval.ads:1]
gnatprove: unproved check messages considered as errors
```

Interestingly, SPARK analysis detects here that the negation operation on line 9 might overflow. That's an example of runtime error detection which will be covered in the chapter on *Detecting Undefined Behavior* (page 1665).

CHAPTER

EIGHTY

ENFORCING STRONG TYPING

Annex C of MISRA C:2012 summarizes the problem succinctly:

> "*ISO C may be considered to exhibit poor type safety as it permits a wide range of implicit type conversions to take place. These type conversions can compromise safety as their implementation-defined aspects can cause developer confusion.*"

The most severe consequences come from inappropriate conversions involving pointer types, as they can cause memory safety violations. Two sections of MISRA C are dedicated to these issues: "Pointer type conversions" (9 rules) and "Pointers and arrays" (8 rules).

Inappropriate conversions between scalar types are only slightly less severe, as they may introduce arbitrary violations of the intended functionality. MISRA C has gone to great lengths to improve the situation, by defining a stricter type system on top of the C language. This is described in Appendix D of MISRA C:2012 and in the dedicated section on "The essential type model" (8 rules).

80.1 Enforcing Strong Typing for Pointers

Pointers in C provide a low-level view of the addressable memory as a set of integer addresses. To write at address 42, just go through a pointer:

Listing 1: main.c

```
int main() {
   int *p = 42;
   *p = 0;
   return 0;
}
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Pointers_C
MD5: 005183ada50cb6642f38a3640d77efff
```

Running this program is likely to hit a segmentation fault on an operating system, or to cause havoc in an embedded system, both because address 42 will not be correctly aligned on a 32-bit or 64-bit machine and because this address is unlikely to correspond to valid addressable data for the application. The compiler might issue a helpful warning on the above code (with option `-Wint-conversion` implied by `-Wall` in GCC or LLVM), but note that the warning disappears when explicitly converting value 42 to the target pointer type, although the problem is still present.

Beyond their ability to denote memory addresses, pointers are also used in C to pass references as inputs or outputs to function calls, to construct complex data structures with indirection or sharing, and to denote arrays of elements. Pointers are thus at once pervasive, powerful and fragile.

80.1.1 Pointers Are Not Addresses

In an attempt to rule out issues that come from direct addressing of memory with pointers, MISRA C states in Rule 11.4 that "*A conversion should not be performed between a pointer to object and an integer type*". As this rule is classified as only Advisory, MISRA C completes it with two Required rules:

- Rule 11.6: "*A cast shall not be performed between pointer to void and an arithmetic type*"
- Rule 11.7: "*A cast shall not be performed between pointer to object and a non-integer arithmetic type*"

In Ada, pointers are not addresses, and addresses are not integers. An opaque standard type `System.Address` is used for addresses, and conversions to/from integers are provided in a standard package `System.Storage_Elements`. The previous C code can be written as follows in Ada:

Listing 2: pointer.adb

```
with System;
with System.Storage_Elements;

procedure Pointer is
   A : constant System.Address := System.Storage_Elements.To_Address (42);
   M : aliased Integer with Address => A;
   P : constant access Integer := M'Access;
begin
   P.all := 0;
end Pointer;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Pointers_Ada
MD5: 32ac91ade61a39d3505d155d7b97a8a5
```

The integer value 42 is converted to a memory address `A` by calling `System.Storage_Elements.To_Address`, which is then used as the address of integer variable `M`. The pointer variable `P` is set to point to `M` (which is allowed because `M` is declared as **`aliased`**).

Ada requires more verbiage than C:

- The integer value `42` must be explicitly converted to type **`Address`**
- To get a pointer to a declared variable such as `M`, the declaration must be marked as **`aliased`**

The added syntax helps first in making clear what is happening and, second, in ensuring that a potentially dangerous feature (assigning to a value at a specific machine address) is not used inadvertently.

The above example is legal in SPARK, but the SPARK analysis tool issues warnings as it cannot control how the program or its environment may update the memory cell at address 42.

80.1.2 Pointers Are Not References

Passing parameters by reference is critical for efficient programs, but the absence of references distinct from pointers in C incurs a serious risk. Any parameter of a pointer type can be copied freely to a variable whose lifetime is longer than the object pointed to, a problem known as "dangling pointers". MISRA C forbids such uses in Rule 18.6: "*The address of an object with automatic storage shall not be copied to another object that persists after the first object has ceased to exist*". Unfortunately, enforcing this rule is difficult, as it is undecidable.

In SPARK, parameters can be passed by reference, but no pointer to the parameter can be stored past the return point of the function, which completely solves this issue. In fact, the decision to pass a parameter by copy or by reference rests in many cases with the compiler, but such compiler dependency has no effect on the functional behavior of a SPARK program. In the example below, the compiler may decide to pass parameter P of procedure `Rotate_X` either by copy or by reference, but regardless of the choice the postcondition of `Rotate_X` will hold: the final value of P will be modified by rotation around the X axis.

Listing 3: geometry.ads

```
package Geometry is

   type Point_3D is record
      X, Y, Z : Float;
   end record;

   procedure Rotate_X (P : in out Point_3D) with
     Post => P = P'Old'Update (Y => P.Z'Old, Z => -P.Y'Old);

end Geometry;
```

Listing 4: geometry.adb

```
package body Geometry is

   procedure Rotate_X (P : in out Point_3D) is
      Tmp : constant Float := P.Y;
   begin
      P.Y := P.Z;
      P.Z := -Tmp;
   end Rotate_X;

end Geometry;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Geometry
MD5: d3801cf1413887ffd5fff8b6b86b7742
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
geometry.ads:8:14: info: postcondition proved
```

SPARK's analysis tool can mathematically prove that the postcondition is true.

80.1.3 Pointers Are Not Arrays

The greatest source of vulnerabilities regarding pointers is their use as substitutes for arrays. Although the C language has a syntax for declaring and accessing arrays, this is just a thin syntactic layer on top of pointers. Thus:

- Array access is just pointer arithmetic;
- If a function is to manipulate an array then the array's length must be separately passed as a parameter; and
- The program is susceptible to the various vulnerabilities originating from the confusion of pointers and arrays, such as buffer overflow.

Consider a function that counts the number of times a value is present in an array. In C, this could be written:

Listing 5: main.c

```c
#include <stdio.h>

int count(int *p, int len, int v) {
   int count = 0;
   while (len--) {
      if (*p++ == v) {
         count++;
      }
   }
   return count;
}

int main() {
   int p[5] = {0, 3, 9, 3, 3};
   int c = count(p, 5, 3);
   printf("value 3 is seen %d times in p\n", c);
   return 0;
}
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Arrays_C
MD5: 34e3f7c2352e89a7c834184761293e57
```

Runtime output

```
value 3 is seen 3 times in p
```

Function `count` has no control over the range of addresses accessed from pointer `p`. The critical property that the `len` parameter is a valid length for an array of integers pointed to by parameter `p` rests completely with the caller of `count`, and `count` has no way to check that this is true.

To mitigate the risks associated with pointers being used for arrays, MISRA C contains eight rules in a section on "Pointers and arrays". These rules forbid pointer arithmetic (Rule 18.4) or, if this Advisory rule is not followed, require pointer arithmetic to stay within bounds (Rule 18.1). But, even if we rewrite the loop in `count` to respect all decidable MISRA C rules, the program's correctness still depends on the caller of `count` passing a correct value of `len`:

Listing 6: main.c

```c
#include <stdio.h>

int count(int *p, int len, int v) {
```

(continues on next page)

(continued from previous page)

```
   int count = 0;
   for (int i = 0; i < len; i++) {
      if (p[i] == v) {
         count++;
      }
   }
   return count;
}

int main() {
   int p[5] = {0, 3, 9, 3, 3};
   int c = count(p, 5, 3);
   printf("value 3 is seen %d times in p\n", c);
   return 0;
}
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Arrays_MISRA_C
MD5: d04179de3f1e309541b3d88e53eb5e3a
```

Runtime output

```
value 3 is seen 3 times in p
```

The resulting code is more readable, but still vulnerable to incorrect values of parameter `len` passed by the caller of `count`, which violates undecidable MISRA C Rules 18.1 (pointer arithmetic should stay within bounds) and 1.3 (no undefined behavior). Contrast this with the same function in SPARK (and Ada):

Listing 7: types.ads

```
package Types is
   type Int_Array is array (Positive range <>) of Integer;
end Types;
```

Listing 8: count.ads

```
with Types; use Types;

function Count (P : Int_Array; V : Integer) return Natural;
```

Listing 9: count.adb

```
function Count (P : Int_Array; V : Integer) return Natural is
   Count : Natural := 0;
begin
   for I in P'Range loop
      if P (I) = V then
         Count := Count + 1;
      end if;
   end loop;
   return Count;
end Count;
```

Listing 10: test_count.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Count;
```

(continues on next page)

(continued from previous page)

```
4
5  procedure Test_Count is
6     P : constant Int_Array := (0, 3, 9, 3, 3);
7     C : constant Integer := Count (P, 3);
8  begin
9     Put_Line ("value 3 is seen" & C'Img & " times in p");
10 end Test_Count;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Arrays_Ada
MD5: 82e9d18d4b8ad8aa87ca8520bd7b830c
```

Runtime output

```
value 3 is seen 3 times in p
```

The array parameter P is not simply a homogeneous sequence of Integer values. The compiler must represent P so that its lower and upper bounds (P'First and P'Last) and thus also its length (P'Length) can be retrieved. Function **Count** can simply loop over the range of valid array indexes P'First .. P'Last (or P'Range for short). As a result, function **Count** can be verified in isolation to be free of vulnerabilities such as buffer overflow, as it does not depend on the values of parameters passed by its callers. In fact, we can go further in SPARK and show that the value returned by **Count** is no greater than the length of parameter P by stating this property in the postcondition of **Count** and asking the SPARK analysis tool to prove it:

Listing 11: types.ads

```
1  package Types is
2     type Int_Array is array (Positive range <>) of Integer;
3  end Types;
```

Listing 12: count.ads

```
1  with Types; use Types;
2
3  function Count (P : Int_Array; V : Integer) return Natural with
4    Post => Count'Result <= P'Length;
```

Listing 13: count.adb

```
1  function Count (P : Int_Array; V : Integer) return Natural
2  is
3     Count : Natural := 0;
4  begin
5     for I in P'Range loop
6        pragma Loop_Invariant (Count <= I - P'First);
7        if P (I) = V then
8           Count := Count + 1;
9        end if;
10    end loop;
11    return Count;
12 end Count;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Arrays_Ada
MD5: 4c9a34614d53c4d268cbff787c9b73e6
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: flow analysis and proof ...
count.adb:6:30: info: loop invariant preservation proved
count.adb:6:30: info: loop invariant initialization proved
count.adb:6:41: info: overflow check proved
count.adb:8:25: info: overflow check proved
count.ads:4:11: info: postcondition proved
count.ads:4:28: info: range check proved
```

The only help that SPARK analysis required from the programmer, in order to prove the postcondition, is a loop invariant (a special kind of assertion) that reflects the value of `Count` at each iteration.

80.1.4 Pointers Should Be Typed

The C language defines a special pointer type `void*` that corresponds to an untyped pointer. It is legal to convert any pointer type to and from `void*`, which makes it a convenient way to simulate C++ style templates. Consider the following code which indirectly applies `assign_int` to integer `i` and `assign_float` to floating-point `f` by calling `assign` on both:

Listing 14: main.c

```c
#include <stdio.h>

void assign_int (int *p) {
   *p = 42;
}

void assign_float (float *p) {
   *p = 42.0;
}

typedef void (*assign_fun)(void *p);

void assign(assign_fun fun, void *p) {
   fun(p);
}

int main() {
   int i;
   float f;
   assign((assign_fun)&assign_int, &i);
   assign((assign_fun)&assign_float, &f);
   printf("i = %d; f = %f\n", i, f);
}
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Typed_Pointers_C
MD5: fc00ba9eb9764003748856934759 1cc2
```

Runtime output

```
i = 42; f = 42.000000
```

The references to the variables `i` and `f` are implicitly converted to the `void*` type as a way to apply `assign` to any second parameter `p` whose type matches the argument type of its first argument `fun`. The use of an untyped argument means that the responsibility for the correct typing rests completely with the programmer. Swap `i` and `f` in the calls to

assign and you still get a compilable program without warnings, that runs and produces completely bogus output:

```
i = 1109917696; f = 0.000000
```

instead of the expected:

```
i = 42; f = 42.000000
```

Generics in SPARK (and Ada) can implement the desired functionality in a fully typed way, with any errors caught at compile time, where procedure Assign applies its parameter procedure Initialize to its parameter V:

Listing 15: assign.ads

```
generic
   type T is private;
   with procedure Initialize (V : out T);
procedure Assign (V : out T);
```

Listing 16: assign.adb

```
procedure Assign (V : out T) is
begin
   Initialize (V);
end Assign;
```

Listing 17: apply_assign.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Assign;

procedure Apply_Assign is
   procedure Assign_Int (V : out Integer) is
   begin
      V := 42;
   end Assign_Int;

   procedure Assign_Float (V : out Float) is
   begin
      V := 42.0;
   end Assign_Float;

   procedure Assign_I is new Assign (Integer, Assign_Int);
   procedure Assign_F is new Assign (Float, Assign_Float);

   I : Integer;
   F : Float;
begin
   Assign_I (I);
   Assign_F (F);
   Put_Line ("I =" & I'Img & "; F =" & F'Img);
end Apply_Assign;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Typed_Pointers_Ada
MD5: af23d6f8a742676139aac38a385c7bf7
```

Runtime output

```
I = 42; F = 4.20000E+01
```

The generic procedure `Assign` must be instantiated with a specific type for T and a specific procedure (taking a single **`out`** parameter of this type) for `Initialize`. The procedure resulting from the instantiation applies to a variable of this type. So switching `I` and `F` above would result in an error detected by the compiler. Likewise, an instantiation such as the following would also be a compile-time error:

```
procedure Assign_I is new Assign (Integer, Assign_Float);
```

80.2 Enforcing Strong Typing for Scalars

In C, all scalar types can be converted both implicitly and explicitly to any other scalar type. The semantics is defined by rules of *promotion* and *conversion*, which can confuse even experts. One example was noted earlier, in the *Preface* (page 1609). Another example appears in an article introducing a safe library for manipulating scalars[346] by Microsoft expert David LeBlanc. In its conclusion, the author acknowledges the inherent difficulty in understanding scalar type conversions in C, by showing an early buggy version of the code to produce the minimum signed integer:

```
return (T)(1 << (BitCount()-1));
```

The issue here is that the literal `1` on the left-hand side of the shift is an **`int`**, so on a 64-bit machine with 32-bit **`int`** and 64-bit type T, the above is shifting 32-bit value `1` by 63 bits. This is a case of undefined behavior, producing an unexpected output with the Microsoft compiler. The correction is to convert the first literal `1` to T before the shift:

```
return (T)((T)1 << (BitCount()-1));
```

Although he'd asked some expert programmers to review the code, no one found this problem.

To avoid these issues as much as possible, MISRA C defines its own type system on top of C types, in the section on "The essential type model" (eight rules). These can be seen as additional typing rules, since all rules in this section are decidable, and can be enforced at the level of a single translation unit. These rules forbid in particular the confusing cases mentioned above. They can be divided into three sets of rules:

- restricting operations on types
- restricting explicit conversions
- restricting implicit conversions

80.2.1 Restricting Operations on Types

Apart from the application of some operations to floating-point arguments (the bitwise, mod and array access operations) which are invalid and reported by the compiler, all operations apply to all scalar types in C. MISRA C Rule 10.1 constrains the types on which each operation is possible as follows.

[346] https://msdn.microsoft.com/en-us/library/ms972705.aspx

Arithmetic Operations on Arithmetic Types

Adding two Boolean values, or an Apple and an Orange, might sound like a bad idea, but it is easily done in C:

Listing 18: main.c

```c
#include <stdbool.h>
#include <stdio.h>

int main() {
   bool b1 = true;
   bool b2 = false;
   bool b3 = b1 + b2;

   typedef enum {Apple, Orange} fruit;
   fruit f1 = Apple;
   fruit f2 = Orange;
   fruit f3 = f1 + f2;

   printf("b3 = %d; f3 = %d\n", b3, f3);

   return 0;
}
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Pointer_Arith_C
MD5: 30e28b34f616f8e6d35233a4ce698c23
```

Runtime output

```
b3 = 1; f3 = 1
```

No error from the compiler here. In fact, there is no undefined behavior in the above code. Variables b3 and f3 both end up with value 1. Of course it makes no sense to add Boolean or enumerated values, and thus MISRA C Rule 18.1 forbids the use of all arithmetic operations on Boolean and enumerated values, while also forbidding most arithmetic operations on characters. That leaves the use of arithmetic operations for signed or unsigned integers as well as floating-point types and the use of modulo operation `%` for signed or unsigned integers.

Here's an attempt to simulate the above C code in SPARK (and Ada):

Listing 19: bad_arith.ads

```
package Bad_Arith is

   B1 : constant Boolean := True;
   B2 : constant Boolean := False;
   B3 : constant Boolean := B1 + B2;

   type Fruit is (Apple, Orange);
   F1 : constant Fruit := Apple;
   F2 : constant Fruit := Orange;
   F3 : constant Fruit := F1 + F2;

end Bad_Arith;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Pointer_Arith_Ada
MD5: 984381fdcf1a682e1998f7881c0532f9
```

Build output

```
bad_arith.ads:5:32: error: there is no applicable operator "+" for type "Standard.
 ↪Boolean"
bad_arith.ads:10:30: error: there is no applicable operator "+" for type "Fruit"␣
 ↪defined at line 7
gprbuild: *** compilation phase failed
```

It is possible, however, to get the predecessor of a Boolean or enumerated value with `Value'Pred` and its successor with `Value'Succ`, as well as to iterate over all values of the type:

Listing 20: ok_arith.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Ok_Arith is

   B1 : constant Boolean := False;
   B2 : constant Boolean := Boolean'Succ (B1);
   B3 : constant Boolean := Boolean'Pred (B2);

   type Fruit is (Apple, Orange);
   F1 : constant Fruit := Apple;
   F2 : constant Fruit := Fruit'Succ (F1);
   F3 : constant Fruit := Fruit'Pred (F2);

begin
   pragma Assert (B1 = B3);
   pragma Assert (F1 = F3);

   for B in Boolean loop
      Put_Line (B'Img);
   end loop;

   for F in Fruit loop
      Put_Line (F'Img);
   end loop;
end Ok_Arith;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Pointer_Arith_Ada
MD5: 6ad400913a48fd815845b6a99d90ec2d
```

Runtime output

```
FALSE
TRUE
APPLE
ORANGE
```

Boolean Operations on Boolean

"Two bee or not two bee? Let's C":

Listing 21: main.c

```c
#include <stdbool.h>
#include <stdio.h>

int main() {
   typedef enum {Ape, Bee, Cat} Animal;
   bool answer = (2 * Bee) || ! (2 * Bee);
   printf("two bee or not two bee? %d\n", answer);
   return 0;
}
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Boolean_C
MD5: a9d4886827c983df51c9285fe3fd6c77
```

Runtime output

```
two bee or not two bee? 1
```

The answer to the question posed by Shakespeare's Hamlet is 1, since it reduces to A `or not` A and this is true in classical logic.

As previously noted, MISRA C forbids the use of the multiplication operator with an operand of an enumerated type. Rule 18.1 also forbids the use of Boolean operations "and", "or", and "not" (&&, ||, !, respectively, in C) on anything other than Boolean operands. It would thus prohibit the Shakespearian code above.

Below is an attempt to express the same code in SPARK (and Ada), where the Boolean operators are **and**, **or**, and **not**. The **and** and **or** operators evaluate both operands, and the language also supplies short-circuit forms that evaluate the left operand and only evaluate the right operand when its value may affect the result.

Listing 22: bad_hamlet.ads

```
package Bad_Hamlet is
   type Animal is (Ape, Bee, Cat);
   Answer : Boolean := 2 * Bee or not 2 * Bee; -- Illegal
end Bad_Hamlet;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Boolean_Ada
MD5: 9089114f9cc6495dabd6957b54b33bd2
```

Build output

```
bad_hamlet.ads:3:28: error: expected type universal integer
bad_hamlet.ads:3:28: error: found type "Animal" defined at line 2
bad_hamlet.ads:3:43: error: expected a modular type
bad_hamlet.ads:3:43: error: found type "Animal" defined at line 2
gprbuild: *** compilation phase failed
```

As expected, the compiler rejects this code. There is no available * operation that works on an enumeration type, and likewise no available **or** or **not** operation.

Bitwise Operations on Unsigned Integers

Here's a genetic engineering example that combines a Bee with a Dog to produce a Cat, by manipulating the atomic structure (the bits in its representation):

Listing 23: main.c

```c
#include <stdbool.h>
#include <assert.h>

int main() {
   typedef enum {Ape, Bee, Cat, Dog} Animal;
   Animal mutant = Bee ^ Dog;
   assert (mutant == Cat);
   return 0;
}
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Bitwise_C
MD5: 645b0b6155f1cb17d02c7bcbb976993c
```

This algorithm works by accessing the underlying bitwise representation of Bee and Dog (0x01 and 0x03, respectively) and, by applying the exclusive-or operator ^, transforming it into the underlying bitwise representation of a Cat (0x02). While powerful, manipulating the bits in the representation of values is best reserved for unsigned integers as illustrated in the book Hacker's Delight[347]. MISRA C Rule 18.1 thus forbids the use of all bitwise operations on anything but unsigned integers.

Below is an attempt to do the same in SPARK (and Ada). The bitwise operators are **and**, **or**, **xor**, and **not**, and the related bitwise functions are Shift_Left, Shift_Right, Shift_Right_Arithmetic, Rotate_Left and Rotate_Right:

Listing 24: bad_genetics.ads

```
package Bad_Genetics is
   type Animal is (Ape, Bee, Cat, Dog);
   Mutant : Animal := Bee xor Dog;  --  ERROR
   pragma Assert (Mutant = Cat);
end Bad_Genetics;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Bitwise_Ada
MD5: 3f7c3dd616f065016590d574200cf1db
```

Build output

```
bad_genetics.ads:3:27: error: there is no applicable operator "Xor" for type
 ↪"Animal" defined at line 2
gprbuild: *** compilation phase failed
```

The declaration of Mutant is illegal, since the **xor** operator is only available for Boolean and unsigned integer (modular) values; it is not available for Animal. The same restriction applies to the other bitwise operators listed above. If we really wanted to achieve the effect of the above code in legal SPARK (or Ada), then the following approach will work (the type Unsigned_8 is an 8-bit modular type declared in the predefined package Interfaces).

[347] http://www.hackersdelight.org/

Listing 25: unethical_genetics.ads

```
with Interfaces; use Interfaces;
package Unethical_Genetics is
   type Animal is (Ape, Bee, Cat, Dog);
   A      : constant array (Animal) of Unsigned_8 :=
               (Animal'Pos (Ape), Animal'Pos (Bee),
                Animal'Pos (Cat), Animal'Pos (Dog));
   Mutant : Animal := Animal'Val (A (Bee) xor A (Dog));
   pragma Assert (Mutant = Cat);
end Unethical_Genetics;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Bitwise_Ada_2
MD5: 359439d40740fe2d99e6f334ed3500f9
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
```

Note that **and**, **or**, **not** and **xor** are used both as logical operators and as bitwise operators, but there is no possible confusion between these two uses. Indeed the use of such operators on values from modular types is a natural generalization of their uses on Boolean, since values from modular types are often interpreted as arrays of Booleans.

80.2.2 Restricting Explicit Conversions

A simple way to bypass the restrictions of Rule 10.1 is to explicitly convert the arguments of an operation to a type that the rule allows. While it can often be useful to cast a value from one type to another, many casts that are allowed in C are either downright errors or poor replacements for clearer syntax.

One example is to cast from a scalar type to Boolean. A better way to express (**bool**)x is to compare x to the zero value of its type: x `!= 0` for integers, x `!= 0.0` for floats, x `!= '0'` for characters, x `!=` Enum where Enum is the first enumerated value of the type. Thus, MISRA C Rule 10.5 advises avoiding casting non-Boolean values to Boolean.

Rule 10.5 also advises avoiding other casts that are, at best, obscure:

- from a Boolean to any other scalar type
- from a floating-point value to an enumeration or a character
- from any scalar type to an enumeration

The rules are not symmetric, so although a float should not be cast to an enum, casting an enum to a float is allowed. Similarly, although it is advised to not cast a character to an enum, casting an enum to a character is allowed.

The rules in SPARK are simpler. There are no conversions between numeric types (integers, fixed-point and floating-point) and non-numeric types (such as Boolean, Character, and other enumeration types). Conversions between different non-numeric types are limited to those that make semantic sense, for example between a derived type and its parent type. Any numeric type can be converted to any other numeric type, with precise rules for rounding/truncating values when needed and run-time checking that the converted value is in the range associated with the target type.

80.2.3 Restricting Implicit Conversions

Rules 10.1 and 10.5 restrict operations on types and explicit conversions. That's not enough to avoid problematic C programs; a program violating one of these rules can be expressed using only implicit type conversions. For example, the Shakespearian code in section *Boolean Operations on Boolean* (page 1642) can be reformulated to satisfy both Rules 10.1 and 10.5:

Listing 26: main.c

```c
#include <stdbool.h>
#include <stdio.h>

int main() {
   typedef enum {Ape, Bee, Cat} Animal;
   int b = Bee;
   bool t = 2 * b;
   bool answer = t || ! t;
   printf("two bee or not two bee? %d\n", answer);
   return 0;
}
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Implicit_Conversion_C
MD5: a157dd05c5fe8926886361b533305e14
```

Runtime output

```
two bee or not two bee? 1
```

Here, we're implicitly converting the enumerated value Bee to an int, and then implicitly converting the integer value `2 * b` to a Boolean. This does not violate 10.1 or 10.5, but it is prohibited by MISRA C Rule 10.3: "*The value of an expression shall not be assigned to an object with a narrower essential type or of a different essential type category*".

Rule 10.1 also does not prevent arguments of an operation from being inconsistent, for example comparing a floating-point value and an enumerated value. But MISRA C Rule 10.4 handles this situation: "*Both operands of an operator in which the usual arithmetic conversions are performed shall have the same essential type category*".

In addition, three rules in the "Composite operators and expressions" section avoid common mistakes related to the combination of explicit/implicit conversions and operations.

The rules in SPARK (and Ada) are far simpler: there are no implicit conversions! This applies both between types of a different *essential type category* as MISRA C puts it, as well as between types that are structurally the same but declared as different types.

Listing 27: bad_conversions.adb

```
procedure Bad_Conversions is
   pragma Warnings (Off);
   F : Float := 0.0;
   I : Integer := 0;
   type Animal is (Ape, Bee, Cat);
   type My_Animal is new Animal; -- derived type
   A : Animal := Cat;
   M : My_Animal := Bee;
   B : Boolean := True;
   C : Character := 'a';
begin
   F := I;  --  ERROR
```

(continues on next page)

(continued from previous page)

```
   I := A;  --  ERROR
   A := B;  --  ERROR
   M := A;  --  ERROR
   B := C;  --  ERROR
   C := F;  --  ERROR
end Bad_Conversions;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Strong_Typing.Implicit_Conversion_Bad_
 ↪Ada
MD5: f10b50048595df0b4ed77c06a7508412
```

Build output

```
bad_conversions.adb:12:09: error: expected type "Standard.Float"
bad_conversions.adb:12:09: error: found type "Standard.Integer"
bad_conversions.adb:13:09: error: expected type "Standard.Integer"
bad_conversions.adb:13:09: error: found type "Animal" defined at line 5
bad_conversions.adb:14:09: error: expected type "Animal" defined at line 5
bad_conversions.adb:14:09: error: found type "Standard.Boolean"
bad_conversions.adb:15:09: error: expected type "My_Animal" defined at line 6
bad_conversions.adb:15:09: error: found type "Animal" defined at line 5
bad_conversions.adb:16:09: error: expected type "Standard.Boolean"
bad_conversions.adb:16:09: error: found type "Standard.Character"
bad_conversions.adb:17:09: error: expected type "Standard.Character"
bad_conversions.adb:17:09: error: found type "Standard.Float"
gprbuild: *** compilation phase failed
```

The compiler reports a mismatch on every statement in the above procedure (the declarations are all legal).

Adding explicit conversions makes the assignments to F and M valid, since SPARK (and Ada) allow conversions between numeric types and between a derived type and its parent type, but all other conversions are illegal:

Listing 28: bad_conversions.adb

```
procedure Bad_Conversions is
   pragma Warnings (Off);
   F : Float := 0.0;
   I : Integer := 0;
   type Animal is (Ape, Bee, Cat);
   type My_Animal is new Animal; -- derived type
   A : Animal := Cat;
   M : My_Animal := Bee;
   B : Boolean := True;
   C : Character := 'a';
begin
   F := Float (I);       --  OK
   I := Integer (A);     --  ERROR
   A := Animal (B);      --  ERROR
   M := My_Animal (A);   --  OK
   B := Boolean (C);     --  ERROR
   C := Character (F);   --  ERROR
end Bad_Conversions;
```

Code block metadata

```

gprbuild: *** compilation phase failed
```

Although an enumeration value cannot be converted to an integer (or *vice versa*) either implicitly or explicitly, SPARK (and Ada) provide functions to obtain the effect of a type conversion. For any enumeration type T, the function `T'Pos(e)` takes an enumeration value from type T and returns its relative position as an integer, starting at `0`. For example, `Animal'Pos(Bee)` is `1`, and `Boolean'Pos(False)` is `0`. In the other direction, `T'Val(n)`, where n is an integer, returns the enumeration value in type T at relative position n. If n is negative or greater then `T'Pos(T'Last)` then a run-time exception is raised.

Hence, the following is valid SPARK (and Ada) code; **`Character`** is defined as an enumeration type:

Listing 29: ok_conversions.adb

```
1  procedure Ok_Conversions is
2     pragma Warnings (Off);
3     F : Float := 0.0;
4     I : Integer := 0;
5     type Animal is (Ape, Bee, Cat);
6     type My_Animal is new Animal;
7     A : Animal := Cat;
8     M : My_Animal := Bee;
9     B : Boolean := True;
10    C : Character := 'a';
11 begin
12    F := Float (I);
13    I := Animal'Pos (A);
14    I := My_Animal'Pos (M);
15    I := Boolean'Pos (B);
16    I := Character'Pos (C);
17    I := Integer (F);
18    A := Animal'Val (2);
19 end Ok_Conversions;
```

CHAPTER

EIGHTYONE

INITIALIZING DATA BEFORE USE

As with most programming languages, C does not require that variables be initialized at their declaration, which makes it possible to unintentionally read uninitialized data. This is a case of undefined behavior, which can sometimes be used to attack the program.

81.1 Detecting Reads of Uninitialized Data

MISRA C attempts to prevent reads of uninitialized data in a specific section on "Initialization", containing five rules. The most important is Rule 9.1: "*The value of an object with automatic storage duration shall not be read before it has been set*". The first example in the rule is interesting, as it shows a non-trivial (and common) case of conditional initialization, where a function f initializes an output parameter p only in some cases, and the caller g of f ends up reading the value of the variable u passed in argument to f in cases where it has not been initialized:

Listing 1: f.h

```
#include <stdint.h>

void f ( int b, uint16_t *p );
```

Listing 2: f.c

```
#include "f.h"

void f ( int b, uint16_t *p )
{
  if ( b )
  {
     *p = 3U;
  }
}
```

Listing 3: g.c

```
#include <stdint.h>
#include "f.h"

static void g (void)
{
   uint16_t u;

   f ( 0, &u );

   if ( u == 3U )
```

(continues on next page)

(continued from previous page)

```
   {
      /* Non-compliant use - "u" has not been assigned a value. */
   }
}
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Initialization.Read_Uninitialized_Data_C
MD5: f36430141f48b34810d53a43294c7d74
```

Detecting the violation of Rule 9.1 can be arbitrarily complex, as the program points corresponding to a variable's initialization and read can be separated by many calls and conditions. This is one of the undecidable rules, for which most MISRA C checkers won't detect all violations.

In SPARK, the guarantee that all reads are to initialized data is enforced by the SPARK analysis tool, GNATprove, through what is referred to as *flow analysis*. Every subprogram is analyzed separately to check that it cannot read uninitialized data. To make this modular analysis possible, SPARK programs need to respect the following constraints:

- all inputs of a subprogram should be initialized on subprogram entry
- all outputs of a subprogram should be initialized on subprogram return

Hence, given the following code translated from C, GNATprove reports that function F might not always initialize output parameter P:

Listing 4: init.ads

```
with Interfaces; use Interfaces;

package Init is
   procedure F (B : Boolean; P : out Unsigned_16);
   procedure G;
end Init;
```

Listing 5: init.adb

```
package body Init is

   procedure F (B : Boolean; P : out Unsigned_16) is
   begin
      if B then
         P := 3;
      end if;
   end F;

   procedure G is
      U : Unsigned_16;
   begin
      F (False, U);

      if U = 3 then
         null;
      end if;
   end G;

end Init;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Initialization.Read_Uninitialized_Data_
 ↪Ada
MD5: d54bc9901b3bff4f0cfea9942a795156
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
init.ads:4:30: medium: "P" might not be initialized in "F" [reason for check: OUT␣
 ↪parameter should be initialized on return] [possible fix: initialize "P" on all␣
 ↪paths or make "P" an IN OUT parameter]
gnatprove: unproved check messages considered as errors
```

We can correct the program by initializing P to value 0 when condition B is not satisfied:

Listing 6: init.ads

```
with Interfaces; use Interfaces;

package Init is
   procedure F (B : Boolean; P : out Unsigned_16);
   procedure G;
end Init;
```

Listing 7: init.adb

```
package body Init is

   procedure F (B : Boolean; P : out Unsigned_16) is
   begin
      if B then
         P := 3;
      else
         P := 0;
      end if;
   end F;

   procedure G is
      U : Unsigned_16;
   begin
      F (False, U);

      if U = 3 then
         null;
      end if;
   end G;

end Init;
```

Phase 2 of 2: analysis of data and information flow ...
init.adb:13:07: info: initialization of "U" proved
init.ads:4:30: info: initialization of "P" proved
```

GNATprove now does not report any possible reads of uninitialized data. On the contrary, it confirms that all reads are made from initialized data.

In contrast with C, SPARK does not guarantee that global data (called *library-level* data in SPARK and Ada) is zero-initialized at program startup. Instead, GNATprove checks that all global data is explicitly initialized (at declaration or elsewhere) before it is read. Hence it goes beyond the MISRA C Rule 9.1, which considers global data as always initialized even if the default value of all-zeros might not be valid data for the application. Here's a variation of the above code where variable U is now global:

Listing 8: init.ads

```
with Interfaces; use Interfaces;

package Init is
   U : Unsigned_16;
   procedure F (B : Boolean);
   procedure G;
end Init;
```

Listing 9: init.adb

```
package body Init is

   procedure F (B : Boolean) is
   begin
      if B then
         U := 3;
      end if;
   end F;

   procedure G is
   begin
      F (False);

      if U = 3 then
         null;
      end if;
   end G;

end Init;
```

Listing 10: call_init.adb

```
with Init;

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Initialization.Read_Uninitialized_Data_
 ↪Ada
MD5: a85cde45a658727975367b041a1a5dc3
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
call_init.adb:5:08: medium: "U" might not be initialized after elaboration of main␣
```

(continues on next page)

(continued from previous page)

```
 ↪program "Call_Init"
init.adb:14:07: warning: statement has no effect
gnatprove: unproved check messages considered as errors
```

GNATprove reports here that variable U might not be initialized at program startup, which is indeed the case here. It reports this issue on the main program `Call_Init` because its analysis showed that F needs to take U as an initialized input (since F is not initializing U on all paths, U keeps its value on the other path, which needs to be an initialized value), which means that G which calls F also needs to take U as an initialized input, which in turn means that `Call_Init` which calls G also needs to take U as an initialized input. At this point, we've reached the main program, so the initialization phase (referred to as *elaboration* in SPARK and Ada) should have taken care of initializing U. This is not the case here, hence the message from GNATprove.

It is possible in SPARK to specify that G should initialize variable U; this is done with a *data dependency* contract introduced with aspect `Global` following the declaration of procedure G:

Listing 11: init.ads

```
with Interfaces; use Interfaces;

package Init is
   U : Unsigned_16;
   procedure F (B : Boolean);
   procedure G with Global => (Output => U);
end Init;
```

Listing 12: init.adb

```
package body Init is

   procedure F (B : Boolean) is
   begin
      if B then
         U := 3;
      end if;
   end F;

   procedure G is
   begin
      F (False);

      if U = 3 then
         null;
      end if;
   end G;

end Init;
```

Listing 13: call_init.adb

```
with Init;

procedure Call_Init is
begin
   Init.G;
end Call_Init;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Initialization.Read_Uninitialized_Data_
 ↪Ada
MD5: 100122ca3c8c60c134822a85d564a60a
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
init.adb:12:07: high: "U" is not initialized
init.adb:12:07: high: "U" is not an input in the Global contract of subprogram "G"␣
 ↪at init.ads:6
init.adb:12:07: high: either make "U" an input in the Global contract or␣
 ↪initialize it before use
init.adb:14:07: warning: statement has no effect
gnatprove: unproved check messages considered as errors
```

GNATprove reports the error on the call to F in G, as it knows at this point that F needs U to be initialized but the calling context in G cannot provide that guarantee. If we provide the same data dependency contract for F, then GNATprove reports the error on F itself, similarly to what we saw for an output parameter U.

81.2 Detecting Partial or Redundant Initialization of Arrays and Structures

The other rules in the section on "Initialization" deal with common errors in initializing aggregates and *designated initializers* in C99 to initialize a structure or array at declaration. These rules attempt to patch holes created by the lax syntax and rules in C standard. For example, here are five valid initializations of an array of 10 elements in C:

Listing 14: main.c

```
int main() {
   int a[10] = {0};
   int b[10] = {0, 0};
   int c[10] = {0, [8] = 0};
   int d[10] = {0, [8] = 0, 0};
   int e[10] = {0, [8] = 0, 0, [8] = 1};
   return 0;
}
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Initialization.Redundant_Init
MD5: 1212a5565fc3a382e7f967d1cf0b48f9
```

Only a is fully initialized to all-zeros in the above code snippet. MISRA C Rule 9.3 thus forbids all other declarations by stating that "*Arrays shall not be partially initialized*". In addition, MISRA C Rule 9.4 forbids the declaration of e by stating that "*An element of an object shall not be initialised more than once*" (in e's declaration, the element at index 8 is initialized twice).

The same holds for initialization of structures. Here is an equivalent set of declarations with the same potential issues:

Listing 15: main.c

```
int main() {
   typedef struct { int x; int y; int z; } rec;
```

(continues on next page)

(continued from previous page)

```
   rec a = {0};
   rec b = {0, 0};
   rec c = {0, .y = 0};
   rec d = {0, .y = 0, 0};
   rec e = {0, .y = 0, 0, .y = 1};
   return 0;
}
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Initialization.Redundant_Init
MD5: e562ef70b8c8a170d2bd09281cf2a075
```

Here only a, d and e are fully initialized. MISRA C Rule 9.3 thus forbids the declarations of b and c. In addition, MISRA C Rule 9.4 forbids the declaration of e.

In SPARK and Ada, the aggregate used to initialize an array or a record must fully cover the components of the array or record. Violations lead to compilation errors, both for records:

Listing 16: init_record.ads

```
package Init_Record is
   type Rec is record
      X, Y, Z : Integer;
   end record;
   R : Rec := (X => 1);  --  ERROR, Y and Z not specified
end Init_Record;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Initialization.Init_Record_1
MD5: 6b28bffe6270c5ea5055123c5b89c508
```

Build output

```
init_record.ads:5:15: error: no value supplied for component "Y"
init_record.ads:5:15: error: no value supplied for component "Z"
gprbuild: *** compilation phase failed
```

and for arrays:

Listing 17: init_array.ads

```
package Init_Array is
   type Arr is array (1 .. 10) of Integer;
   A : Arr := (1 => 1);  --  ERROR, elements 2..10 not specified
end Init_Array;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Initialization.Init_Array_1
MD5: 81aa6363ba770ded10bef8d3d8776914
```

Build output

```
init_array.ads:3:15: warning: too few elements for type "Arr" defined at line 2␣
 ↪[enabled by default]
init_array.ads:3:15: warning: expected 10 elements; found 1 element [enabled by␣
 ↪default]
init_array.ads:3:15: warning: Constraint_Error will be raised at run time [enabled␣
 ↪by default]
```

Similarly, redundant initialization leads to compilation errors for records:

Listing 18: init_record.ads

```
package Init_Record is
   type Rec is record
      X, Y, Z : Integer;
   end record;
   R : Rec := (X => 1, Y => 1, Z => 1, X => 2);  --  ERROR, X duplicated
end Init_Record;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Initialization.Init_Record_2
MD5: 07d3f790009be97cef2daaf08b2f7afd
```

Build output

```
init_record.ads:5:40: error: more than one value supplied for "X"
gprbuild: *** compilation phase failed
```

and for arrays:

Listing 19: init_array.ads

```
package Init_Array is
   type Arr is array (1 .. 10) of Integer;
   A : Arr := (1 .. 8 => 1, 9 .. 10 => 2, 7 => 3);  --  ERROR, A(7) duplicated
end Init_Array;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Initialization.Init_Array_2
MD5: 12f5fa4615abccde43f63f72340fd4a0
```

Build output

```
init_array.ads:3:43: error: index value in array aggregate duplicates the one␣
 ↪given at line 3
init_array.ads:3:43: error:   7
gprbuild: *** compilation phase failed
```

Finally, while it is legal in Ada to leave uninitialized parts in a record or array aggregate by using the box notation (meaning that the default initialization of the type is used, which may be no initialization at all), SPARK analysis rejects such use when it leads to components not being initialized, both for records:

Listing 20: init_record.ads

```
package Init_Record is
   type Rec is record
      X, Y, Z : Integer;
   end record;
   R : Rec := (X => 1, others => <>);  --  ERROR, Y and Z not specified
end Init_Record;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Initialization.Init_Record_3
MD5: a7736f2b563c39fb4ab10007e927ad97
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...

and for arrays:

Listing 21: init_array.ads

```
1 package Init_Array is
2    type Arr is array (1 .. 10) of Integer;
3    A : Arr := (1 .. 8 => 1, 9 .. 10 => <>);  --  ERROR, A(9..10) not specified
4 end Init_Array;
```

CHAPTER

EIGHTYTWO

CONTROLLING SIDE EFFECTS

As with most programming languages, C allows side effects in expressions. This leads to subtle issues about conflicting side effects, when subexpressions of the same expression read/write the same variable.

82.1 Preventing Undefined Behavior

Conflicting side effects are a kind of undefined behavior; the C Standard (section 6.5) defines the concept as follows:

> "*Between two sequence points, an object is modified more than once, or is modified and the prior value is read other than to determine the value to be stored*"

This legalistic wording is somewhat opaque, but the notion of sequence points is summarized in Annex C of the C90 and C99 standards. MISRA C repeats these conditions in the Amplification of Rule 13.2, including the read of a volatile variable as a side effect similar to writing a variable.

This rule is undecidable, so MISRA C completes it with two rules that provide simpler restrictions preventing some side effects in expressions, thus reducing the potential for undefined behavior:

- Rule 13.3: "*A full expression containing an increment (++) or decrement (--) operator should have no other potential side effects other than that caused by the increment or decrement operator*".
- Rule 13.4: "*The result of an assignment operator should not be used*".

In practice, conflicting side effects usually manifest themselves as portability issues, since the result of the evaluation of an expression depends on the order in which a compiler decides to evaluate its subexpressions. So changing the compiler version or the target platform might lead to a different behavior of the application.

To reduce the dependency on evaluation order, MISRA C Rule 13.1 states: "*Initializer lists shall not contain persistent side effects*". This case is theoretically different from the previously mentioned conflicting side effects, because initializers that comprise an initializer list are separated by sequence points, so there is no risk of undefined behavior if two initializers have conflicting side effects. But given that initializers are executed in an unspecified order, the result of a conflict is potentially as damaging for the application.

82.2 Reducing Programmer Confusion

Even in cases with no undefined or unspecified behavior, expressions with multiple side effects can be confusing to programmers reading or maintaining the code. This problem arises in particular with C's increment and decrement operators that can be applied prior to or after the expression evaluation, and with the assignment operator = in C since it can easily be mistaken for equality. Thus MISRA C forbids the use of the increment / decrement (Rule 13.3) and assignment (Rule 13.4) operators in expressions that have other potential side effects.

In other cases, the presence of expressions with side effects might be confusing, if the programmer wrongly thinks that the side effects are guaranteed to occur. Consider the function `decrease_until_one_is_null` below, which decreases both arguments until one is null:

Listing 1: main.c

```c
#include <stdio.h>

void decrease_until_one_is_null (int *x, int *y) {
   if (x == 0 || y == 0) {
      return;
   }
   while (--*x != 0 && --*y != 0) {
      // nothing
   }
}

int main() {
   int x = 42, y = 42;
   decrease_until_one_is_null (&x, &y);
   printf("x = %d, y = %d\n", x, y);
   return 0;
}
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Side_Effect.Side_Effect_C
MD5: a3e991881894bc3fb25a5f49a083fd2e
```

Runtime output

```
x = 0, y = 1
```

The program produces the following output:

```
x = 0, y = 1
```

I.e., starting from the same value 42 for both x and y, only x has reached the value zero after `decrease_until_one_is_null` returns. The reason is that the side effect on y is performed only conditionally. To avoid such surprises, MISRA C Rule 13.5 states: "*The right hand operand of a logical && or || operator shall not contain persistent side effects*"; this rule forbids the code above.

MISRA C Rule 13.6 similarly states: "*The operand of the sizeof operator shall not contain any expression which has potential side effects*". Indeed, the operand of **`sizeof`** is evaluated only in rare situations, and only according to C99 rules, which makes any side effect in such an operand a likely mistake.

82.3 Side Effects and SPARK

In SPARK, expressions cannot have side effects; only statements can. In particular, there are no increment/decrement operators, and no assignment operator. There is instead an assignment statement, whose syntax using := clearly distinguishes it from equality (using =). And in any event an expression is not allowed as a statement and this a construct such as X = Y; would be illegal. Here is how a variable X can be assigned, incremented and decremented:

```
X := 1;
X := X + 1;
X := X - 1;
```

There are two possible side effects when evaluating an expression:

- a read of a volatile variable
- a side effect occurring inside a function that the expression calls

Reads of volatile variables in SPARK are restricted to appear immediately at statement level, so the following is not allowed:

Listing 2: volatile_read.ads

```
1 package Volatile_Read is
2    X : Integer with Volatile;
3    procedure P (Y : out Integer);
4 end Volatile_Read;
```

Listing 3: volatile_read.adb

```
1 package body Volatile_Read is
2    procedure P (Y : out Integer) is
3    begin
4       Y := X - X;  --  ERROR
5    end P;
6 end Volatile_Read;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Side_Effect.Volatile_Read_1
MD5: 7ec58b4d1432d03d60b5ea6019cc031e
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
volatile_read.adb:4:12: error: volatile object cannot appear in this context␣
 ↪(SPARK RM 7.1.3(10))
volatile_read.adb:4:16: error: volatile object cannot appear in this context␣
 ↪(SPARK RM 7.1.3(10))
gnatprove: error during generation of Global contracts
```

Instead, every read of a volatile variable must occur immediately before being assigned to another variable, as follows:

Listing 4: volatile_read.ads

```
1 package Volatile_Read is
2    X : Integer with Volatile;
3    procedure P (Y : out Integer);
4 end Volatile_Read;
```

Listing 5: volatile_read.adb

```
package body Volatile_Read is
   procedure P (Y : out Integer) is
      X1 : constant Integer := X;
      X2 : constant Integer := X;
   begin
      Y := X1 - X2;
   end P;
end Volatile_Read;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Side_Effect.Volatile_Read_2
MD5: 1224af597a12a8ca77b96976c76b422f
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
volatile_read.ads:3:17: info: initialization of "Y" proved
```

Note here that the order of capture of the volatile value of X might be significant. For example, X might denote a quantity which only increases, like clock time, so that the above expression X1 - X2 would always be negative or zero.

Even more significantly, functions in SPARK cannot have side effects; only procedures can. The only effect of a SPARK function is the computation of a result from its inputs, which may be passed as parameters or as global variables. In particular, SPARK functions cannot have **out** or **in out** parameters:

Listing 6: bad_function.ads

```
function Bad_Function (X, Y : Integer; Sum, Max : out Integer) return Boolean;
--  ERROR, since "out" parameters are not allowed
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Side_Effect.Function_With_Out_Param
MD5: 204dd22df61fe15208ae34ebc3828974
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
bad_function.ads:1:10: error: function with "out" parameter is not allowed in SPARK
bad_function.ads:1:10: error: violation of pragma SPARK_Mode at /vagrant/frontend/

 ↪With_Out_Param/204dd22df61fe15208ae34ebc3828974/main_spark.adc:12
gnatprove: error during analysis of data and information flow
```

More generally, SPARK does not allow functions that have a side effect in addition to returning their result, as is typical of many idioms in other languages, for example when setting a new value and returning the previous one:

Listing 7: bad_functions.ads

```
package Bad_Functions is
   function Set (V : Integer) return Integer;
   function Get return Integer;
end Bad_Functions;
```

Listing 8: bad_functions.adb

```
package body Bad_Functions is

   Value : Integer := 0;

   function Set (V : Integer) return Integer is
      Previous : constant Integer := Value;
   begin
      Value := V;  --  ERROR
      return Previous;
   end Set;

   function Get return Integer is (Value);

end Bad_Functions;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Side_Effect.Side_Effect_Ada
MD5: 3337b6025c4996e7fa8c7e27b4df42c1
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
bad_functions.ads:2:13: error: function with output global "Value" is not allowed␣
 ↪in SPARK
gnatprove: error during analysis of data and information flow
```

GNATprove detects that function Set has a side effect on global variable Value and issues an error. The correct idiom in SPARK for such a case is to use a procedure with an **out** parameter to return the desired result:

Listing 9: ok_subprograms.ads

```
package Ok_Subprograms is
   procedure Set (V : Integer; Prev : out Integer);
   function Get return Integer;
end Ok_Subprograms;
```

Listing 10: ok_subprograms.adb

```
package body Ok_Subprograms is

   Value : Integer := 0;

   procedure Set (V : Integer; Prev : out Integer) is
   begin
      Prev := Value;
      Value := V;
   end Set;

   function Get return Integer is (Value);

end Ok_Subprograms;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Side_Effect.No_Side_Effect_Ada
MD5: 04e2235b8b6a01706434d35f6636674c
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
ok_subprograms.ads:2:32: info: initialization of "Prev" proved
```

With the above restrictions in SPARK, none of the conflicts of side effects that can occur in C can occur in SPARK, and this is guaranteed by flow analysis.

CHAPTER

EIGHTYTHREE

DETECTING UNDEFINED BEHAVIOR

Undefined behavior (and critical unspecified behavior, which we'll treat as undefined behavior) are the plague of C programs. Many rules in MISRA C are designed to avoid undefined behavior, as evidenced by the twenty occurrences of "undefined" in the MISRA C:2012 document.

MISRA C Rule 1.3 is the overarching rule, stating very simply:

> "*There shall be no occurrence of undefined or critical unspecified behaviour.*"

The deceptive simplicity of this rule rests on the definition of *undefined or critical unspecified behaviour*. Appendix H of MISRA:C 2012 lists hundreds of cases of undefined and critical unspecified behavior in the C programming language standard, a majority of which are not individually decidable.

It is therefore not surprising that a majority of MISRA C checkers do not make a serious attempt to verify compliance with MISRA C Rule 1.3.

83.1 Preventing Undefined Behavior in SPARK

Since SPARK is a subset of the Ada programming language, SPARK programs may exhibit two types of undefined behaviors that can occur in Ada:

- *bounded error*: when the program enters a state not defined by the language semantics, but the consequences are bounded in various ways. For example, reading uninitialized data can lead to a bounded error, when the value read does not correspond to a valid value for the type of the object. In this specific case, the Ada Reference Manual states that either a predefined exception is raised or execution continues using the invalid representation.
- *erroneous execution*: when when the program enters a state not defined by the language semantics, but the consequences are not bounded by the Ada Reference Manual. This is the closest to an undefined behavior in C. For example, concurrently writing through different tasks to the same unprotected variable is a case of erroneous execution.

Many cases of undefined behavior in C would in fact raise exceptions in SPARK. For example, accessing an array beyond its bounds raises the exception `Constraint_Error` while reaching the end of a function without returning a value raises the exception `Program_Error`.

The SPARK Reference Manual defines the SPARK subset through a combination of *legality rules* (checked by the compiler, or the compiler-like phase preceding analysis) and *verification rules* (checked by the formal analysis tool GNATprove). Bounded errors and erroneous execution are prevented by a combination of legality rules and the *flow analysis* part of GNATprove, which in particular detects potential reads of uninitialized data, as described in *Detecting Reads of Uninitialized Data* (page 1649). The following discussion focuses on how SPARK can verify that no exceptions can be raised.

83.2 Proof of Absence of Run-Time Errors in SPARK

The most common run-time errors are related to misuse of arithmetic (division by zero, overflows, exceeding the range of allowed values), arrays (accessing beyond an array bounds, assigning between arrays of different lengths), and structures (accessing components that are not defined for a given variant).

Arithmetic run-time errors can occur with signed integers, unsigned integers, fixed-point and floating-point (although with IEEE 754 floating-point arithmetic, errors are manifest as special run-time values such as NaN and infinities rather than as exceptions that are raised). These errors can occur when applying arithmetic operations or when converting between numeric types (if the value of the expression being converted is outside the range of the type to which it is being converted).

Operations on enumeration values can also lead to run-time errors; e.g., `T'Pred(T'First)` or `T'Succ(T'Last)` for an enumeration type `T`, or `T'Val(N)` where `N` is an integer value that is outside the range `0 .. T'Pos(T'Last)`.

The `Update` procedure below contains what appears to be a simple assignment statement, which sets the value of array element `A(I+J)` to `P/Q`.

Listing 1: show_runtime_errors.ads

```
package Show_Runtime_Errors is

   type Nat_Array is array (Integer range <>) of Natural;
   --  The values in subtype Natural are 0 , 1, ... Integer'Last

   procedure Update (A : in out Nat_Array; I, J, P, Q : Integer);

end Show_Runtime_Errors;
```

Listing 2: show_runtime_errors.adb

```
package body Show_Runtime_Errors is

   procedure Update (A : in out Nat_Array; I, J, P, Q : Integer) is
   begin
      A (I + J) := P / Q;
   end Update;

end Show_Runtime_Errors;
```

Code block metadata

```

```

(continues on next page)

(continued from previous page)

```
show_runtime_errors.adb:5:22: medium: divide by zero might fail [possible fix: add␣
 ↪precondition (Q /= 0) to subprogram at show_runtime_errors.ads:6]
show_runtime_errors.adb:5:22: medium: overflow check might fail, cannot prove␣
 ↪lower bound for P / Q [reason for check: result of division must fit in a 32-
 ↪bits machine integer] [possible fix: add precondition (P / Q in Integer) to␣
 ↪subprogram at show_runtime_errors.ads:6]
show_runtime_errors.adb:5:22: medium: range check might fail, cannot prove lower␣
 ↪bound for P / Q [reason for check: result of division must fit in the target␣
 ↪type of the assignment] [possible fix: add precondition (P / Q in Natural) to␣
 ↪subprogram at show_runtime_errors.ads:6]
gnatprove: unproved check messages considered as errors
```

However, for an arbitrary invocation of this procedure, say `Update(A, I, J, P, Q)`, an exception can be raised in a variety of circumstances:

- The computation `I+J` may overflow, for example if `I` is `Integer'Last` and `J` is positive.

```
A (Integer'Last + 1) := P / Q;
```

- The value of `I+J` may be outside the range of the array `A`.

```
A (A'Last + 1) := P / Q;
```

- The division `P / Q` may overflow in the special case where `P` is `Integer'First` and `Q` is `-1`, because of the asymmetric range of signed integer types.

```
A (I + J) := Integer'First / -1;
```

- Since the array can only contain non-negative numbers (the element subtype is `Natural`), it is also an error to store a negative value in it.

```
A (I + J) := 1 / -1;
```

- Finally, if `Q` is 0 then a divide by zero error will occur.

```
A (I + J) := P / 0;
```

For each of these potential run-time errors, the compiler will generate checks in the executable code, raising an exception if any of the checks fail:

```
A (Integer'Last + 1) := P / Q;
--  raised CONSTRAINT_ERROR : overflow check failed

A (A'Last + 1) := P / Q;
--  raised CONSTRAINT_ERROR : index check failed

A (I + J) := Integer'First / (-1);
--  raised CONSTRAINT_ERROR : overflow check failed

A (I + J) := 1 / (-1);
--  raised CONSTRAINT_ERROR : range check failed

A (I + J) := P / 0;
--  raised CONSTRAINT_ERROR : divide by zero
```

These run-time checks incur an overhead in program size and execution time. Therefore it may be appropriate to remove them if we are confident that they are not needed.

The traditional way to obtain the needed confidence is through testing, but it is well known that this can never be complete, at least for non-trivial programs. Much better is to guarantee the absence of run-time errors through sound static analysis, and that's where SPARK and GNATprove can help.

More precisely, GNATprove logically interprets the meaning of every instruction in the program, taking into account both control flow and data/information dependencies. It uses this analysis to generate a logical formula called a *verification condition* for each possible check.

```
A (Integer'Last + 1) := P / Q;
--  medium: overflow check might fail

A (A'Last + 1) := P / Q;
--  medium: array index check might fail

A (I + J) := Integer'First / (-1);
--  medium: overflow check might fail

A (I + J) := 1 / (-1);
--  medium: range check might fail

A (I + J) := P / 0;
--  medium: divide by zero might fail
```

The verification conditions are then given to an automatic prover. If every verification condition can be proved, then no run-time errors will occur.

GNATprove's analysis is sound — it will detect all possible instances of run-time exceptions being raised — while also having high precision (i.e., not producing a cascade of "false alarms").

The way to program in SPARK so that GNATprove can guarantee the absence of run-time errors entails:

- declaring variables with precise constraints, and in particular to specify precise ranges for scalars; and
- defining preconditions and postconditions on subprograms, to specify respectively the constraints that callers should respect and the guarantees that the subprogram should provide on exit.

For example, here is a revised version of the previous example, which can guarantee through proof that no possible run-time error can be raised:

Listing 3: no_runtime_errors.ads

```
1  package No_Runtime_Errors is
2
3     subtype Index_Range is Integer range 0 .. 100;
4
5     type Nat_Array is array (Index_Range range <>) of Natural;
6
7     procedure Update (A    : in out Nat_Array;
8                       I, J : Index_Range;
9                       P, Q : Positive)
10    with
11      Pre => I + J in A'Range;
12
13 end No_Runtime_Errors;
```

Listing 4: no_runtime_errors.adb

```
1  package body No_Runtime_Errors is
2
3     procedure Update (A    : in out Nat_Array;
4                       I, J : Index_Range;
5                       P, Q : Positive) is
```

(continues on next page)

(continued from previous page)

```
   begin
      A (I + J) := P / Q;
   end Update;

end No_Runtime_Errors;
```

CHAPTER

EIGHTYFOUR

DETECTING UNREACHABLE CODE AND DEAD CODE

MISRA C defines *unreachable code* as code that cannot be executed, and it defines *dead code* as code that can be executed but has no effect on the functional behavior of the program. (These definitions differ from traditional terminology, which refers to the first category as "dead code" and the second category as "useless code".) Regardless of the terminology, however, both types are actively harmful, as they might confuse programmers and lead to errors during maintenance.

The "Unused code" section of MISRA C contains seven rules that deal with detecting both unreachable code and dead code. The two most important rules are:

- Rule 2.1: "*A project shall not contain unreachable code*", and
- Rule 2.2: "*There shall not be dead code*".

Other rules in the same section prohibit unused entities of various kinds (type declarations, tag declarations, macro declarations, label declarations, function parameters).

While some simple cases of unreachable code can be detected by static analysis (typically if a condition in an **if** statement can be determined to be always true or false), most cases of unreachable code can only be detected by performing coverage analysis in testing, with the caveat that code reported as not being executed is not necessarily unreachable (it could simply reflect gaps in the test suite). Note that *statement coverage*, rather than the more comprehensive *decision coverage* or *modified condition / decision coverage* (MC/DC) as defined in the DO-178C standard for airborne software, is sufficient to detect potential unreachable statements, corresponding to code that is not covered during the testing campaign.

The presence of dead code is much harder to detect, both statically and dynamically, as it requires creating a complete dependency graph linking statements in the code and their effect on visible behavior of the program.

SPARK can detect some cases of both unreachable and dead code through its precise construction of a dependency graph linking a subprogram's statements to all its inputs and outputs. This analysis might not be able to detect complex cases, but it goes well beyond what other analyses do in general.

Listing 1: much_ado_about_little.ads

```
procedure Much_Ado_About_Little (X, Y, Z : Integer; Success : out Boolean);
```

Listing 2: much_ado_about_little.adb

```
procedure Much_Ado_About_Little (X, Y, Z : Integer; Success : out Boolean) is

   procedure Ok is
   begin
      Success := True;
   end Ok;

```

(continues on next page)

(continued from previous page)

```
8     procedure NOk is
9     begin
10       Success := False;
11    end NOk;
12
13 begin
14    Success := False;
15
16    for K in Y .. Z loop
17       if K < X and not Success then
18          Ok;
19       end if;
20    end loop;
21
22    if X > Y then
23       Ok;
24    else
25       NOk;
26    end if;
27
28    if Z > Y then
29       NOk;
30       return;
31    else
32       Ok;
33       return;
34    end if;
35
36    if Success then
37       Success := not Success;
38    end if;
39 end Much_Ado_About_Little;
```

Code block metadata

```
Project: Courses.SPARK_For_The_MISRA_C_Dev.Unreachable_And_Dead_Code.Much_Ado_
 ↪About_Little

```

Build output

```
much_ado_about_little.adb:36:04: warning: unreachable code [enabled by default]
```

Prover output

```
Phase 1 of 2: generation of Global contracts ...
Phase 2 of 2: analysis of data and information flow ...
much_ado_about_little.adb:5:15: warning: unused assignment, in call inlined at␣
 ↪much_ado_about_little.adb:18
much_ado_about_little.adb:5:15: warning: unused assignment, in call inlined at␣
 ↪much_ado_about_little.adb:23
much_ado_about_little.adb:10:15: warning: unused assignment, in call inlined at␣
 ↪much_ado_about_little.adb:25
much_ado_about_little.adb:14:12: warning: unused assignment
much_ado_about_little.adb:16:20: warning: statement has no effect
much_ado_about_little.adb:17:07: warning: statement has no effect
much_ado_about_little.adb:22:04: warning: statement has no effect
much_ado_about_little.adb:36:04: warning: unreachable code [enabled by default]
much_ado_about_little.adb:36:04: warning: this statement is never reached
much_ado_about_little.adb:37:15: warning: this statement is never reached
much_ado_about_little.ads:1:34: warning: unused initial value of "X"
```

The only code in the body of `Much_Ado_About_Little` that affects the result of the procedure's execution is the `if Z > Y...` statement, since this statement sets `Success` to either True or False regardless of what the previous statements did. I.e., the statements preceding this `if` are dead code in the MISRA C sense. Since both branches of the `if Z > Y...` statement return from the procedure, the subsequent `if Success...` statement is unreachable. GNATprove detects and issues warnings about both the dead code and the unreachable code.

CHAPTER

EIGHTYFIVE

CONCLUSION

The C programming language is "close to the metal" and has emerged as a *lingua franca* for the majority of embedded platforms of all sizes. However, its software engineering deficiencies (such as the absence of data encapsulation) and its many traps and pitfalls present major obstacles to those developing critical applications. To some extent, it is possible to put the blame for programming errors on programmers themselves, as Linus Torvalds admonished:

> "*Learn C, instead of just stringing random characters together until it compiles (with warnings).*"

But programmers are human, and even the best would be hard pressed to be 100% correct about the myriad of semantic details such as those discussed in this document. Programming language abstractions have been invented precisely to help developers focus on the "big picture" (thinking in terms of problem-oriented concepts) rather than low-level machine-oriented details, but C lacks these abstractions. As Kees Cook from the Kernel Self Protection Project puts it (during the Linux Security Summit North America 2018):

> "*Talking about C as a language, and how it's really just a fancy assembler*"

Even experts sometimes have problems with the C programming language rules, as illustrated by Microsoft expert David LeBlanc (see *Enforcing Strong Typing for Scalars* (page 1639)) or the MISRA C Committee itself (see the *Preface* (page 1609)).

The rules in MISRA C represent an impressive collective effort to improve the reliability of C code in critical applications, with a focus on avoiding error-prone features rather than enforcing a particular programming style. The Rationale provided with each rule is a clear and unobjectionable justification of the rule's benefit.

At a fundamental level, however, MISRA C is still built on a base language that was not really designed with the goal of supporting large high-assurance applications. As shown in this document, there are limits to what static analysis can enforce with respect to the MISRA C rules. It's hard to retrofit reliability, safety and security into a language that did not have these as goals from the start.

The SPARK language took a different approach, starting from a base language (Ada) that was designed from the outset to support solid software engineering, and eliminating features that were implementation dependent or otherwise hard to formally analyze. In this document we have shown how the SPARK programming language and its associated formal verification tools can contribute usefully to the goal of producing error-free software, going beyond the guarantees that can be achieved in MISRA C.

REFERENCES

86.1 About MISRA C

The official website of the MISRA association https://www.misra.org.uk/ has many freely available resources about MISRA C, some of which can be downloaded after registering on the MISRA Bulletin Board at https://www.misra.org.uk/forum/ (such as the examples from the MISRA C:2012 standard, which includes a one-line description of each guideline).

The following documents are freely available:

- *MISRA Compliance 2016: Achieving compliance with MISRA coding guidelines*, 2016, which explains the rationale and process for compliance, including a thorough discussions of acceptable deviations
- *MISRA C:2012 - Amendment 1: Additional security guidelines for MISRA C:2012*, 2016, which contains 14 additional guidelines focusing on security. This is a minor addition to MISRA C.

The main MISRA C:2012 document can be purchased from the MISRA webstore.

PRQA is the company that first developed MISRA C, and they have been heavily involved in every version since then. Their webpage http://www.prqa.com/coding-standards/misra/ contains many resources about MISRA C: product datasheets, white papers, webinars, professional courses.

The PRQA Resources Library at http://info.prqa.com/resources-library?filter=white_paper has some freely available white papers on MISRA C and the use of static analyzers:

- An introduction to MISRA C:2012 at http://info.prqa.com/MISRA C-2012-whitepaper-evaluation-lp
- *The Myth of Perfect MISRA Compliance* at http://info.prqa.com/myth-of-perfect-MISRA Compliance-evaluation-lp, providing background information on the use and limitations of static analyzers for checking MISRA C compliance

In 2013 ISO standardized a set of 45 rules focused on security, available in the *C Secure Coding Rules*. A draft is freely available at http://www.open-std.org/jtc1/sc22/wg14/www/docs/n1624.pdf

In 2018 MISRA published *MISRA C:2012 - Addendum 2: Coverage of MISRA C:2012 against ISO/IEC TS 17961:2013* "*C Secure*", mapping ISO rules to MISRA C:2012 guidelines. This document is freely available from https://www.misra.org.uk/.

86.2 About SPARK

The e-learning website https://learn.adacore.com/ contains a freely available interactive course on SPARK.

The SPARK User's Guide is available at http://docs.adacore.com/spark2014-docs/html/ug/.

The SPARK Reference Manual is available at http://docs.adacore.com/spark2014-docs/html/lrm/.

A student-oriented textbook on SPARK is *Building High Integrity Applications with SPARK* by John McCormick and Peter Chapin, published by Cambridge University Press. It covers the latest version of the language, SPARK 2014.

A historical account of the evolution of SPARK technology and its use in industry is covered in the article *Are We There Yet? 20 Years of Industrial Theorem Proving with SPARK* by Roderick Chapman and Florian Schanda, at http://proteancode.com/keynote.pdf

The website https://www.adacore.com/sparkpro is a portal for up-to-date information and resources on SPARK. AdaCore blog's site https://blog.adacore.com/ contains a number of SPARK-related posts.

The booklet *AdaCore Technologies for Cyber Security* shows how AdaCore's technology can be used to prevent or mitigate the most common security vulnerabilities in software. See https://www.adacore.com/books/adacore-tech-for-cyber-security/.

The booklet *AdaCore Technologies for CENELEC EN 50128:2011* shows how AdaCore's technology can be used in conjunction with the CENELEC EN 50128:2011 software standard for railway control and protection systems. It describes in particular where the SPARK technology fits best and how it can be used to meet various requirements of the standard. See: https://www.adacore.com/books/cenelec-en-50128-2011/.

The booklet *AdaCore Technologies for DO-178C/ED-12C* similarly shows how AdaCore's technology can be used in conjunction with the DO-178C/ED-12C standard for airborne software, and describes in particular how SPARK can be used in conjunction with the Formal Methods supplement DO-333/ED-216. See https://www.adacore.com/books/do-178c-tech/.

86.3 About MISRA C and SPARK

The blog post at https://blog.adacore.com/MISRA-C-2012-vs-spark-2014-the-subset-matching-game reviews the 27 undecidable rules in MISRA C:2012 and describes how SPARK addresses them.

The white paper *A Comparison of SPARK with MISRA C and Frama-C* at https://www.adacore.com/papers/compare-spark-MISRA-C-frama-c compares SPARK to MISRA C and to the formal verification tool Frama-C for C programs.

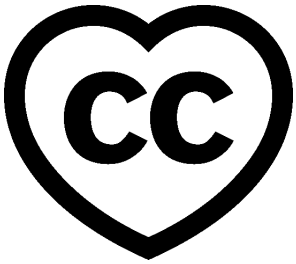
This book is published under a CC BY-SA license, which means that you can copy, redistribute, remix, transform, and build upon the content for any purpose, even commercially, as long as you give appropriate credit, provide a link to the license, and indicate if changes were made. If you remix, transform, or build upon the material, you must distribute your contributions under the same license as the original. You can find license details on this page[348]



This course presents an introduction to the GNAT toolchain. The course includes first steps to get started with the toolchain and some details on the project manager (GPRbuild) and the integrated development environment (GNAT Studio).

This document was written by Gustavo A. Hoffmann, with contributions and review from Richard Kenner and Robert Duff.

Note: The code examples in this course use an 80-column limit, which is a typical limit for Ada code. Note that, on devices with a small screen size, some code examples might be difficult to read.

CHAPTER

EIGHTYSEVEN

GNAT TOOLCHAIN BASICS

This chapter presents a couple of basic commands from the GNAT toolchain.

87.1 Basic commands

Now that the toolchain is installed, you can start using it. From the command line, you can compile a project using **gprbuild**. For example:

```
gprbuild -P project.gpr
```

You can find the binary built with the command above in the *obj* directory. You can the run it in the same way as you would do with any other executable on your platform. For example:

```
obj/main
```

A handy command-line option for **gprbuild** you might want to use is `-p`, which automatically creates directories such as `obj` if they aren't in the directory tree:

```
gprbuild -p -P project.gpr
```

Ada source-code are stored in *.ads* and *.adb* files. To view the content of these files, you can use **GNAT Studio**. To open **GNAT Studio**, double-click on the *.gpr* project file or invoke **GNAT Studio** on the command line:

```
gps -P project.gpr
```

To compile your project using **GNAT Studio**, use the top-level menu to invoke `Build` → `Project` → `main.adb` (or press the keyboard shortcut F4). To run the main program, click on `Build` → Run → `main` (or press the keyboard shortcut `Shift` + F2).

87.2 Compiler warnings

One of the strengths of the GNAT compiler is its ability to generate many useful warnings. Some are displayed by default but others need to be explicitly enabled. In this section, we discuss some of these warnings, their purpose, and how you activate them.

87.2.1 -gnatwa switch and warning suppression

Section author: Robert Duff

We first need to understand the difference between a *warning* and an *error*. Errors are violations of the Ada language rules as specified in the Ada Reference Manual; warnings don't indicate violations of those rules, but instead flag constructs in a program that seem suspicious to the compiler. Warnings are GNAT-specific, so other Ada compilers might not warn about the same things GNAT does or might warn about them in a different way. Warnings are typically conservative; meaning that some warnings are false alarms. The programmer needs to study the code to determine if each warning is describing a real problem.

Some warnings are produced by default while others are produced only if a switch enables them. Use the `-gnatwa` switch to turn on (almost) all warnings.

Warnings are useless if you don't do anything about them. If you give your team member some code that causes warnings, how are they supposed to know whether they represent real problems? If you don't address each warning, people will soon starting ignoring warnings and there'll be lots of things that generates warnings scattered all over your code. To avoid this, you may want to use the `-gnatwae` switch to both turn on (almost) all warnings and to treat warnings as errors. This forces you to get a clean (no warnings or errors) compilation.

However, as we said, some warnings are false alarms. Use **pragma** *Warnings* (Off) to suppress those warnings. It's best to be as specific as possible and narrow down to a single line of code and a single warning. Then use a comment to explain why the warning is a false alarm if it's not obvious.

Let's look at the following example:

```
with Ada.Text_IO; use Ada.Text_IO;

package body Warnings_Example is

   procedure Mumble (X : Integer) is
   begin
      Put_Line ("Mumble processing...");
   end Mumble;

end Warnings_Example;
```

We compile the above code with `-gnatwae`:

```
gnat compile -gnatwae ./src/warnings_example.adb
```

This causes GNAT to complain:

```
warnings_example.adb:5:22: warning: formal parameter "X" is not referenced
```

But the following compiles cleanly:

```
with Ada.Text_IO; use Ada.Text_IO;

package body Warnings_Example is

   pragma Warnings (Off, "formal parameter ""X"" is not referenced");
   procedure Mumble (X : Integer) is
   pragma Warnings (On, "formal parameter ""X"" is not referenced");

   --  X is ignored here, because blah blah blah...
   begin
      Put_Line ("Mumble processing...");
```

(continues on next page)

(continued from previous page)

```
   end Mumble;

end Warnings_Example;
```

Here we've suppressed a specific warning message on a specific line.

If you get many warnings of a specific type and it's not feasible to fix all of them, you can suppress that type of message so the good warnings won't get buried beneath a pile of bogus ones. For example, you can use the `-gnatwaeF` switch to silence the warning on the first version of `Mumble` above: the `F` suppresses warnings on unreferenced formal parameters. It would be a good idea to use it if you have many of those.

As discussed above, `-gnatwa` activates almost all warnings, but not all. Refer to the section on warnings[349] of the GNAT User's Guide to get a list of the remaining warnings you could enable in your project. One is `-gnatw.o`, which displays warnings when the compiler detects modified but unreferenced **`out`** parameters. Consider the following example:

```
package Warnings_Example is

   procedure Process (X : in out Integer;
                      B :    out Boolean);

end Warnings_Example;
```

```
package body Warnings_Example is

   procedure Process (X : in out Integer;
                      B :    out Boolean) is
   begin
      if X = Integer'First or else X = Integer'Last then
         B := False;
      else
         X := X + 1;
         B := True;
      end if;
   end Process;

end Warnings_Example;
```

```
with Ada.Text_IO; use Ada.Text_IO;

with Warnings_Example; use Warnings_Example;

procedure Main  is
   X : Integer := 0;
   Success : Boolean;
begin
   Process (X, Success);
   Put_Line (Integer'Image (X));
end Main;
```

If we build the main application using the `-gnatw.o` switch, the compiler warns us that we didn't reference the `Success` variable, which was modified in the call to `Process`:

```
main.adb:8:16: warning: "Success" modified by call, but value might not be␣
↪referenced
```

In this case, this actually points us to a bug in our program, since `X` only contains a valid value if `Success` is **`True`**. The corrected code for `Main` is:

[349] https://docs.adacore.com/gnat_ugn-docs/html/gnat_ugn/gnat_ugn/building_executable_programs_with_gnat.html#warning-message-control

```
-- ...
begin
   Process (X, Success);

   if Success then
      Put_Line (Integer'Image (X));
   else
      Put_Line ("Couldn't process variable X.");
   end if;
end Main;
```

We suggest turning on as many warnings as makes sense for your project. Then, when you see a warning message, look at the code and decide if it's real. If it is, fix the code. If it's a false alarm, suppress the warning. In either case, we strongly recommend you make the warning disappear before you check your code into your configuration management system.

87.2.2 Style checking

GNAT provides many options to configure style checking of your code. The main compiler switch for this is `-gnatyy`, which sets almost all standard style check options. As indicated by the section on style checking[350] of the GNAT User's Guide, using this switch "is equivalent to `-gnaty3aAbcefhiklmnprst`, that is all checking options enabled with the exception of `-gnatyB`, `-gnatyd`, `-gnatyI`, `-gnatyLnnn`, `-gnatyo`, `-gnaty0`, `-gnatyS`, `-gnatyu`, and `-gnatyx`."

You may find that selecting the appropriate coding style is useful to detect issues at early stages. For example, the `-gnaty0` switch checks that overriding subprograms are explicitly marked as such. Using this switch can avoid surprises when you didn't intentionally want to override an operation for some data type. We recommend studying the list of coding style switches and selecting the ones that seem relevant for your project. When in doubt, you can start by using all of them — using `-gnatyy` and `-gnatyBdIL4o0Sux`, for example — and deactivating the ones that cause too much *noise* during compilation.

CHAPTER

EIGHTYEIGHT

GPRBUILD

This chapter presents a brief overview of **GPRbuild**, the project manager of the GNAT toolchain. It can be used to manage complex builds. In terms of functionality, it's similar to **make** and **cmake**, just to name two examples.

For a detailed presentation of the tool, please refer to the GPRbuild User's Guide[351].

88.1 Basic commands

As mentioned in the previous chapter, you can build a project using **gprbuild** from the command line:

```
gprbuild -P project.gpr
```

In order to clean the project, you can use **gprclean**:

```
gprclean -P project.gpr
```

88.2 Project files

You can create project files using **GNAT Studio**, which presents many options on its graphical interface. However, you can also edit project files manually as a normal text file in an editor, since its syntax is human readable. In fact, project files use a syntax similar to the one from the Ada language. Let's look at the basic structure of project files and how to customize them.

88.2.1 Basic structure

The main element of a project file is a project declaration, which contains definitions for the current project. A project file may also include other project files in order to compose a complex build. One of the simplest form of a project file is the following:

```
project Default is

   for Main use ("main");
   for Source_Dirs use ("src");

end Default;
```

[351] https://docs.adacore.com/gprbuild-docs/html/gprbuild_ug.html

In this example, we declare a project named `Default`. The `for Main use` expression indicates that the `main.adb` file is used as the entry point (main source-code file) of the project. The main file doesn't necessary need to be called `main.adb`; we could use any source-code implementing a main application, or even have a list of multiple main files. The `for Source_Dirs use` expression indicates that the `src` directory contains the source-file for the application (including the main file).

88.2.2 Customization

GPRbuild support scenario variables, which allow you to control the way binaries are built. For example, you may want to distinguish between debug and optimized versions of your binary. In principle, you could pass command-line options to **gprbuild** that turn debugging on and off, for example. However, defining this information in the project file is usually easier to handle and to maintain. Let's define a scenario variable called `ver` in our project:

```
project Default is

   Ver := external ("ver", "debug");

   for Main use ("main");
   for Source_Dirs use ("src");

end Default;
```

In this example, we're specifying that the scenario variable `Ver` is initialized with the external variable `ver`. Its default value is set to debug.

We can now set this variable in the call to **gprbuild**:

```
gprbuild -P project.gpr -Xver=debug
```

Alternatively, we can simply specify an environment variable. For example, on Unix systems, we can say:

```
export ver=debug

# Value from environment variable "ver" used in the following call:

gprbuild -P project.gpr
```

In the project file, we can use the scenario variable to customize the build:

```
project Default is
   Ver := external ("ver", "debug");

   for Main use ("main.adb");
   for Source_Dirs use ("src");

   --  Using "ver" variable for obj directory
   for Object_Dir use "obj/" & Ver;

   package Compiler is
      case Ver is
         when "debug" =>
            for Switches ("Ada") use ("-g");
         when "opt" =>
            for Switches ("Ada") use ("-O2");
         when others =>
            null;
      end case;
```

(continues on next page)

(continued from previous page)

```
   end Compiler;

end Default;
```

We're now using `Ver` in the `for Object_Dir` clause to specify a subdirectory of the `obj` directory that contains the object files. Also, we're using `Ver` to select compiler options in the `Compiler` package declaration.

We could also specify all available options in the project file by creating a typed variable. For example:

```
project Default is

   type Ver_Option is ("debug", "opt");
   Ver : Ver_Option := external ("ver", "debug");

   for Source_Dirs use ("src");
   for Main use ("main.adb");

   --  Using "ver" variable for obj directory
   for Object_Dir use "obj/" & Ver;

   package Compiler is
      case Ver is
         when "debug" =>
            for Switches ("Ada") use ("-g");
         when "opt" =>
            for Switches ("Ada") use ("-O2");
         when others =>
            null;
      end case;
   end Compiler;

end Default;
```

The advantage of this approach is that **gprbuild** can now check whether the value that you provide for the `ver` variable is available on the list of possible values and give you an error if you're entering a wrong value.

88.3 Project dependencies

GPRbuild supports project dependencies. This allows you to reuse information from existing projects. Specifically, the keyword **with** allows you to include another project within the current project.

88.3.1 Simple dependency

Let's look at a very simple example. We have a package called `Test_Pkg` associated with the project file `test_pkg.gpr`, which contains:

```
project Test_Pkg is
    for Source_Dirs use ("src");
    for Object_Dir use "obj";
end Test_Pkg;
```

This is the code for the `Test_Pkg` package:

```
package Test_Pkg is

   type T is record
      X : Integer;
      Y : Integer;
   end record;

   function Init return T;

end Test_Pkg;
```

```
package body Test_Pkg is

   function Init return T is
   begin
      return V : T do
         V.X := 0;
         V.Y := 0;
      end return;
   end Init;

end Test_Pkg;
```

For this example, we use a directory `test_pkg` containing the project file and a subdirectory `test_pkg/src` containing the source files. The directory structure looks like this:

```
|- test_pkg
|    | test_pkg.gpr
|    |- src
|    |    | test_pkg.adb
|    |    | test_pkg.ads
```

Suppose we want to use the `Test_Pkg` package in a new application. Instead of directly including the source files of `Test_Pkg` in the project file of our application (either directly or indirectly), we can instead reference the existing project file for the package by using `with "test_pkg.gpr"`. This is the resulting project file:

```
with "../test_pkg/test_pkg.gpr";

project Default is
    for Source_Dirs use ("src");
    for Object_Dir use "obj";
    for Main use ("main.adb");
end Default;
```

And this is the code for the main application:

```
with Test_Pkg; use Test_Pkg;

procedure Main is
   A : T;
begin
   A := Init;
end Main;
```

When we build the main project file (`default.gpr`), we're automatically building all dependent projects. More specifically, the project file for the main application automatically includes the information from the dependent projects such as `test_pkg.gpr`. Using a `with` in the main project file is all we have to do for that to happen.

88.3.2 Dependencies to dynamic libraries

We can structure project files to make use of dynamic (shared) libraries using a very similar approach. It's straightforward to convert the project above so that `Test_Pkg` is now compiled into a dynamic library and linked to our main application. All we need to do is to make a few additions to the project file for the `Test_Pkg` package:

```
library project Test_Pkg is
    for Source_Dirs use ("src");
    for Object_Dir use "obj";
    for Library_Name use "test_pkg";
    for Library_Dir use "lib";
    for Library_Kind use "Dynamic";
end Test_Pkg;
```

This is what we had to do:

- We changed the `project` to `library project`.
- We added the specification for `Library_Name`, `Library_Dir` and `Library_Kind`.

We don't need to change the project file for the main application because **GPRbuild** automatically detects the dependency information (e.g., the path to the dynamic library) from the project file for the `Test_Pkg` package. With these small changes, we're able to compile the `Test_Pkg` package to a dynamic library and link it with our main application.

88.4 Configuration pragma files

Configuration pragma files contain a set of pragmas that modify the compilation of source files according to external requirements. For example, you may use pragmas to either relax or strengthen requirements depending on your environment.

In **GPRbuild**, we can use `Local_Configuration_Pragmas` (in the `Compiler` package) to indicate the configuration pragmas file we want **GPRbuild** to use with the source files in our project.

The file `gnat.adc` shown here is an example of a configuration pragma file:

```
pragma Suppress (Overflow_Check);
```

We can use this in our project by declaring a `Compiler` package. Here's the complete project file:

```
project Default is

   for Source_Dirs use ("src");
   for Object_Dir use "obj";
   for Main use ("main.adb");

   package Compiler is
      for Local_Configuration_Pragmas use "gnat.adc";
   end Compiler;

end Default;
```

Each pragma contained in `gnat.adc` is used in the compilation of each file, as if that pragma was placed at the beginning of each file.

88.5 Configuration packages

You can control the compilation of your source code by creating variants for various cases and selecting the appropriate variant in the compilation package in the project file. One example where this is useful is conditional compilation using Boolean constants, shown in the code below:

```
with Ada.Text_IO; use Ada.Text_IO;

with Config;

procedure Main is
begin

   if Config.Debug then
      Put_Line ("Debug version");
   else
      Put_Line ("Release version");
   end if;
end Main;
```

In this example, we declared the Boolean constant in the `Config` package. By having multiple versions of that package, we can create different behavior for each usage. For this simple example, there are only two possible cases: either Debug is **`True`** or **`False`**. However, we can apply this strategy to create more complex cases.

In our next example, we store the packages in the subdirectories debug and `release` of the source code directory. Here's the content of the `src/debug/config.ads` file:

```
package Config is

   Debug : constant Boolean := True;

end Config;
```

Here's the `src/release/config.ads` file:

```
package Config is

   Debug : constant Boolean := False;

end Config;
```

In this case, **`GPRbuild`** selects the appropriate directory to look for the `config.ads` file according to information we provide for the compilation process. We do this by using a scenario type called Mode_Type in our project file:

```
gprbuild -P default.gpr -Xmode=release
```

```
project Default is

   type Mode_Type is ("debug", "release");

   Mode : Mode_Type := external ("mode", "debug");

   for Source_Dirs use ("src", "src/" & Mode);
   for Object_Dir use "obj";
   for Main use ("main.adb");

end Default;
```

We declare the scenario variable `Mode` and use it in the `Source_Dirs` declaration to add the desired path to the subdirectory containing the `config.ads` file. The expression `"src/" & Mode` concatenates the user-specified mode to select the appropriate subdirectory. For more complex cases, we could use either a tree of subdirectories or multiple scenario variables for each aspect that we need to configure.

CHAPTER

EIGHTYNINE

GNAT STUDIO

This chapter presents an introduction to the GNAT Studio, which provides an IDE to develop applications in Ada. For a detailed overview, please refer to the GNAT Studio tutorial[352]. Also, you can refer to the GNAT Studio product page[353] for some introductory videos.

In this chapter, all indications using "→" refer to options from the GNAT Studio menu that you can click in order to execute commands.

89.1 Start-up

The first step is to start-up the GNAT Studio. The actual step depends on your platform.

89.1.1 Windows

- You may find an icon (shortcut to **`GNAT Studio`**) on your desktop.
- Otherwise, start **`GNAT Studio`** by typing `gnatstudio` on the command prompt.

89.1.2 Linux

- Start **`GNAT Studio`** by typing `gnatstudio` on a shell.

89.2 Creating projects

After starting-up **`GNAT Studio`**, you can create a project. These are the steps:

- Click on `Create new project` in the welcome window
  - Alternatively, if the *wizard* (which let's you customize new projects) isn't already opened, click on `File` → `New Project...` to open it.
  - After clicking on `Create new project`, you should see a window with this title: `Create Project from Template`.
- Select one of the options from the list and click on `Next`.
  - The simplest one is `Basic > Simple Ada Project`, which creates a project containing a main application.
- Select the project location and basic settings, and click on `Apply`.

[352] https://docs.adacore.com/live/wave/gps/html/gps_tutorial/index.html
[353] https://www.adacore.com/gnatpro/toolsuite/gps

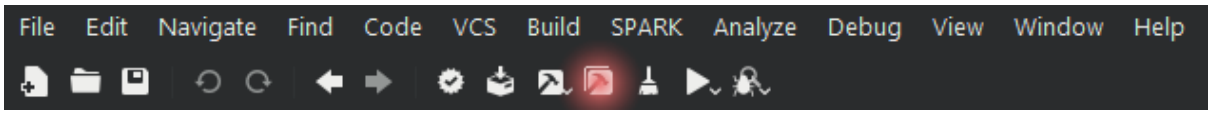
  - If you selected "Simple Ada Project" in the previous step, you may now select the name of the project and of the main file.
  - Note that you can select any name for the main file.

You should now have a working project file.

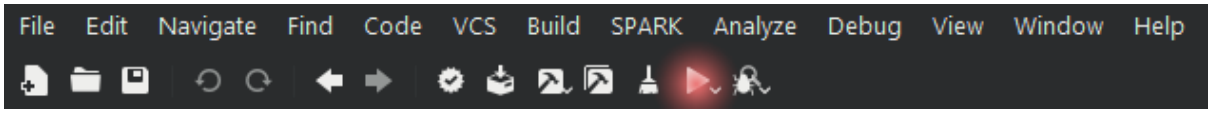
89.3 Building

As soon as you've created a project file, you can use it to build an application. These are the required steps:

- Click on `Build` → `Project` → `Build All`
  - You can also click on this icon:



- Alternatively, you can click on `Build` → `Project` → `Build & Run` → `<name of your main application>`
  - You can also click on this icon:



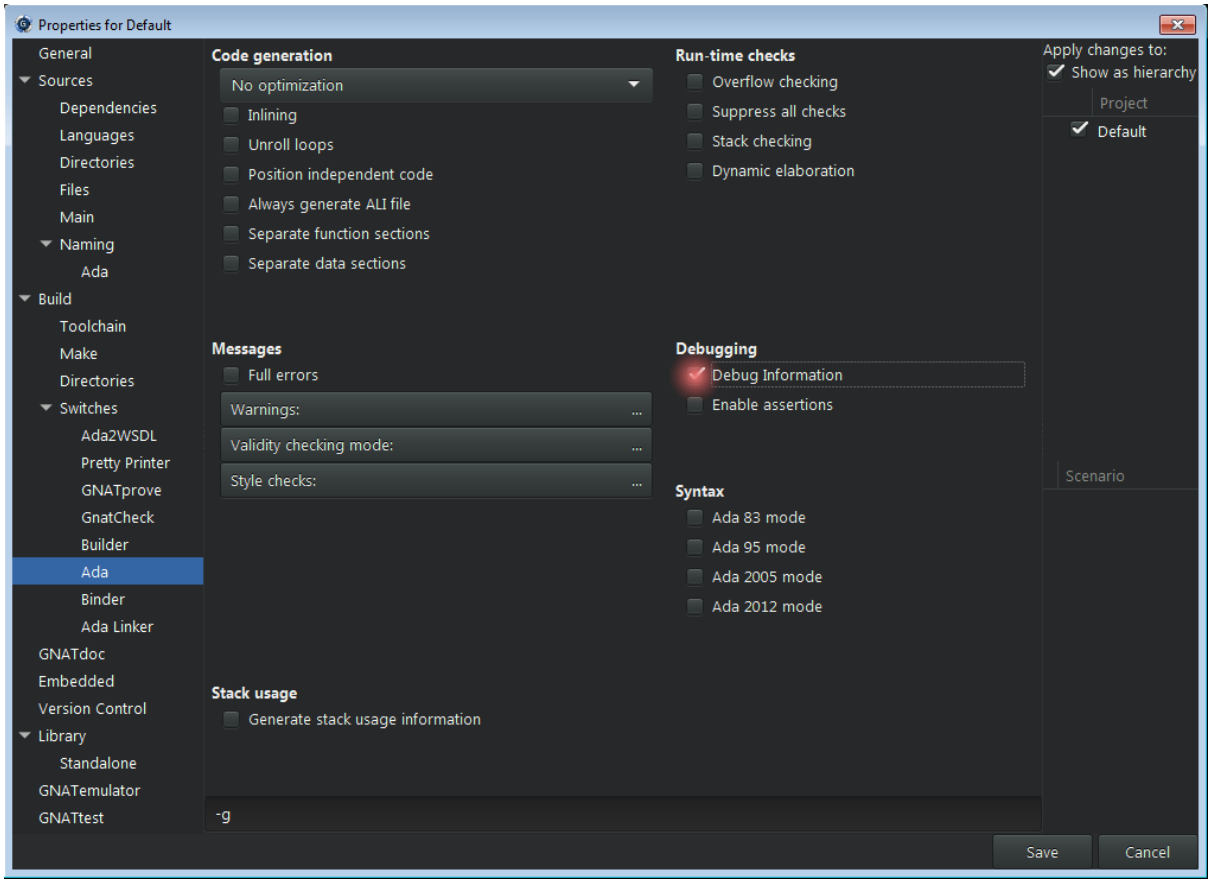
- You can also use the keyboard for building and running the main application:
  - Press F4 to open a window that allows you to build the main application and click on `Execute`.
  - Then, press `Shift + F2` to open a window that allows you to run the application, and click on `Execute`.

89.4 Debugging

89.4.1 Debug information

Before you can debug a project, you need to make sure that debugging symbols have been included in the binary build. You can do this by manually adding a debug version into your project, as described in the previous chapter (see *GPRbuild* (page 1687)).

Alternatively, you can change the project properties directly in **`GNAT Studio`**. In order to do that, click on `Edit` → `Project Properties...`, which opens the following window:



Click on `Build` → `Switches` → `Ada` on this window, and make sure that the `Debug Information` option is selected.

89.4.2 Improving main application

If you selected "Simple Ada Project" while creating your project in the beginning, you probably still have a very simple main application that doesn't do anything useful. Therefore, in order to make the debugging activity more interesting, please enter some statements to your application. For example:

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
begin
   Put_Line ("Hello World!");
   Put_Line ("Hello again!");
end Main;
```

89.4.3 Debugging the application

You can now build and debug the application by clicking on Build → Project → Build & Debug → <name of your main application>.

You can then click on Debug → Run... to open a window that allows you to start the application. Alternatively, you can press Shift + F9. As soon as the application has started, you can press F5 to step through the application or press F6 to execute until the next line. Both commands are available in the menu by clicking on Debug → Step or Debug → Next.

When you've finished debugging your application, you need to terminate the debugger. To do this, you can click on Debug → Terminate.

89.5 Formal verification

In order to see how SPARK can detect issues, let's creating a simple application that accumulates values in a variable A:

```
procedure Main
  with SPARK_Mode is

   procedure Acc (A : in out Natural;
                  V :        Natural) is
   begin
      A := A + V;
   end Acc;

   A : Natural := 0;
begin
   Acc (A, Natural'Last);
   Acc (A, 1);
end Main;
```

You can now click on SPARK → Prove All, which opens a window with various options. For example, on this window, you can select the proof level — varying between 0 and 4 — on the Proof level list. Next, click on Execute. After the prover has completed its analysis, you'll see a list of issues found in the source code of your application.

For the example above, the prover complains about an overflow check that might fail. This is due to the fact that, in the Acc procedure, we're not dealing with the possibility that the result of the addition might be out of range. In order to fix this, we could define a new saturating addition Sat_Add that makes use of a custom type T with an extended range. For example:

```
procedure Main
  with SPARK_Mode is

   function Sat_Add (A : Natural;
                     V : Natural) return Natural
   is
      type T is range Natural'First .. Natural'Last * 2;

      A2     : T          := T (A);
      V2     : constant T := T (V);
      A_Last : constant T := T (Natural'Last);
   begin
      A2 := A2 + V2;

      --  Saturate result if needed
```

(continues on next page)

(continued from previous page)

```
      if A2 > A_Last then
         A2 := A_Last;
      end if;

      return Natural (A2);
   end Sat_Add;

   procedure Acc (A : in out Natural;
                  V :        Natural) is
   begin
      A := Sat_Add (A, V);
   end Acc;

   A : Natural := 0;
begin
   Acc (A, Natural'Last);
   Acc (A, 1);
end Main;
```

Now, when running the prover again with the modified code, no issues are found.

CHAPTER

NINETY

GNAT TOOLS

In chapter we present a brief overview of some of the tools included in the GNAT toolchain. For further details on how to use these tools, please refer to the GNAT User's Guide[354].

90.1 gnatchop

gnatchop renames files so they match the file structure and naming convention expected by the rest of the GNAT toolchain. The GNAT compiler expects specifications to be stored in `.ads` files and bodies (implementations) to be stored in `.adb` files. It also expects file names to correspond to the content of each file. For example, it expects the specification of a package `Pkg.Child` to be stored in a file named `pkg-child.ads`.

However, we may not want to use that convention for our project. For example, we may have multiple Ada packages contained in a single file. Consider a file `example.ada` containing the following:

```
with Ada.Text_IO; use Ada.Text_IO;

package P is
   procedure Test;
end P;

package body P is
   procedure Test is
   begin
      Put_Line("Test passed.");
   end Test;
end P;

with P; use P;

procedure P_Main is
begin
   P.Test;
end P_Main;
```

To compile this code, we first pass the file containing our source code to **gnatchop** before we call **gprbuild**:

```
gnatchop example.ada
gprbuild p_main
```

This generates source files for our project, extracted from `example_ada`, that conform to the default naming convention and then builds the executable binary `p_main` from those

[354] https://docs.adacore.com/gnat_ugn-docs/html/gnat_ugn/gnat_ugn.html

files. In this example **gnatchop** created the files `p.ads`, `p.adb`, and `p_main.adb` using the package names in `example.ada`.

When we use this mechanism, any warnings or errors the compiler displays refers to the files generated by **gnatchop**. We can, however, instruct **gnatchop** to instrument the generated files so the compiler refers to the original file (`example.ada` in our case) when displaying messages. We do this by using the `-r` switch:

```
gnatchop -r example.ada
gprbuild p_main
```

If, for example, we had an unused variable in `example.ada`, the compiler warning would now refer to the line in the original file, not in one of the generated ones.

For documentation of other switches available for **gnatchop**, please refer to the gnatchop chapter[355] of the GNAT User's Guide.

90.2 gnatprep

We may want to use conditional compilation in some situations. For example, we might need a customized implementation of a package for a specific platform or need to select a specific version of an algorithm depending on the requirements of the target environment. A traditional way to do this uses a source-code preprocessor. However, in many cases where conditional compilation is needed, we can instead use the syntax of the Ada language or the functionality provided by **GPRbuild** to avoid using a preprocessor in those cases. The conditional compilation section[356] of the GNAT User's Guide discusses how to do this in detail.

Nevertheless, using a preprocessor is often the most straightforward option in complex cases. When we encounter such a case, we can use **gnatprep**, which provides a syntax that reminds us of the C and C++ preprocessor. However, unlike in C and C++, this syntax is not part of the Ada standard and can only be used with **gnatprep**. Also, you'll notice some differences in the syntax from that preprocessor, such as shown in the example below:

```
#if VERSION'Defined and then (VERSION >= 4) then
   --  Implementation for version 4.0 and above...
#else
   --  Standard implementation for older versions...
#end if;
```

Of course, in this simple case, we could have used the Ada language directly and avoided the preprocessor entirely:

```
package Config is
   Version : constant Integer := 4;
end Config;

with Config;
procedure Do_Something is
begin
   if Config.Version >= 4 then
      null;
      --  Implementation for version 4.0 and above...
   else
      null;
```

(continues on next page)

[355] https://docs.adacore.com/gnat_ugn-docs/html/gnat_ugn/gnat_ugn/the_gnat_compilation_model.html#renaming-files-with-gnatchop
[356] https://docs.adacore.com/gnat_ugn-docs/html/gnat_ugn/gnat_ugn/the_gnat_compilation_model.html#conditional-compilation

(continued from previous page)

```
      --  Standard implementation for older versions...
   end if;
end Do_Something;
```

But for the sake of illustrating the use of **gnatprep**, let's use that tool in this simple case. This is the complete procedure, which we place in file `do_something.org.adb`:

```
procedure Do_Something is
begin
   #if VERSION'Defined and then (VERSION >= 4) then
   --  Implementation for version 4.0 and above...
   null;
   #else
   --  Standard implementation for older versions...
   null;
   #end if;
end Do_Something;
```

To preprocess this file and build the application, we call **gnatprep** followed by **GPRbuild**:

```
gnatprep do_something.org.adb do_something.adb
gprbuild do_something
```

If we look at the resulting file after preprocessing, we see that the `#else` implementation was selected by **gnatprep**. To cause it to select the newer "version" of the code, we include the symbol and its value in our call to **gnatprep**, just like we'd do for C/C++:

```
gnatprep -DVERSION=5 do_something.org.adb do_something.adb
```

However, a cleaner approach is to create a symbol definition file containing all symbols we use in our implementation. Let's create the file and name it `prep.def`:

```
VERSION := 5
```

Now we just need to pass it to **gnatprep**:

```
gnatprep do_something.org.adb do_something.adb prep.def
gprbuild do_something
```

When we use **gnatprep** in that way, the line numbers of the output file differ from those of the input file. To preserve line numbers, we can use one of these command-line switches:

- `-b`: replace stripped-out code by blank lines
- `-c`: comment-out the stripped-out code

For example:

```
gnatprep -b do_something.org.adb do_something.adb prep.def
gnatprep -c do_something.org.adb do_something.adb prep.def
```

When we use one of these options, **gnatprep** ensures that the output file `do_something.adb` has the same line numbering as the original file (`do_something.org.adb`).

The gnatprep chapter[357] of the GNAT User's Guide contains further details about this tool, such as how to integrate **gnatprep** with project files for **GPRbuild** and how to replace symbols without using preprocessing directives (using the `$symbol` syntax).

[357] https://docs.adacore.com/gnat_ugn-docs/html/gnat_ugn/gnat_ugn/the_gnat_compilation_model.html#preprocessing-with-gnatprep

90.3 gnatmem

Memory allocation errors involving mismatches between allocations and deallocations are a common source of memory leaks. To test an application for memory allocation issues, we can use **gnatmem**. This tool monitors all memory allocations in our application. We use this tool by linking our application to a special version of the memory allocation library (`libgmem.a`).

Let's consider this simple example:

```
procedure Simple_Mem is
   I_Ptr : access Integer := new Integer;
begin
   null;
end Simple_Mem;
```

To generate a memory report for this code, we need to:

- Build the application, linking it to `libgmem.a`;
- Run the application, which generates an output file (`gmem.out`);
- Run **gnatmem** to generate a report from `gmem.out`.

For our example above, we do the following:

```
# Build application using gmem
gnatmake -g simple_mem.adb -largs -lgmem

# Run the application and generate gmem.out
./simple_mem

# Call gnatmem to display the memory report based on gmem.out
gnatmem simple_mem
```

For this example, **gnatmem** produces the following output:

```
Global information
------------------
   Total number of allocations        :   1
   Total number of deallocations      :   0
   Final Water Mark (non freed mem)   : 4 Bytes
   High Water Mark                    : 4 Bytes

Allocation Root # 1
-------------------
 Number of non freed allocations    :   1
 Final Water Mark (non freed mem)   : 4 Bytes
 High Water Mark                    : 4 Bytes
 Backtrace                          :
   simple_mem.adb:2 simple_mem
```

This shows all the memory we allocated and tells us that we didn't deallocate any of it.

Please refer to the chapter on gnatmem[358] of the GNAT User's Guide for a more detailed discussion of **gnatmem**.

[358] https://docs.adacore.com/gnat_ugn-docs/html/gnat_ugn/gnat_ugn/gnat_and_program_execution.html#the-gnatmem-tool

90.4 gnatmetric

We can use the GNAT metric tool (**gnatmetric**) to compute various programming metrics, either for individual files or for our complete project.

For example, we can compute the metrics of the body of package P above by running **gnatmetric** as follows:

```
gnatmetric p.adb
```

This produces the following output:

```
Line metrics summed over 1 units
  all lines            : 13
  code lines           : 11
  comment lines        : 0
  end-of-line comments : 0
  comment percentage   : 0.00
  blank lines          : 2

Average lines in body: 4.00

Element metrics summed over 1 units
  all statements      : 2
  all declarations    : 3
  logical SLOC        : 5

 2 subprogram bodies in 1 units

Average cyclomatic complexity: 1.00
```

Please refer to the section on gnatmetric[359] of the GNAT User's Guide for the many switches available for **gnatmetric**, including the ability to generate reports in XML format.

90.5 gnatdoc

Use **GNATdoc** to generate HTML documentation for your project. It scans the source files in the project and extracts information from package, subprogram, and type declarations.

The simplest way to use it is to provide the name of the project or to invoke **GNATdoc** from a directory containing a project file:

```
gnatdoc -P some_directory/default.gpr

# Alternatively, when the :file:`default.gpr` file is in the same directory

gnatdoc
```

Just using this command is sufficient if your goal is to generate a list of the packages and a list of subprograms in each. However, to create more meaningful documentation, you can annotate your source code to add a description of each subprogram, parameter, and field. For example:

```
package P is
--  Collection of auxiliary subprograms
```

(continues on next page)

[359] https://docs.adacore.com/gnat_ugn-docs/html/gnat_ugn/gnat_ugn/gnat_utility_programs.html#the-gnat-metrics-tool-gnatmetric

(continued from previous page)

```
   function Add_One
     (V : Integer
      --  Coefficient to be incremented
     ) return Integer;
   --  @return Coefficient incremented by one

end P;
```

```
package body P is

   function Add_One (V : Integer) return Integer is
   begin
      return V + 1;
   end Add_One;

end P;
```

```
with P; use P;

procedure Main is

   I : Integer;

begin
   I := Add_One (0);
end Main;
```

When we run this example, **GNATdoc** will extract the documentation from the specification of package P and add the description of each element, which we provided as a comment in the line below the actual declaration. It will also extract the package description, which we wrote as a comment in the line right after `package P is`. Finally, it will extract the documentation of function Add_One (both the description of the V parameter and the return value).

In addition to the approach we've just seen, **GNATdoc** also supports the tagged format that's commonly found in tools such as Javadoc and uses the `@` syntax. We could rewrite the documentation for package P as follows:

```
package P is
-- @summary Collection of auxiliary subprograms

   function Add_One
     (V : Integer
     ) return Integer;
   -- @param V Coefficient to be incremented
   -- @return Coefficient incremented by one

end P;
```

You can control what parts of the source-code **GNATdoc** parses to extract the documentation. For example, you can specify the `-b` switch to request that the package body be parsed for additional documentation and you can use the `-p` switch to request **GNATdoc** to parse the private part of package specifications. For a complete list of switches, please refer to the GNATdoc User's Guide[360].

[360] http://docs.adacore.com/gnatdoc-docs/users_guide/_build/html/index.html

90.6 gnatpp

The term 'pretty-printing' refers to the process of formatting source code according to a pre-defined convention. **gnatpp** is used for the pretty-printing of Ada source-code files.

Let's look at this example, which contains very messy formatting:

```
PrOcEDuRE Main
                  IS

   FUNCtioN
                        Init_2
                  RETurn
     inteGER                 iS
                                  (2);

                I : INTeger;

     BeGiN
            I             :=        Init_2;
                 ENd;
```

We can request **gnatpp** to clean up this file by using the command:

```
gnatpp main.adb
```

gnatpp reformats the file in place. After this command, `main.adb` looks like this:

```
procedure Main is

   function Init_2 return Integer is (2);

   I : Integer;

begin
   I := Init_2;
end Main;
```

We can also process all source code files from a project at once by specifying a project file. For example:

```
gnatpp -P default.gpr
```

gnatpp has an extensive list of options, which allow for specifying the formatting of many aspects of the source and implementing many coding styles. These are extensively discussed in the section on gnatpp[361] of the GNAT User's Guide.

[361] https://docs.adacore.com/gnat_ugn-docs/html/gnat_ugn/gnat_ugn/gnat_utility_programs.html#the-gnat-pretty-printer-gnatpp

90.7 gnatstub

Suppose you've created a complex specification of an Ada package. You can create the corresponding package body by copying and adapting the content of the package specification. But you can also have **gnatstub** do much of that job for you. For example, let's consider the following package specification:

```
package Aux is

   function Add_One (V : Integer) return Integer;

   procedure Reset (V : in out Integer);

end Aux;
```

We call **gnatstub**, passing the file containing the package specification:

```
gnatstub aux.ads
```

This generates the file aux.adb with the following contents:

```
pragma Ada_2012;
package body Aux is

   -------------
   -- Add_One --
   -------------

   function Add_One (V : Integer) return Integer is
   begin
      --  Generated stub: replace with real body!
      pragma Compile_Time_Warning (Standard.True, "Add_One unimplemented");
      return raise Program_Error with "Unimplemented function Add_One";
   end Add_One;

   -----------
   -- Reset --
   -----------

   procedure Reset (V : in out Integer) is
   begin
      --  Generated stub: replace with real body!
      pragma Compile_Time_Warning (Standard.True, "Reset unimplemented");
      raise Program_Error with "Unimplemented procedure Reset";
   end Reset;

end Aux;
```

As we can see in this example, not only has **gnatstub** created a package body from all the elements in the package specification, but it also created:

- Headers for each subprogram (as comments);
- Pragmas and exceptions that prevent us from using the unimplemented subprograms in our application.

This is a good starting point for the implementation of the body. Please refer to the section on gnatstub[362] of the GNAT User's Guide for a detailed discussion of **gnatstub** and its options.

[362] https://docs.adacore.com/gnat_ugn-docs/html/gnat_ugn/gnat_ugn/gnat_utility_programs.html#the-body-stub-generator-gnatstub

CHAPTER

NINETYONE

INTRODUCTION

Ada is a general purpose, high-level programming language designed to support the construction of long-lived, highly-reliable applications. Like all general-purpose languages, only a subset of the full language is appropriate for safety-critical applications because the full language includes facilities that are difficult to analyze and verify to the degree required. This document facilitates identification of subsets appropriate for the highest levels of integrity, including safety-critical applications.

SPARK is a statically verifiable subset of Ada designed specifically for the most critical applications. Ada constructs not amenable to verification are precluded, such as arbitrary use of access types and full tasking. SPARK is also a superset of Ada, with additional contracts for specifying and verifying programs. Many of the guidelines (and more) are implicit in the design of SPARK.

Therefore, this document defines guidelines for the development of high-integrity, safety-critical applications in either the Ada or SPARK programming languages, or both (because the two can be mixed).

91.1 Scope

This document provides guidelines for development decisions, both at the system level and at the unit level, regarding the use of the programming languages Ada and SPARK, as well as related tools, such as static analyzers and unit test generators. It is not concerned with presentation issues such as naming, use of whitespace, or the like.

91.2 Structure

Rather than defining a specific set of rules defining a single subset, this document defines a set of criteria, in the form of guidelines, used by system architects to identify project-specific subsets appropriate to a given project.

The guidelines are separated into related categories, such as storage management, object-oriented programming, concurrency management, and so on. Each guideline is in a separate table, specifying the rule name, a unique identifier, and additional attributes common to each table.

91.3 Enforcement

Detection and enforcement mechanisms are indicated for each guideline. These mechanisms typically consist of the application of a language standard pragma named `Restrictions`, with policy-specific restriction identifiers given as parameters to the pragma [AdaRM2016]. Violations of the given restrictions are then detected and enforced by the Ada compiler.

Alternatively, the AdaCore GNATcheck utility program has rules precisely corresponding to those restriction identifiers, with the same degree of detection and enforcement. For example, the language restriction identifier `No_Unchecked_Deallocation` corresponds to the GNATcheck **+RRestrictions:No_Unchecked_Deallocation** rule.

The advantage of GNATcheck over the compiler is that all generated messages will be collected in the GNATcheck report that can be used as evidence of the level of adherence to the coding standard. In addition, GNATcheck provides a mechanism to deal with accepted exemptions.

In some cases the enforcement mechanism is the SPARK language and analyzer. Many of the guidelines (and more) are implicit in the design of SPARK and are, therefore, automatically enforced.

In some (very) rare cases the enforcement mechanism is manual program inspection, although alternatives (e.g., SPARK) are usually available and recommended. These guidelines are included because they are considered invaluable in this domain.

91.4 About the Rules

Although we refer to them as **rules** in the tables for the sake of brevity, these entries should be considered **guidance** because they require both thought and consideration of project-specific characteristics. For example, in some cases the guidance is to make a selection from among a set of distinct enumerated policies. In other cases a single guideline should be followed but not without some exceptional situations allowing it to be violated. The project lead should consider which guidelines to apply and how best to apply each guideline selected.

91.4.1 Mapping to Other Standards

Many of these rules can also be considered *good* programming practices. As such, many of them can be directly correlated to the *ISO/IEC Guidance to Avoiding Vulnerabilities in Programming Languages* [TR24772]. When a rule addresses one of these vulnerabilities, it is listed in the appropriate subsection.

In addition, MITRE's list of Common Weakness Enumerations [MITRE_CWE] contains many software issues that can be addressed by rules within this standard. Where appropriate, each rule lists the CWE(s) that can be addressed. Note that software CWEs tend to be generalized across all languages, so that many of the weaknesses may be prevented by the language itself. For this reason, the CWEs identified within this document specifically address vulnerabilities that would not be addressed by the Ada language itself (i.e., using the language is not sufficient to prevent the vulnerability).

CHAPTER

NINETYTWO

DEFINITIONS

This section contains terms and values used in the definitions of the rules set forth in this chapter.

92.1 Level

Level is the compliance level for the rule. Possible values are:

Mandatory
: Non-compliance with a *Mandatory* recommendation level corresponds to a **high risk** of a software bug. There would need to be a good reason for non-conformity to a mandatory rule and, although it is accepted that exceptional cases may exist, any non-conformance should be accompanied by a clear technical explanation of the exceptional circumstance.

Required
: Non-compliance with a *Required* recommendation level corresponds to a **medium to high risk** of a software bug. Much like a *Mandatory* recommendation, there would need to be a good reason for non-conformity to a required rule. Although it is accepted that more exceptional cases may exist, non-conformance should be accompanied by a clear technical explanation of the exceptional circumstance.

Advisory
: Failure to follow an *Advisory* recommendation does not necessarily result in a software bug; the risk of a direct correlation between non-conformance of an advisory rule and a software bug is low. Non-compliance with an advisory recommendation level does not require a supporting technical explanation, however, as the quality of the code may be impacted, the reason for the non-conformance should be understood.

92.2 Remediation

Remediation indicates the the level of difficulty to modify/update code that does not follow this particular rule.

High
: Failure to follow this rule will likely cause an unreasonable amount of modifications/updates to bring the code base into compliance.

Medium
: Failure to follow this rule will likely cause a large amount of modifications/updates to bring the code base into compliance, but those changes may still be cost-effective.

Low
: Failure to follow this rule may cause a small amount of modifications/updates to bring the code base into compliance, but those changes will be minor compared to the benefit.

N/A
: This rule is more of a design decision (as opposed to a coding flaw) and therefore, if the rule is violated, it is done so with a specific purpose.

CHAPTER

NINETYTHREE

DYNAMIC STORAGE MANAGEMENT (DYN)

Goal

Maintainability
✓

Reliability
✓

Portability
Performance
✓

Security
✓

Description
Have a plan for managing dynamic memory allocation and deallocation.

Rules
DYN01, DYN02, DYN03, DYN04, DYN05, DYN06

In Ada, objects are created by being either *declared* or *allocated*. Declared objects may be informally thought of as being created "on the stack" although such details are not specified by the language. *Allocated* objects may be thought of as being allocated "from the heap", which is, again, an informal term. Allocated objects are created by the evaluation of allocators represented by the reserved word `new` and, unlike declared objects, have lifetimes independent of scope.

The terms *static* and *dynamic* tend to be used in place of *declared* and *allocated*, although in traditional storage management terminology all storage allocation in Ada is dynamic. In the following discussion, the term *dynamic allocation* refers to storage that is allocated by allocators. *Static* object allocation refers to objects that are declared. *Deallocation* refers to the reclamation of allocated storage.

Unmanaged dynamic storage allocation and deallocation can lead to storage exhaustion; the required analysis is difficult under those circumstances. Furthermore, access values can establish aliases that complicate verification, and explicit deallocation of dynamic storage can lead to specific errors (e.g., "double free", "use after free") having unpredictable results. As a result, the prevalent approach to storage management in high-integrity systems is to disallow dynamic management techniques completely. [SEI-C] [MISRA2013] [Holzmann2006] [ISO2000]

However, restricted forms of storage management and associated feature usage can support the necessary reliability and analyzability characteristics while retaining sufficient expressive power to justify the analysis expense. The following sections present possible approaches, including the traditional approach in which no dynamic behavior is allowed. Individual projects may then choose which storage management approach best fits their requirements and apply appropriate tailoring, if necessary, to the specific guidelines.

Realization
There is a spectrum of management schemes possible, trading ease of analysis against

increasing expressive power. At one end there is no dynamic memory allocation (and hence, deallocation) allowed, making analysis trivial. At the other end, nearly the full expressive power of the Ada facility is available, but with analyzability partially retained. In the latter, however, the user must create the allocators in such a manner as to ensure proper behavior.

Rule DYN01 is Required, as it avoids problematic features whatever the strategy chosen. Rules DYN02-05 are marked as Advisory, because one of them should be chosen and enforced throughout a given software project.

93.1 Common High Integrity Restrictions (DYN01)

93.1.1 Reference

Ada Reference Manual: H.4 High Integrity Restrictions[364]

93.1.2 Description

The following restrictions must be in effect:

- `No_Anonymous_Allocators`
- `No_Coextensions`
- `No_Access_Parameter_Allocators`
- `Immediate_Reclamation`

The first three restrictions prevent problematic usage that, for example, may cause unreclaimed (and unreclaimable) storage. The last restriction ensures any storage allocated by the compiler at run-time for representing objects is reclaimed at once. (That restriction does not apply to objects created by allocators in the application.)

[364] http://www.ada-auth.org/standards/12rm/html/RM-H-4.html

93.1.3 Applicable Vulnerability within ISO TR 24772-2

- 4.10 Storage Pool

93.1.4 Applicable Common Weakness Enumeration

- CWE-401 - Missing Release of Memory after Effective Lifetime[365]
- CWE-415 - Double Free[366]
- CWE-416 - Use After Free[367]

93.1.5 Noncompliant Code Example

For No_Anonymous_Allocators:

```
X : access String := new String'("Hello");
...
X := new String'("Hello");
```

For No_Coextensions:

```
type Object (Msg : access String) is ...
Obj : Object (Msg => new String'("Hello"));
```

For No_Access_Parameter_Allocators:

```
procedure P (Formal : access String);
...
P (Formal => new String'("Hello"));
```

93.1.6 Compliant Code Example

For No_Anonymous_Allocators, use a named access type:

```
type String_Reference is access all String;
S : constant String_Reference := new String'("Hello");
X : access String := S;
...
X := S;
```

For No_Coextensions, use a variable of a named access type:

```
type Object (Msg : access String) is ...
type String_Reference is access all String;
S : String_Reference := new String'("Hello");
Obj : Object (Msg => S);
```

For No_Access_Parameter_Allocators, use a variable of a named access type:

[365] https://cwe.mitre.org/data/definitions/401.html
[366] https://cwe.mitre.org/data/definitions/415.html
[367] https://cwe.mitre.org/data/definitions/416.html

```
procedure P (Formal : access String);
type String_Reference is access all String;
S : String_Reference := new String'("Hello");
...
P (Formal => S);
```

93.1.7 Notes

The compiler will detect violations of the first three restrictions. Note that GNATcheck can detect violations in addition to the compiler.

The fourth restriction is a directive for implementation behavior, not subject to source-based violation detection.

93.2 Traditional Static Allocation Policy (DYN02)

Verification Method → Compiler restrictions

93.2.1 Reference

MISRA C Dir 4.12: "Dynamic memory allocation shall not be used."

93.2.2 Description

The following restrictions must be in effect:

- `No_Allocators`
- `No_Task_Allocators`

Under the traditional approach, no dynamic allocations and no deallocations occur. Only declared objects are used and no access types of any kind appear in the code.

Without allocations there is no issue with deallocation as there would be nothing to deallocate. *Heap* storage exhaustion and fragmentation are clearly prevented although storage may still be exhausted due to insufficient stack size allotments.

In this approach the following constructs are not allowed:

- Allocators
- Access-to-constant access types
- Access-to-variable access types
- User-defined storage pools
- Unchecked Deallocations

93.2.3 Applicable Vulnerability within ISO TR 24772-2

- 4.10 Storage Pool

93.2.4 Applicable Common Weakness Enumeration

- CWE-401 - Missing Release of Memory after Effective Lifetime[368]
- CWE-758 - Reliance on Undefined, Unspecified, or Implementation-Defined Behavior[369]
- CWE-771 - Missing Reference to Active Allocated Resource[370]
- CWE-1325 - Improperly Controlled Sequential Memory Allocation[371]

93.2.5 Noncompliant Code Example

Any code using the constructs listed above.

[368] https://cwe.mitre.org/data/definitions/401.html
[369] https://cwe.mitre.org/data/definitions/758.html
[370] https://cwe.mitre.org/data/definitions/771.html
[371] https://cwe.mitre.org/data/definitions/1325.html

93.2.6 Compliant Code Example

N/A

93.2.7 Notes

The compiler, and/or GNATcheck, will detect violations of the restrictions.

93.3 Access Types Without Allocators Policy (DYN03)

Level → Advisory

Verification Method → Compiler restrictions

93.3.1 Reference

MISRA C Rule 21.3: "The memory allocation and deallocation functions of <stdlib.h> shall not be used."

93.3.2 Description

The following restrictions must be in effect:

- `No_Allocators`
- `No_Dependence => Ada.Unchecked_Deallocation`

In this approach dynamic access values are only created via the attribute `'Access` applied to aliased objects. Allocation and deallocation never occur. As a result, storage exhaustion cannot occur because no *dynamic* allocations occur. Fragmentation cannot occur because there are no deallocations.

In this approach the following constructs are not allowed:

- Allocators

- User-defined storage pools
- Unchecked Deallocations

Aspects should be applied to all access types in this approach, specifying a value of zero for the storage size. Although the restriction `No_Allocators` is present, such clauses may be necessary to prevent any default storage pools from being allocated for the access types, even though the pools would never be used. A direct way to accomplish this is to use **pragma** *Default_Storage_Pool* with a parameter of **null** like so:

```
pragma Default_Storage_Pool (null);
```

The above would also ensure no allocations can occur with access types that have the default pool as their associated storage pool (per Ada Reference Manual: 13.11.3 (6.1/3) Default Storage Pools[372]).

93.3.3 Applicable Vulnerability within ISO TR 24772-2

- 6.14 Dangling reference to heap [XYK]

93.3.4 Applicable Common Weakness Enumeration

- CWE-401 - Missing Release of Memory after Effective Lifetime[373]
- CWE-415 - Double Free[374]
- CWE-416 - Use After Free[375]
- CWE-771 - Missing Reference to Active Allocated Resource[376]
- CWE-1325 - Improperly Controlled Sequential Memory Allocation[377]

93.3.5 Noncompliant Code Example

Any code using the constructs listed above.

93.3.6 Compliant Code Example

```
type Descriptor is ...;
type Descriptor_Ref is access all Descriptor;
...
Device : aliased Descriptor;
...
P : Descriptor_Ref := Device'Access;
...
```

✓

Goal

Maintainability
✓

Reliability
✓

Portability
Performance
Security

Remediation → Low

Verification Method → Compiler restrictions

93.4.1 Reference

Power of Ten rule 3: "Do not use dynamic memory allocation after initialization."

93.4.2 Description

The following restrictions must be in effect:

- `No_Local_Allocators`
- `No_Dependence => Ada.Unchecked_Deallocation`

In this approach dynamic allocation is only allowed during "start-up" and no later. Deallocations never occur. As a result, storage exhaustion should never occur assuming the initial allotment is sufficient. This assumption is as strong as when using only declared objects on the "stack" because in that case a sufficient initial storage allotment for the stack must be made.

In this approach the following constructs are not allowed:

- Unchecked Deallocations

Note that some operating systems intended for this domain directly support this policy.

93.4.3 Applicable Vulnerability within ISO TR 24772-2

- 4.10 Storage Pool

93.4.4 Applicable Common Weakness Enumeration

- CWE-401 - Missing Release of Memory after Effective Lifetime[378]
- CWE-415 - Double Free[379]
- CWE-416 - Use After Free[380]
- CWE-771 - Missing Reference to Active Allocated Resource[381]
- CWE-1325 - Improperly Controlled Sequential Memory Allocation[382]

93.4.5 Noncompliant Code Example

Any code using the constructs listed above.

93.4.6 Compliant Code Example

Code performing dynamic allocations any time prior to an arbitrary point designated as the end of the "startup" interval.

93.4.7 Notes

The compiler, and/or GNATcheck, will detect violations of the restrictions.

93.5 User-Defined Storage Pools Policy (DYN05)

Verification Method → Code inspection

93.5.1 Reference

MISRA C Rule 21.3: "The memory allocation and deallocation functions of <stdlib.h> shall not be used."

93.5.2 Description

There are two issues that make storage utilization analysis difficult:

1. the predictability of the allocation and deallocation implementation, and
2. how access values are used by the application.

The behavior of the underlying implementation is largely undefined and may, for example, consist of calls to the operating system (if present). Application code can manipulate access values beyond the scope of analysis.

Under this policy, the full expressive power of access-to-object types is provided but one of the two areas of analysis difficulty is removed. Specifically, predictability of the allocation and deallocation implementation is achieved via user-defined storage pools. With these storage pools, the implementation of allocation (`new`) and deallocation (instances of `Ada.Unchecked_Deallocation`) is defined by the pool type.

If the pool type is implemented with fixed-size blocks on the stack, allocation and deallocation timing behavior are predictable.

Such an implementation would also be free from fragmentation.

Given an analysis providing the worst-case allocations and deallocations, it would be possible to verify that pool exhaustion does not occur. However, as mentioned such analysis can be quite difficult. A mitigation would be the use of the "owning" access-to-object types provided by SPARK.

In this approach no storage-related constructs are disallowed unless the SPARK subset is applied.

93.5.3 Applicable Vulnerability within ISO TR 24772-2

- 4.10 Storage Pool

93.5.4 Applicable Common Weakness Enumeration

- CWE-401 - Missing Release of Memory after Effective Lifetime[383]
- CWE-415 - Double Free[384]
- CWE-416 - Use After Free[385]

93.5.5 Noncompliant Code Example

Allocation via an access type not tied to a user-defined storage pool.

93.5.6 Compliant Code Example

```
Heap : Sequential_Fixed_Blocks.Storage_Pool
         (Storage_Size => Required_Storage_Size,
          Element_Size => Representable_Obj_Size,
          Alignment    => Representation_Alignment);
type Pointer is access all Unsigned_Longword with
   Storage_Pool => Heap;
Ptr : Pointer;
...
Ptr := new Unsigned_Longword; -- from Heap
```

93.5.7 Notes

Enforcement of this approach can only be provided by manual code review unless SPARK is used.

However, the User-Defined Storage Pools Policy can be enforced statically by specifying `Default_Storage_Pool (null)`. This essentially requires all access types to have a specified storage pool if any allocators are used with the access type.

Verification Method → Static analysis tools

93.6.1 Reference

N/A

93.6.2 Description

Each Ada application task has a stack, as does the "environment task" that elaborates library packages and calls the main subprogram. A tool to statically determine the maximum storage required for these stacks must be used, per task.

This guideline concerns another kind of dynamic memory utilization. The previous guidelines concerned the management of storage commonly referred to as the "heap." This guideline concerns the storage commonly referred to as the "stack." (Neither term is defined by the language, but both are commonly recognized and are artifacts of the underlying run-time library or operating system implementation.)

93.6.3 Applicable Vulnerability within ISO TR 24772-2

- 4.10 Storage Pool

93.6.4 Applicable Common Weakness Enumeration

- CWE-770 - Allocation of Resources Without Limits or Throttling[386]
- CWE-789 - Uncontrolled Memory Allocation[387]

93.6.5 Noncompliant Code Example

N/A

[386] https://cwe.mitre.org/data/definitions/770.html
[387] https://cwe.mitre.org/data/definitions/789.html

93.6.6 Compliant Code Example

N/A

93.6.7 Notes

The GNATstack[388] tool can statically determine the maximum requirements per task.

94.1.1 Reference

N/A

94.1.2 Description

Never deallocate the storage designated by a given access value more than once.

94.1.3 Applicable Vulnerability within ISO TR 24772-2

- 6.39 Memory leak and heap fragmentation [XYL]

94.1.4 Applicable Common Weakness Enumeration

- CWE-415 - Double Free[389]
- CWE-416 - Use After Free[390]

94.1.5 Noncompliant Code Example

```
   type String_Reference is access all String;
   procedure Free is new Ada.Unchecked_Deallocation
      (Object => String, Name => String_Reference);
   S : String_Reference := new String'("Hello");
   Y : String_Reference;
begin
   Y := S;
   Free (S);
   Free (Y);
```

94.1.6 Compliant Code Example

Remove the call to `Free (Y)`.

[389] https://cwe.mitre.org/data/definitions/415.html
[390] https://cwe.mitre.org/data/definitions/416.html

94.1.7 Notes

Enforcement of this rule can be provided by manual code review, unless deallocation is forbidden via `No_Unchecked_Deallocation` or SPARK is used, as ownership analysis in SPARK detects such cases. Note that storage utilization analysis tools such as Valgrind can usually find this sort of error. In addition, a GNAT-defined storage pool is available to help debug such errors.

94.2 Only Reclaim Allocated Storage (RCL02)

94.2.1 Reference

[SEI-C] MEM34-C: Only Free Memory Allocated Dynamically

94.2.2 Description

Only deallocate storage that was dynamically allocated by the evaluation of an allocator (i.e., `new`).

This is possible because Ada allows creation of access values designating declared (aliased) objects.

94.2.3 Applicable Vulnerability within ISO TR 24772-2

- 6.39 Memory leak and heap fragmentation [XYL]

94.2.4 Applicable Common Weakness Enumeration

- CWE-590 - Free of Memory not on the Heap[391]

94.2.5 Noncompliant Code Example

```
   type String_Reference is access all String;
   procedure Free is new Ada.Unchecked_Deallocation
     (Object => String, Name => String_Reference);
   S : aliased String := "Hello";
   Y : String_Reference := S'Access;
begin
   Free (Y);
```

94.2.6 Compliant Code Example

Remove the call to `Free (Y)`.

94.2.7 Notes

Enforcement of this rule can only be provided by manual code review, unless deallocation is forbidden via `No_Unchecked_Deallocation`.

94.3 Only Reclaim to the Same Pool (RCL03)

[391] https://cwe.mitre.org/data/definitions/590.html

Remediation → High

Verification Method → Code inspection

94.3.1 Reference

N/A

94.3.2 Description

When deallocating, ensure that the pool to which the storage will be returned is the same pool from which it was allocated. Execution is erroneous otherwise, meaning anything can happen (Ada Reference Manual: 13.11.2 (16) Unchecked Storage Deallocation[392]).

Each access type has an associated storage pool, either implicitly by default, or explicitly with a storage pool specified by the programmer. The implicit default pool might not be the same pool used for another access type, even an access type designating the same subtype.

94.3.3 Applicable Vulnerability within ISO TR 24772-2

- 6.39 Memory leak and heap fragmentation [XYL]

94.3.4 Applicable Common Weakness Enumeration

- CWE-401 - Missing Release of Memory after Effective Lifetime[393]

94.3.5 Noncompliant Code Example

```
   type Pointer1 is access all Integer;
   type Pointer2 is access all Integer;
   P1 : Pointer1;
   P2 : Pointer2;
   procedure Free is new Ada.Unchecked_Deallocation
      (Object => Integer, Name => Pointer2);
begin
   P1 := new Integer;
   P2 := Pointer2 (P1);
   Call_Something ( P2.all );
   ...
   Free (P2);
```

In the above, P1.**all** was allocated from Pointer1'Storage_Pool, but, via the type conversion, the code above is attempting to return it to Pointer2'Storage_Pool, which may be a different pool.

[392] http://www.ada-auth.org/standards/12rm/html/RM-13-11-2.html
[393] https://cwe.mitre.org/data/definitions/401.html

94.3.6 Compliant Code Example

```
   type Pointer1 is access all Integer;
   type Pointer2 is access all Integer;
   P1 : Pointer1;
   P2 : Pointer2;
   procedure Free is new Ada.Unchecked_Deallocation
      (Object => Integer, Name => Pointer1);
begin
   P1 := new Integer;
   P2 := Pointer2 (P1);
   Call_Something ( P2.all );
   ...
   Free (P1);
```

94.3.7 Notes

Enforcement of this rule can only be provided by manual code review, unless deallocation is forbidden via `No_Unchecked_Deallocation`.

CHAPTER

NINETYFIVE

CONCURRENCY (CON)

Goal

Maintainability
✓

Reliability
✓

Portability
✓

Performance
✓

Security

Description
Have a plan for managing the use of concurrency in high-integrity applications having real-time requirements.

Rules
CON01, CON02, CON03

The canonical approach to applications having multiple periodic and aperiodic activities is to map those activities onto independent tasks, i.e., threads of control. The advantages for the application are both a matter of software engineering and also ease of implementation. For example, when the different periods are not harmonics of one another, the fact that each task executes independently means that the differences are trivially represented. In contrast, such periods are not easily implemented in a cyclic scheduler, which, by definition, involves only one (implicit) thread of control with one frame rate.

High integrity applications are subject to a number of stringent analyses, including, for example, safety analyses and certification against rigorous industry standards. In addition, high integrity applications with real-time requirements must undergo timing analysis because they must be shown to meet deadlines prior to deployment — failure to meet hard deadlines is unacceptable in this domain.

These analyses are applied both to the application and to the implementation of the underlying run-time library. However, analysis of the complete set of general Ada tasking features is not tractable, neither technically nor in terms of cost. A subset of the language is required.

The Ravenscar profile [AdaRM2016] is a subset of the Ada concurrency facilities that supports determinism, schedulability analysis, constrained memory utilization, and certification to the highest integrity levels. Four distinct application domains are specifically intended:

- Hard real-time applications requiring predictability;
- Safety-critical systems requiring formal, stringent certification;
- High-integrity applications requiring formal static analysis and verification;

- Embedded applications requiring both a small memory footprint and low execution overhead.

Those tasking constructs that preclude analysis at the source level or analysis of the tasking portion of the underlying run-time library are disallowed.

The Ravenscar profile is necessarily strict in terms of what it removes so that it can support the stringent analyses, such as safety analysis, that go beyond the timing analysis required for real-time applications. In addition, the strict subset facilitates that timing analysis in the first place.

However, not all high-integrity applications are amenable to expression in the Ravenscar profile subset. The Jorvik profile [AdaRM2020] is an alternative subset of the Ada concurrency facilities. It is based directly on the Ravenscar profile but removes selected restrictions in order to increase expressive power, while retaining analyzability and performance. As a result, typical idioms for protected objects can be used, for example, and relative delays statements are allowed. Timing analysis is still possible but slightly more complicated, and the underlying run-time library is slightly larger and more complex.

When the most stringent analyses are required and the tightest timing is involved, use the Ravenscar profile. When a slight increase in complexity is tolerable, i.e., in those cases not undergoing all of these stringent analyses, consider using the Jorvik profile.

95.1.1 Reference

Ada Reference Manual: D.13 The Ravenscar and Jorvik Profiles[394]

95.1.2 Description

The following profile must be in effect:

```
pragma Profile (Ravenscar);
```

The profile is equivalent to the following set of pragmas:

```
pragma Task_Dispatching_Policy (FIFO_Within_Priorities);
pragma Locking_Policy (Ceiling_Locking);
pragma Detect_Blocking;
pragma Restrictions (
        No_Abort_Statements,
        No_Dynamic_Attachment,
        No_Dynamic_CPU_Assignment,
        No_Dynamic_Priorities,
        No_Implicit_Heap_Allocations,
        No_Local_Protected_Objects,
        No_Local_Timing_Events,
        No_Protected_Type_Allocators,
        No_Relative_Delay,
        No_Requeue_Statements,
        No_Select_Statements,
        No_Specific_Termination_Handlers,
        No_Task_Allocators,
        No_Task_Hierarchy,
        No_Task_Termination,
        Simple_Barriers,
        Max_Entry_Queue_Length => 1,
        Max_Protected_Entries => 1,
        Max_Task_Entries => 0,
        No_Dependence => Ada.Asynchronous_Task_Control,
        No_Dependence => Ada.Calendar,
        No_Dependence => Ada.Execution_Time.Group_Budgets,
        No_Dependence => Ada.Execution_Time.Timers,
        No_Dependence => Ada.Synchronous_Barriers,
        No_Dependence => Ada.Task_Attributes,
        No_Dependence => System.Multiprocessors.Dispatching_Domains);
```

95.1.3 Applicable Vulnerability within ISO TR 24772-2

- 6.59 Concurrency - Activation [GGA]
- 6.60 Concurrency - Directed termination [CGT]
- 6.61 Concurrent data access [CGX]
- 6.62 Concurrency - Premature termination [CGS]
- 6.63 Lock protocol errors [CGM]

[394] http://www.ada-auth.org/standards/12rm/html/RM-D-13.html

95.1.4 Applicable Common Weakness Enumeration

- CWE-362 - Concurrent Execution using Shared Resource with Improper Synchronization[395]
- CWE-367 - Time-of-check Time-of-use (TOCTOU) Race Condition[396]
- CWE-366 - Race Condition within a Thread[397]

95.1.5 Noncompliant Code Example

Any code disallowed by the profile. Remediation is **high** because use of the facilities outside the subset can be difficult to retrofit into compliance.

```
task body Task_T is
begin
   loop
      -- Error: No_Relative_Delay
      delay 1.0;
      Put_Line ("Hello World");
   end loop;
end Task_T;
```

95.1.6 Compliant Code Example

```
task body Task_T is
   Period     : constant Time_Span := Milliseconds (10);
   Activation : Time               := Clock;
begin
   loop
      delay until Activation;
      Put_Line ("Hello World");
      Activation := Activation + Period;
   end loop;
end Task_T;
```

95.1.7 Notes

The Ada builder will detect violations if the programmer specifies this profile or corresponding pragmas. GNATcheck also can detect violations of profile restrictions.

[395] https://cwe.mitre.org/data/definitions/362.html

Remediation → High

Verification Method → GNATcheck rule: `uses_profile:jorvik`

Mutually Exclusive → CON01

95.2.1 Reference

Ada Reference Manual: D.13 The Ravenscar and Jorvik Profiles[398]

95.2.2 Description

The following profile must be in effect:

```
pragma Profile (Jorvik);
```

The profile is equivalent to the following set of pragmas:

```
pragma Task_Dispatching_Policy (FIFO_Within_Priorities);
pragma Locking_Policy (Ceiling_Locking);
pragma Detect_Blocking;
pragma Restrictions (
           No_Abort_Statements,
           No_Dynamic_Attachment,
           No_Dynamic_CPU_Assignment,
           No_Dynamic_Priorities,
           No_Local_Protected_Objects,
           No_Local_Timing_Events,
           No_Protected_Type_Allocators,
           No_Requeue_Statements,
           No_Select_Statements,
           No_Specific_Termination_Handlers,
```

(continues on next page)

[398] http://www.ada-auth.org/standards/12rm/html/RM-D-13.html

(continued from previous page)

```
            No_Task_Allocators,
            No_Task_Hierarchy,
            No_Task_Termination,
            Pure_Barriers,
            Max_Task_Entries => 0,
            No_Dependence => Ada.Asynchronous_Task_Control,
            No_Dependence => Ada.Execution_Time.Group_Budgets,
            No_Dependence => Ada.Execution_Time.Timers,
            No_Dependence => Ada.Task_Attributes,
            No_Dependence => System.Multiprocessors.Dispatching_Domains);
```

The following restrictions are part of the Ravenscar profile but **not** part of the Jorvik profile.

```
No_Implicit_Heap_Allocations
No_Relative_Delay
Max_Entry_Queue_Length => 1
Max_Protected_Entries => 1
No_Dependence => Ada.Calendar
No_Dependence => Ada.Synchronous_Barriers
```

Jorvik also replaces restriction `Simple_Barriers` with `Pure_Barriers` (a weaker requirement than the restriction `Simple_Barriers`).

95.2.3 Applicable Vulnerability within ISO TR 24772-2

- 6.59 Concurrency - Activation [GGA]
- 6.60 Concurrency - Directed termination [CGT]
- 6.61 Concurrent data access [CGX]
- 6.62 Concurrency - Premature termination [CGS]
- 6.63 Lock protocol errors [CGM]

95.2.4 Applicable Common Weakness Enumeration

- CWE-362 - Concurrent Execution using Shared Resource with Improper Synchronization[399]
- CWE-367 - Time-of-check Time-of-use (TOCTOU) Race Condition[400]
- CWE-366 - Race Condition within a Thread[401]

95.2.5 Noncompliant Code Example

Any code disallowed by the profile. Remediation is **high** because use of the facilities outside the subset can be difficult to retrofit into compliance.

```
   task body Task_T is
   begin
      -- Error: Max_Task_Entries => 0
      accept Entry_Point do
         Put_Line ("Hello World");
```

(continues on next page)

[399] https://cwe.mitre.org/data/definitions/362.html
[400] https://cwe.mitre.org/data/definitions/367.html
[401] https://cwe.mitre.org/data/definitions/366.html

(continued from previous page)

```
      end Entry_Point;
      loop
         delay 1.0;
         Put_Line ("Ping");
      end loop;
   end Task_T;
```

95.2.6 Compliant Code Example

```
   task body Task_T is
   begin
      delay 1.0;
      Put_Line ("Hello World");
      loop
         delay 1.0;
         Put_Line ("Ping");
      end loop;
   end Task_T;
```

95.2.7 Notes

The Ada builder will detect violations. GNATcheck can also detect violations.

95.3 Avoid Shared Variables for Inter-task Communication (CON03)

Security

Remediation → High

Verification Method → GNATcheck rule: `Volatile_Objects_Without_Address_Clauses`

95.3.1 Reference

Ada Reference Manual: D.13 The Ravenscar Profile[402]

95.3.2 Description

Although the Ravenscar and Jorvik profiles allow the use of shared variables for inter-task communication, such use is less robust and less reliable than encapsulating shared variables within protected objects.

95.3.3 Applicable Vulnerability within ISO TR 24772-2

- 6.56 Undefined behaviour [EWF]

95.3.4 Applicable Common Weakness Enumeration

- CWE-567 - Unsynchronized Access to Shared Data in a Multithreaded Context[403]
- CWE-667 - Improper Locking[404]

95.3.5 Noncompliant Code Example

```
Global_Object : Integer
  with Volatile;
function Get return Integer is (Global_Object);
```

Note that variables marked as `Atomic` are also `Volatile`, per the Ada Reference Manual: C.6 (8/3) Shared Variable Control[405]

95.3.6 Compliant Code Example

When assigned to a memory address, a `Volatile` variable can be used to interact with a memory-mapped device, among other similar usages.

```
Global_Object : Integer
  with Volatile,
       Address => To_Address (16#1234_5678#);
function Get return Integer is (Global_Object);
```

[402] http://www.ada-auth.org/standards/12rm/html/RM-D-13.html
[403] https://cwe.mitre.org/data/definitions/567.html
[404] https://cwe.mitre.org/data/definitions/667.html
[405] http://www.ada-auth.org/standards/12rm/html/RM-C-6.html

95.3.7 Notes

In additon to GNATcheck, SPARK and CodePeer can also detect conflicting access to unprotected variables.

Verification Method → GNATcheck rule: `OTHERS_In_CASE_Statements`

96.1.1 Reference

[SEI-C] MSC01-C

96.1.2 Description

Case statement alternatives and case-expressions must not include use of the **others** discrete choice option. This rule prevents accidental coverage of a choice added after the initial case statement is written, when an explicit handler was intended for the addition.

Note that this is opposite to typical C guidelines such as [SEI-C] MSC01-C. The reason is that in C, the **default** alternative plays the role of defensive code to mitigate the switch statement's non-exhaustivity. In Ada, the **case** construct is exhaustive: the compiler statically verifies that for every possible value of the **case** expression there is a branch alternative, and there is also a dynamic check against invalid values which serves as implicit defensive code. As a result, Ada's **others** alternative doesn't play C's defensive code role and therefore a stronger guideline can be adopted.

96.1.3 Applicable Vulnerability within ISO TR 24772-2

- 6.27 Switch statements and static analysis [CLL]

96.1.4 Applicable Common Weakness Enumeration

- CWE-478 - Missing Default Case in Multiple Condition Expression[406]

96.1.5 Noncompliant Code Example

```
case Digit_T (C) is
   when '0' | '9' =>
      C := Character'succ (C);
   when others =>
      C := Character'pred (C);
end case;
```

96.1.6 Compliant Code Example

```
case Digit_T (C) is
   when '0' | '9' =>
      C := Character'succ (C);
   when '1' | '2' | '3' | '4' | '5' | '6' | '7' | '8' =>
      C := Character'pred (C);
end case;
```

Performance
Security

Remediation → Low

Verification Method → GNATcheck rule: `Enumeration_Ranges_In_CASE_Statements`

96.2.1 Reference

Similar to RPP01

96.2.2 Description

A range of enumeration literals must not be used as a choice in a **`case`** statement or a **`case`** expression. This includes explicit ranges (`A .. B`), subtypes, and the `'Range` attribute. Much like the use of **`others`** in **`case`** statement alternatives, the use of ranges makes it possible for a new enumeration value to be added but not handled with a specific alternative, when a specific alternative was intended.

96.2.3 Applicable Vulnerability within ISO TR 24772-2

- 6.5 Enumerator issues [CCB]

96.2.4 Applicable Common Weakness Enumeration

N/A

96.2.5 Noncompliant Code Example

```
case Digit_T (C) is
   when '0' | '9' =>
      C := Character'Succ (C);
   when '1' .. '8' =>
      C := Character'Pred (C);
end case;
```

96.2.6 Compliant Code Example

```
case Digit_T (C) is
   when '0' | '9' =>
      C := Character'Succ (C);
   when '1' | '2' | '3' | '4' | '5' | '6' | '7' | '8' =>
      C := Character'Pred (C);
end case;
```

Goal

Maintainability
✓

Reliability
✓

Portability
✓

Performance
Security

Remediation → Low

Verification Method → GNATcheck rule: `OTHERS_In_Aggregates`

96.3.1 Reference

Similar to RPP01

96.3.2 Description

Do not use an **`others`** choice in an extension aggregate. In **`record`** and **`array`** aggregates, do not use an **`others`** choice unless it is used either to refer to all components, or to all but one component.

This guideline prevents accidental provision of a general value for a **`record`** component or **`array`** component, when a specific value was intended. This possibility includes the case in which new components are added to an existing composite type.

96.3.3 Applicable Vulnerability within ISO TR 24772-2

- 6.5 Enumerator issues [CCB]
- 6.27 Switch statements and static analysis [CLL]

96.3.4 Applicable Common Weakness Enumeration

- CWE-478 - Missing Default Case in Multiple Condition Expression[407]

96.3.5 Noncompliant Code Example

```
type Record_T is record
   Field1 : Integer   := 1;
   Field2 : Boolean   := False;
   Field3 : Character := ' ';
end record;
type Array_T is array (Character) of Boolean;
Rec : Record_T := (Field1 => 1,
                   Field3 => '2',
                   others => <>);
Arr : Array_T := ('0' .. '9' => True,
                  others     => False);
```

[407] https://cwe.mitre.org/data/definitions/478.html

96.3.6 Compliant Code Example

```
type Record_T is record
   Field1 : Integer   := 1;
   Field2 : Boolean   := False;
   Field3 : Character := ' ';
end record;
type Array_T is array (Character) of Boolean;
Rec : Record_T := (Field1 => 1,
                   others => <>);
Arr : Array_T := (others => False);
```

Portability
✓

Performance
Security

Remediation → High

Verification Method → GNATcheck rule: `Unassigned_OUT_Parameters`

96.4.1 Reference

MISRA C Rule 9.1: "The value of an object with automatic storage duration shall not be read before it has been set."

96.4.2 Description

For any procedure, all formal parameters of mode **out** must be assigned a value if the procedure exits normally. This rule ensures that, upon a normal return, the corresponding actual parameter has a defined value. Ensuring a defined value is especially important for scalar parameters because they are passed by value, such that some value is copied out to the actual. These undefined values can be especially difficult to locate because evaluation of the actual parameter's value might not occur immediately after the call returns.

96.4.3 Applicable Vulnerability within ISO TR 24772-2

- 6.32 Passing parameters and return values [CSJ]

96.4.4 Applicable Common Weakness Enumeration

- CWE-457 - Use of Uninitialized Variable[408]

96.4.5 Noncompliant Code Example

```
for Value_T use
  (Alpha   => 2#1#,
   Baker   => 2#10#,
   Charlie => 2#100#,
   Dog     => 2#1000#,
   Invalid => 2#1111#);

procedure Noncompliant (Register  :     Character;
                        Registera : out Value_T;
                        Registerb : out Value_T) is
begin
   if Register = 'A' then
      Registera := Alpha;
   end if;
end Noncompliant;
```

In the above example, some value is copied back for an output parameter as specified by `Register`. The other parameter is not assigned, and on return the value copied to the actual parameter may not be a valid representation for a value of the type. (We give the enumeration values a non-standard representation for the sake of illustration, i.e., to make it more likely that the undefined value is not valid.)

96.4.6 Compliant Code Example

```
procedure Compliant (Register  :     Character;
                     Registera : out Value_T;
                     Registerb : out Value_T) is
begin
   Registera := Invalid;
   Registerb := Invalid;
   if Register = 'A' then
      Registera := Alpha;
```

(continues on next page)

[408] https://cwe.mitre.org/data/definitions/457.html

(continued from previous page)

```
   end if;
end Compliant;
```

96.4.7 Notes

The GNATcheck rule specified above only detects a trivial case of an unassigned variable and doesn't provide a guarantee that there is no uninitialized access. It is not a replacement for a rigorous check for uninitialized access provided by advanced static analysis tools such as SPARK and CodePeer.

Note that the GNATcheck rule does not check function parameters (as of Ada 2012 functions can have `out` parameters). As a result, the better choice is either SPARK or CodePeer.

96.5 No Use of "others" in Exception Handlers (RPP05)

Level → Required

Category

Safety
✓

Cyber
✓

Goal

Maintainability
✓

Reliability
✓

Portability
✓

Performance
Security

Remediation → Low

Verification Method → GNATcheck rule: `OTHERS_In_Exception_Handlers`

96.5.1 Reference

N/A

96.5.2 Description

Much like the situation with **others** in **case** statements and **case** expressions, the use of **others** in exception handlers makes it possible to omit an intended specific handler for an exception, especially a new exception added to an existing set of handlers. As a result, a subprogram could return normally without having applied any recovery for the specific exception occurrence, which is likely a coding error.

96.5.3 Applicable Vulnerability within ISO TR 24772-2

N/A

96.5.4 Applicable Common Weakness Enumeration

- CWE-396 - Declaration of Catch for Generic Exception[409]

96.5.5 Noncompliant Code Example

```
procedure Noncompliant (X : in out Integer) is
begin
   X := X * X;
exception
   when others =>
      X := -1;
end Noncompliant;
```

96.5.6 Compliant Code Example

```
procedure Compliant (X : in out Integer) is
begin
   X := X * X;
exception
   when Constraint_Error =>
      X := -1;
end Compliant;
```

96.5.7 Notes

ISO TR 24772-2: 6.50.2 slightly contradicts this when applying exception handlers around calls to library routines:

- Put appropriate exception handlers in all routines that call library routines, including the catch-all exception handler **when others** =>
- Put appropriate exception handlers in all routines that are called by library routines, including the catch-all exception handler **when others** =>

ISO TR 24772-2 also recommends "All tasks should contain an exception handler at the outer level to prevent silent termination due to unhandled exceptions."

[409] https://cwe.mitre.org/data/definitions/396.html

96.6 Avoid Function Side-Effects (RPP06)

Level → Advisory

Category

Safety
✓

Cyber
✓

Goal

Maintainability
✓

Reliability
✓

Portability
✓

Performance
Security

Remediation → Medium

Verification Method → Code inspection

96.6.1 Reference

MISRA C Rule 13.2: "The value of an expression and its persistent side effects shall be the same under all permitted evaluation orders."

96.6.2 Description

Functions cannot update an actual parameter or global variable.

A side effect occurs when evaluation of an expression updates an object. This rule applies to function calls, a specific form of expression.

Side effects enable one form of parameter aliasing (see below) and evaluation order dependencies. In general they are a potential point of confusion because the reader expects only a computation of a value.

There are useful idioms based on functions with side effects. Indeed, a random number generator expressed as a function must use side effects to update the seed value. So-called "memo" functions are another example, in which the function tracks the number of times it is called. Therefore, exceptions to this rule are anticipated but should only be allowed on a per-instance basis after careful analysis.

96.6.3 Applicable Vulnerability within ISO TR 24772-2

- 6.24 Side-effects and order of evaluation [SAM]

96.6.4 Applicable Common Weakness Enumeration

N/A

96.6.5 Noncompliant Code Example

```
Call_Count : Integer := 0;
function F return Boolean is
   Result : Boolean;
begin
   ...
   Call_Count := Call_Count + 1;
   return Result;
end F;
```

96.6.6 Compliant Code Example

Remove the update to `Call_Count`, or change the function into a procedure with a parameter for `Call_Count`.

96.6.7 Notes

Violations are detected by SPARK as part of a rule disallowing side effects on expression evaluation.

96.7 Functions Only Have Mode "in" (RPP07)

Verification Method → GNATcheck rule: `function_out_parameters`

96.7.1 Reference

N/A

96.7.2 Description

Functions must have only mode **in**.

As of Ada 2012, functions are allowed to have the same modes as procedures. However, this can lead to side effects and aliasing.

This rule disallows all modes except mode **in** for functions.

96.7.3 Applicable Vulnerability within ISO TR 24772-2

- 6.24 Side-effects and order of evaluation [SAM]

96.7.4 Applicable Common Weakness Enumeration

N/A

96.7.5 Noncompliant Code Example

```
function Noncompliant (Value : in out Integer) return Integer is
begin
   if Value < Integer'last then
      Value := Value + 1;
   end if;
   return Value;
end Noncompliant;
```

96.7.6 Compliant Code Example

```
function Compliant (Value : Integer) return Integer is
begin
   return Value + 1;
end Compliant;
```

OR

```
procedure Compliant (Value : in out Integer) is
begin
   if Value < Integer'last then
      Value := Value + 1;
   end if;
end Compliant;
```

96.7.7 Notes

Violations are detected by SPARK.

96.8.1 Reference

Ada Reference Manual: 6.2 Formal Parameter Modes[410]

SPARK Reference Manual: Anti-Aliasing[411]

96.8.2 Description

In software, an alias is a name which refers to the same object as another name. In some cases, it is an error in Ada to reference an object through a name while updating it through another name in the same subprogram. Most of these cases cannot be detected by a compiler. Even when not an error, the presence of aliasing makes it more difficult to understand the code for both humans and analysis tools, and thus it may lead to errors being introduced during maintenance.

This rule is meant to detect problematic cases of aliasing that are introduced through the actual parameters and between actual parameters and global variables in a subprogram call. It is a simplified version of the SPARK rule for anti-aliasing defined in SPARK Reference Manual, section 6.4.2: Anti-Aliasing[412].

A formal parameter is said to be immutable when the subprogram cannot modify its value or modify the value of an object by dereferencing a part of the parameter of access type

[410] http://www.ada-auth.org/standards/12rm/html/RM-6-2.html
[411] https://docs.adacore.com/spark2014-docs/html/lrm/subprograms.html#anti-aliasing
[412] https://docs.adacore.com/spark2014-docs/html/lrm/subprograms.html#anti-aliasing

(at any depth in the case of SPARK). In Ada and SPARK, this corresponds to either an anonymous access-to-constant parameter or a parameter of mode **in** and not of an access type. Otherwise, the formal parameter is said to be mutable.

A procedure call shall not pass two actual parameters which potentially introduce aliasing via parameter passing unless either:

- both of the corresponding formal parameters are immutable; or
- at least one of the corresponding formal parameters is immutable and is of a by-copy type that is not an access type.

If an actual parameter in a procedure call and a global variable referenced by the called procedure potentially introduce aliasing via parameter passing, then:

- the corresponding formal parameter shall be immutable; and
- if the global variable is written in the subprogram, then the corresponding formal parameter shall be of a by-copy type that is not an access type.

Where one of the rules above prohibits the occurrence of an object or any of its subcomponents as an actual parameter, the following constructs are also prohibited in this context:

- A type conversion whose operand is a prohibited construct;
- A call to an instance of `Unchecked_Conversion` whose operand is a prohibited construct;
- A qualified expression whose operand is a prohibited construct;
- A prohibited construct enclosed in parentheses.

96.8.3 Applicable Vulnerability within ISO TR 24772-2

- 6.32 Passing parameters and return values [CSJ]

96.8.4 Applicable Common Weakness Enumeration

N/A

96.8.5 Noncompliant Code Example

```
   type R is record
     Data : Integer := 0;
   end record;

   procedure Detect_Aliasing (Val_1 : in out R;
                              Val_2 : in R)
   is
   begin
      null;
   end Detect_Aliasing;

   Obj : R;

begin
   Detect_Aliasing (Obj, Obj);
```

96.8.6 Compliant Code Example

Do not pass `Obj` as the actual parameter to both formal parameters.

96.8.7 Notes

All violations are detected by SPARK. The GNAT compiler switch `-gnateA[1]` enables detection of some cases, but not all.

96.9 Use Precondition and Postcondition Contracts (RPP09)

Level → Advisory

Category

Safety
✓

Cyber
✓

Goal

Maintainability
✓

Reliability
✓

Portability
✓

Performance
Security
✓

Remediation → Low

Verification Method → Code inspection

96.9.1 Reference

Power of Ten rule 5: "The assertion density of the code should average to a minimum of two assertions per function."

96.9.2 Description

Subprograms should declare `Pre` and/or `Post` contracts. Developers should consider specifying the Global contract as well, when the default does not apply.

Subprogram contracts complete the Ada notion of a specification, enabling clients to know what the subprogram does without having to know how it is implemented.

Preconditions define those logical (Boolean) conditions required for the body to be able to provide the specified behavior. As such, they are obligations on the callers. These conditions are checked at run-time in Ada, prior to each call, and verified statically in SPARK.

Postconditions define those logical (Boolean) conditions that will hold after the call returns normally. As such, they express obligations on the implementer, i.e., the subprogram body. The implementation must be such that the postcondition holds, either at run-time for Ada, or statically in SPARK.

Not all subprograms will have both a precondition and a postcondition, some will have neither.

The `Global` contract specifies interactions with those objects not local to the corresponding subprogram body. As such, they help complete the specification because, otherwise, one would need to examine the body of the subprogram itself and all those it calls, directly or indirectly, to know whether any global objects were accessed.

96.9.3 Applicable Vulnerability within ISO TR 24772-2

- 6.42 Violations of the Liskov substitution principle or the contract model [BLP]

96.9.4 Applicable Common Weakness Enumeration

- CWE-754 - Improper Check for Unusual or Exceptional Conditions[413]

96.9.5 Noncompliant Code Example

```
type Stack is private;
procedure Push (This : in out Stack;  Item : Element);
```

96.9.6 Compliant Code Example

```
type Stack is private;
procedure Push (This : in out Stack;  Item : Element) with
   Pre  => not Full (This),
   Post => not Empty (This)
           and Top_Element (This) = Item
           and Extent (This) = Extent (This)'Old + 1
           and Unchanged (This'Old, Within => This),
   Global => null;
```

[413] https://cwe.mitre.org/data/definitions/754.html

96.9.7 Notes

This rule must be enforced by manual inspection.

Moreover, the program must be compiled with enabled assertions (GNAT `-gnata` switch) to ensure that the contracts are executed, or a sound static analysis tool such as CodePeer or SPARK toolset should be used to prove that the contracts are always true.

96.10 Do Not Re-Verify Preconditions in Subprogram Bodies (RPP10)

Verification Method → Compiler restrictions

96.11.1 Reference

MISRA C Rule 17.7: "The value returned by a function having non-void return type shall be used," and

Directive 4.7: "If a function returns error information, that error information shall be tested."

96.11.2 Description

In Ada and SPARK, it is not possible to ignore the object returned by a function call. The call must be treated as a value, otherwise the compiler will reject the call. For example, the value must be assigned to a variable, or passed as the actual parameter to a formal parameter of another call, and so on.

However, that does not mean that the value is actually used to compute some further results. Although almost certainly a programming error, one could call a function, assign the result to a variable (or constant), and then not use that variable further.

Note that functions will not have side-effects (due to RPP06) so it is only the returned value that is of interest here.

96.11.3 Applicable Vulnerability within ISO TR 24772-2

- 6.47 Inter-language calling [DJS]

96.11.4 Applicable Common Weakness Enumeration

- CWE-252 - Unchecked Return Value[414]
- CWE-563 - Assignment to Variable without Use[415]

[414] https://cwe.mitre.org/data/definitions/252.html
[415] https://cwe.mitre.org/data/definitions/563.html

96.11.5 Noncompliant Code Example

N/A

96.11.6 Compliant Code Example

N/A

96.11.7 Notes

The GNAT compiler warning switch `-gnatwu` (or the more general `-gnatwa` warnings switch) will cause the compiler to detect variables assigned but not read. CodePeer will detect these unused variables as well. SPARK goes further by checking that all computations contribute all the way to subprogram outputs.

96.12 No Recursion (RPP12)

Verification Method → GNATcheck rule: `Recursive_Subprograms`

96.12.1 Reference

MISRA C Rule 17.2: "Functions shall not call themselves, either directly or indirectly."

96.12.2 Description

No subprogram shall be invoked, directly or indirectly, as part of its own execution.

In addition to making static analysis more complex, recursive calls make static stack usage analysis extremely difficult, requiring, for example, manual supply of call limits.

96.12.3 Applicable Vulnerability within ISO TR 24772-2

- 6.35 Recursion [GDL]

96.12.4 Applicable Common Weakness Enumeration

- CWE-674 - Uncontrolled Recursion[416]

96.12.5 Noncompliant Code Example

```
function Noncompliant (N : Positive) return Positive is
begin
   if N = 1 then
      return 1;
   else
      return N * Noncompliant (N - 1);  -- could overflow
   end if;
end Noncompliant;
```

96.12.6 Compliant Code Example

```
function Compliant (N : Positive) return Positive is
   Result : Positive := 1;
begin
   for K in 2 .. N loop
      Result := Result * K;  -- could overflow
   end loop;
   return Result;
end Compliant;
```

96.12.7 Notes

The compiler will detect violations with the restriction `No_Recursion` in place. Note this is a dynamic check.

The GNATcheck rule specified above is a static check, subject to the limitations described in GNATcheck Reference Manual: Recursive Subprograms[417].

[416] https://cwe.mitre.org/data/definitions/674.html
[417] https://docs.adacore.com/live/wave/lkql/html/gnatcheck_rm/gnatcheck_rm/predefined_rules.html#recursive-subprograms

96.13 No Reuse of Standard Typemarks (RPP13)

96.14.1 Reference

N/A

96.14.2 Description

Extensive use of literals in a program can lead to two problems. First, the meaning of the literal is often obscured or unclear from the context. Second, changing a frequently used literal requires searching the entire program source for that literal and distinguishing the uses that must be modified from those that should remain unmodified.

Avoid these problems by declaring objects with meaningfully named constants, setting their values to the desired literals, and referencing the constants instead of the literals throughout the program. This approach clearly indicates the meaning or intended use of each literal. Furthermore, should the constant require modification, the change is limited to the declaration; searching the code is unnecessary.

Some literals can be replaced with attribute values. For example, when iterating over an array, it is better to use `Array_Object'First .. Array_Object'Last` than using `1 .. Array_Object'Length`.

Description
Have a plan for managing the use of Ada exceptions at the application level.

Rules
EXU01, EXU02, EXU03, EXU04

Exceptions in modern languages present the software architect with a dilemma. On one hand, exceptions can increase integrity by allowing components to signal specific errors in a manner that cannot be ignored, and, in general, allow residual errors to be caught. (Although there should be no unexpected errors in high integrity code, there may be some such errors due, for example, to unforeseeable events such as radiation-induced single-event upsets.) On the other hand, unmanaged use of exceptions increases verification expense and difficulty, especially flow analysis, perhaps to an untenable degree. In that case overall integrity is reduced or unwarranted.

In addition, programming languages may define some system-level errors in terms of language-defined exceptions. Such exceptions may be unavoidable, at least at the system level. For example, in Ada, stack overflow is signalled with the language-defined `Storage_Error` exception. Other system events, such as bus error, may also be mapped to language-defined or vendor-defined exceptions.

Complicating the issue further is the fact that, if exceptions are completely disallowed, there will be no exception handling code in the underlying run-time library. The effects are unpredictable if any exception actually does occur.

Therefore, for the application software the system software architect must decide whether to allow exceptions at all, and if they are to be used, decide the degree and manner of their usage. At the system level, the architect must identify the exceptions that are possible and how they will be addressed.

Verification Method → GNATcheck rule: `Raising_Predefined_Exceptions`

97.1.1 Reference

[SEI-Java] ERR07-J

97.1.2 Description

In no case should the application explicitly raise a language-defined exception.

The Ada language-defined exceptions are raised implicitly in specific circumstances defined by the language standard. Explicitly raising these exceptions would be confusing to application developers. The potential for confusion increases as the exception is propagated up the dynamic call chain, away from the point of the **`raise`** statement, because this increases the number of paths and thus corresponding language-defined checks that could have been the cause.

Verification Method → GNATcheck rule: `Unhandled_Exceptions`

97.2.1 Reference

N/A

97.2.2 Description

All application-defined exceptions must have at least one corresponding handler that is applicable. Otherwise, if an exception is raised, undesirable behavior is possible. The term *applicable* means that there is no dynamic call chain that can reach the active exception which does not also include a handler that will be invoked for that exception, somewhere in that chain.

When an unhandled exception occurs in the sequence of statements of an application task and propagates to task's body, the task terminates abnormally. No *notification* of some sort is required or defined by the language, although some vendors' implementations may print out a log message or provide some other non-standard response. (Note that such a notification implies an external persistent environment, such as an operating system, that may not be present in all platforms.) The task failure does not affect any other tasks unless those other tasks attempt to communicate with it. In short, failure is silent.

Although the language-defined package `Ada.Task_Termination` can be used to provide a response using standard facilities, not all run-time libraries provide that package. For example, under the Ravenscar profile, application tasks are not intended to terminate, neither normally nor abnormally, and the language does not define what happens if they do. A run-time library for a memory-constrained target, especially a bare-metal target without an operating system, might not include any support for task termination when the tasking model is Ravenscar. The effects of task termination in that case are not defined by the language.

When an unhandled exception occurrence reaches the main subprogram and is not handled there, the exception occurrence is propagated to the environment task, which then completes abnormally. Even if the main subprogram does handle the exception, the environment task still completes (normally in that case).

When the environment task completes (normally or abnormally) it waits for the completion of dependent application tasks, if any. Those dependent tasks continue executing normally, i.e., they do not complete as a result of the environment task completion. Alternatively, however, instead of waiting for them, the implementation has permission to abort the dependent application tasks, per Ada Reference Manual: 10.2 (30) Program Execution[422] The resulting application-specific effect is undefined.

Finally, whether the environment task waited for the dependent tasks or aborted them, the semantics of further execution beyond that point are undefined. There is no concept of a calling environment beyond the environment task (Ada Reference Manual: 10.2 (30) Program Execution[423]). In some systems there is no calling environment, such as bare-metal platforms with only an Ada run-time library and no operating system.

97.4.1 Reference

MISRA C Rule 1.3: "There shall be no occurrence of undefined or critical unspecified behaviour."

97.4.2 Description

In many high-integrity systems the possible responses to an exception are limited or nonexistent. In these cases the only approach is to prove exceptions cannot occur in the first place. Additionally, the cost of proving exceptions cannot happen may be less than the cost of analyzing code in which they are allowed to be raised.

The restriction `No_Exceptions` can be used with **`pragma`** *`Restrictions`* to enforce this approach. Specifically, the restriction ensures that **`raise`** statements and exception handlers do not appear in the source code and that language-defined checks are not emitted by the compiler. However, a run-time check performed automatically by the hardware is permitted because it typically cannot be prevented. An example of such a check would be traps on invalid addresses. If a hardware check fails, or if an omitted language-defined check would have failed, execution is unpredictable. As a result, enforcement with the restriction is not ideal. However, proof of the absence of run-time errors is possible using the SPARK subset of Ada.

OBJECT-ORIENTED PROGRAMMING (OOP)

Goal

Maintainability
✓

Reliability
✓

Portability
Performance
Security
✓

Description
Have a plan for selecting the OOP facilities of the language to use.

Rules
OOP01, OOP02, OOP03, OOP04, OOP05, OOP06, OOP07

There are many issues to consider when planning the use of Object Oriented features in a high-integrity application. Choices should be made based on the desired expressive power of the OO features and the required level of certification or safety case.

For example, the use of inheritance can provide abstraction and separation of concerns. However, the extensive use of inheritance, particularly in deep hierarchies, can lead to fragile code bases.

Similarly, when new types of entities are added, dynamic dispatching provides separation of the code that must change from the code that manipulates those types and need not be changed to handle new types. However, analysis of dynamic dispatching must consider every candidate object type and analyze the associated subprogram for appropriate behavior.

Therefore, the system architect has available a range of possibilities for the use of OOP constructs, with tool enforcement available for the selections. Note that full use of OOP, including dynamic dispatching, may not be unreasonable.

The following rules assume use of tagged types, a requirement for full OOP in Ada.

98.1 No Class-wide Constructs Policy (OOP01)

Verification Method → GNATcheck rule: `Deep_Inheritance_Hierarchies:2`

98.3.1 Reference

[AdaOOP2016] section 5.1

98.3.2 Description

A class inheritance hierarchy consists of a set of types related by inheritance. Each class, other than the root class, is a subclass of other classes, and each, except for "leaf" nodes, is a base class for those that are derived from it.

Improperly designed inheritance hierarchies complicate system maintenance and increase the effort in safety certification, in any programming language.

A common characteristic of problematic hierarchies is "excessive" depth, in which a given class is a subclass of many other classes. Depth can be a problem because a change to a class likely requires inspection, modification, recompilation, and retesting/reverification of all classes below it in the hierarchy. The extent of that effect increases as we approach the root class. This rippling effect is known as the *fragile base class* problem. Clearly, the greater the depth the more subclasses there are to be potentially affected. In addition, note that a change to one class may cause a cascade of other secondary changes to subclasses, so the effect is often not limited to a single change made to all the subclasses in question.

Deep inheritance hierarchies also contribute to complexity, rather than lessening it, by requiring the reader to understand multiple superclasses in order to understand the behavior of a given subclass.

98.3.3 Applicable Vulnerability within ISO TR 24772-2

- 6.41 Inheritance [RIP]

98.3.4 Applicable Common Weakness Enumeration

- CWE-1074 - Class with Excessively Deep Inheritance[427]

Portability
✓

Performance
Security

Remediation → Medium (easy fix, but a difficult to detect bug)

Verification Method → GNATcheck rule: `Direct_Calls_To_Primitives`

98.4.1 Reference

N/A

98.4.2 Description

This rule applies only to tagged types, when visibly tagged at the point of a call from one primitive to another of that same type.

By default, subprogram calls are statically dispatched. Dynamic dispatching only occurs when a class-wide value is passed to a primitive operation of a specific type. Forcing an otherwise optional dynamic dispatching call in this case is known as *redispatching.*

When one primitive operation of a given tagged type invokes another distinct primitive operation of that same type, use redispatching so that an overriding version of that other primitive will be invoked if it exists. Otherwise an existing overridden version would not be invoked, which is very likely an error.

This rule does not apply to the common case in which an overriding of a primitive operation calls the "parent" type's version of the overridden operation. Such calls occur in the overridden body when the new version is not replacing, but rather, is augmenting the parent type's version. In this case the new version must do whatever the parent version did, and can then add functionality specific to the new type.

By default, this rule applies to another common case in which static calls from one primitive operation to another make sense. Specifically, *constructors* are often implemented in Ada as functions that create a new value of the tagged type. As constructors, these functions are type-specific. They must call the primitive operations of the type being created, not operations that may be overridden for some type later derived from it. (Note that there is a GNATcheck rule parameter to not flag this case.)

Typically constructor functions only have the tagged type as the result type, not as the type for formal parameters, if any, because actual parameters of the tagged type would themselves likely require construction. This specific usage is the case ignored by the GNATcheck rule parameter.

Note that constructors implemented as procedures also call primitive operations of the specific type, for the same reasons as constructor functions. This usage is allowed by this rule and does not require the GNATcheck parameter. (The difference between function and procedure constructors is that these procedures will have a formal parameter of the tagged type, of mode `out`.)

Verification Method → GNATcheck rule: `Style_Checks:0`

98.5.1 Reference

[AdaOOP2016] section 4.3

98.5.2 Description

The declaration of a primitive operation that overrides an inherited operation must include an explicit **`overriding`** annotation.

The semantics of inheritance in mainstream object-oriented languages may result in two kinds of programming errors: 1) intending, but failing, to override an inherited subprogram, and 2) intending not to override an inherited subprogram, but doing so anyway. Because an overridden subprogram may perform subclass-specific safety or security checks, the invocation of the parent subprogram on a subclass instance can introduce a vulnerability.

The first issue (intending but failing to override) typically occurs when the subprogram name is misspelled. In this case a new or overloaded subprogram is actually declared.

The second issue (unintended overriding) can arise when a new subprogram is added to a parent type in an existing inheritance hierarchy. The new subprogram happens to cause one or more inherited subprograms below it to override the new superclass version. This mistake typically happens during program maintenance.

In Ada, much like other modern languages, one can annotate a subprogram declaration (and body) with an indication that the subprogram is an overriding of an inherited version. This is done with the **`overriding`** reserved word preceding the subprogram specification.

Similarly, in Ada one can explicitly indicate that a subprogram is not an overriding. To do so, the programmer includes the reserved words **`not overriding`** immediately prior to the subprogram specification.

Of course, incorrect marking errors are flagged by the compiler. If a subprogram is explicitly marked as overriding but is not actually overriding, the compiler will reject the code.

Likewise, if a primitive subprogram is explicitly marked as not overriding, but actually is overriding, the compiler will reject the code.

However, most subprograms are not overriding so it would be a heavy burden on the programmer to make them explicitly indicate that fact. That's not to mention the relatively heavy syntax required.

In addition, both annotations are optional for the sake of compatibility with prior versions of the language. Therefore, a subprogram without either annotation might or might not be overriding. A legal program could contain some explicitly annotated subprograms and some that are not annotated at all. But because the compiler will reject explicit annotations that are incorrect, all we require is that one of the two cases be explicitly indicated for all such subprograms. Any unannotated subprograms not flagged as errors are then necessarily not that case, they must be the other one.

Since overriding is less common and involves slightly less syntax to annotate, the guideline requires explicit annotations only for overriding subprograms. It follows that any subprograms not flagged as errors by the compiler are not overriding, so they need not be marked explicitly as such.

This guideline is implemented by compiler switches, or alternatively, by a GNATcheck rule (specified below the table). With this guideline applied and enforced, the two inheritance errors described in the introduction cannot happen.

Note that the compiler switches will also require the explicit overriding indicator when overriding a language-defined operator. The switches also apply to inherited primitive subprograms for non-tagged types.

98.5.3 Applicable Vulnerability within ISO TR 24772-2

- 6.34 Subprogram signature mismatch [OTR]
- 6.41 Inheritance [RIP]

98.5.4 Applicable Common Weakness Enumeration

- CWE-685 - Function Call With Incorrect Number of Arguments[429]

98.5.5 Noncompliant Code Example

```
type Root_T is tagged null record;
procedure Primitive (X : in out Root_T) is null;
```

```
type Noncompliant_Child_T is new Root_T with null record;
procedure Primitive (X : in out Noncompliant_Child_T) is null;
```

[429] https://cwe.mitre.org/data/definitions/685.html

98.5.6 Compliant Code Example

```
type Compliant_Child_T is new Root_T with null record;
overriding procedure Primitive (X : in out Compliant_Child_T) is null;
```

98.5.7 Notes

This rule requires the GNAT compiler switches `-gnaty0` and `-gnatwe` in order for the compiler to flag missing overriding annotations as errors. The first causes the compiler to generate the warnings, and the second causes those warnings to be treated as errors.

98.6.2 Description

For primitive operations of tagged types, use only class-wide pre/post contracts, if any.

The class-wide form of precondition and postcondition expresses conditions that are intended to apply to any version of the subprogram. Therefore, when a subprogram is derived as part of inheritance, only the class-wide form of those contracts is inherited from the parent subprogram, if any are defined. As a result, it only makes sense to use the class-wide form in this situation.

(The same semantics and recommendation applies to type invariants.)

Note: this approach will be required for OOP07 (Ensure Local Type Consistency).

98.6.3 Applicable Vulnerability within ISO TR 24772-2

- 6.42 Violations of the Liskov substitution principle or the contract model [BLP]

98.6.4 Applicable Common Weakness Enumeration

N/A

98.6.5 Noncompliant Code Example

```
type Root_T is tagged null record;
procedure Set_Name (X    : Root_T;
                    Name : String)
  with Pre => Name'length > 0;
function Get_Name (X : Root_T) return String
  with Post => Get_Name'result'length > 0;
```

98.6.6 Compliant Code Example

```
type Root_T is tagged null record;
procedure Set_Name (X    : Root_T;
                    Name : String)
  with Pre'class => Name'length > 0;
function Get_Name (X : Root_T) return String
  with Post'class => Get_Name'result'length > 0;
```

98.7.1 Reference

[AdaOOP2016] See section 4.2.

GNAT User's Guide, section 5.10.11[431]

98.7.2 Description

Either:

- Formally verify local type consistency, or
- Ensure that each tagged type passes all the tests of all the parent types which it can replace.

Rationale:

One of the fundamental benefits of OOP is the ability to manipulate objects in a class inheritance hierarchy without "knowing" at compile-time the specific classes of the objects being manipulated. By *manipulate* we mean invoking the primitive operations, the *methods* defined by the classes.

We will use the words *class* and *type* interchangeably, because classes are composed in Ada and SPARK using a combination of building blocks, especially type declarations. However, we will use the term *subclass* rather than *subtype* because the latter has a specific meaning in Ada and SPARK that is unrelated to OOP.

The objects whose operations are being invoked can be of types anywhere in the inheritance tree, from the root down to the bottom. The location, i.e., the specific type, is transparent to the manipulating code. This type transparency is possible because the invoked operations are dynamically dispatched at run-time, rather than statically dispatched at compile-time.

[431] https://docs.adacore.com/gnat_ugn-docs/html/gnat_ugn/gnat_ugn/gnat_utility_programs.html

Typically, the code manipulating the objects does so in terms of superclasses closer to the root of the inheritance tree. Doing so increases generality because it increases the number of potential subclasses that can be manipulated. The actual superclass chosen will depend on the operations required by the manipulation. In Ada and SPARK, subclasses can add operations but can never remove them, so more operations are found as we move down from the root. That is the nature of specialization. Note that the guarantee of an invoked operations' existence is essential for languages used in this domain.

However, for this transparent manipulation to be functionally correct — to accomplish what the caller intends — the primitive operations of subclasses must be functionally indistinguishable from those of the superclasses. That doesn't mean the subclasses cannot make changes. Indeed, the entire point of subclasses is to make changes. In particular, functional changes can be either introduction of new operations, or overridings of inherited operations. It is these overridings that must be functionally transparent to the manipulating code. (Of course, for an inherited operation that is not overridden, the functionality is inherited as-is, and is thus transparent trivially.)

The concept of functional transparency was introduced, albeit with different terminology, by Liskov and Wing in 1994 [LiskovWing1994] and is, therefore, known as the Liskov Substitution Principle, or LSP. The *substitution* in LSP means that a subclass must be substitutable for its superclass, i.e., a subclass instance should be usable whenever a superclass instance is required.

Unfortunately, requirements-based testing will not detect violations of LSP because unit-level requirements do not concern themselves with superclass substitutability.

However, the OO supplement of DO-178C [DO178C] offers solutions, two of which are in fact the options recommended by this guideline.

Specifically, the supplement suggests adding a specific verification activity it defines as Local Type Consistency Verification. This activity ensures LSP is respected and, in so doing, addresses the vulnerability.

Verification can be accomplished statically with formal methods in SPARK, or dynamically via a modified form of testing.

For the static approach, type consistency is verified by examining the properties of the overriding operation's preconditions and postconditions. These are the properties required by Design by Contract, as codified by Bertrand Meyer [Meyer1997]. Specifically, an overridden primitive may only replace the precondition with one weaker than that of the parent version, and may only replace the postcondition with one stronger. In essence, relative to the parent version, an overridden operation can only require the same or less, and provide the same or more. Satisfying that requirement is sufficient to ensure functional transparency because the manipulating code only "knows" the contracts of the class it manipulates, i.e., the view presented by the type, which may very well be a superclass of the one actually invoked.

In Ada and SPARK, the class-wide form of preconditions and postconditions are inherited by overridden primitive operations of tagged types. The inherited precondition and that of the overriding (if any) are combined into a conjunction. All must hold, otherwise the precondition fails. Likewise, the inherited postcondition is combined with the overriding postcondition into a disjunction. At least one of them must hold. In Ada these are tested at run-time. In SPARK, they are verified statically (or not, in which case proof fails and an error is indicated).

To verify substitutability via testing, all the tests for all superclass types are applied to objects of the given subclass type. If all the parent tests pass, this provides a high degree of confidence that objects of the new tagged type can properly substitute for parent type objects. Note that static proof of consistency provides an even higher degree of confidence.

98.7.3 Applicable Vulnerability within ISO TR 24772-2

- 6.42 Violations of the Liskov substitution principle of the contract model [BLP]
- 6.43 Redispatching [PPH]
- 6.44 Polymorphic variables [BKK]

98.7.4 Applicable Common Weakness Enumeration

N/A

98.7.5 Noncompliant Code Example

```
package P is
   pragma Elaborate_Body;
   type Rectangle is tagged private;
   procedure Set_Width (This  : in out Rectangle;
                        Value : Positive)
   with
      Post => Width (This) = Value and
              Height (This) = Height (This'Old);

   function Width (This : Rectangle) return Positive;

   procedure Set_Height (This  : in out Rectangle;
                         Value : Positive)
   with
      Post => Height (This) = Value and
              Width (This) = Width (This'Old);

   function Height (This : Rectangle) return Positive;

private
   ...
end P;
```

The postcondition for `Set_Width` states that the `Height` is not changed. Likewise, for `Set_Height`, the postcondition asserts that the `Width` is not changed. However, these postconditions are not class-wide so they are not inherited by subclasses.

Now, in a subclass `Square`, the operations are overridden so that setting the width also sets the height to the same value, and vice versa. Thus the overridden operations do not maintain type consistency, but this fact is neither detected at run-time, nor could SPARK verify it statically (and SPARK is not used at all in these versions of the packages).

```
with P; use P;
package Q is
   pragma Elaborate_Body;
   type Square is new Rectangle with private;

   overriding
   procedure Set_Width (This  : in out Square;
                        Value : Positive)
   with
  Post => Width (This) = Height (This);

   overriding
   procedure Set_Height (This  : in out Square;
```

(continues on next page)

(continued from previous page)

```
                        Value : Positive)
   with
  Post  => Width (This) = Height (This);

private
   ...
end Q;
```

98.7.6 Compliant Code Example

```
package P with SPARK_Mode is
   pragma Elaborate_Body;
   type Rectangle is tagged private;

   procedure Set_Width (This  : in out Rectangle;
                        Value : Positive)
   with
      Post'Class => Width (This) = Value and
                    Height (This) = Height (This'Old);

   function Width (This : Rectangle) return Positive;

   procedure Set_Height (This  : in out Rectangle;
                         Value : Positive)
   with
      Post'Class => Height (This) = Value and
                    Width (This) = Width (This'Old);

   function Height (This : Rectangle) return Positive;

private
   ...
end P;
```

Now the postconditions are class-wide so they are inherited by subclasses. In the subclass Square, the postconditions will not hold at run-time. Likewise, SPARK can now prove that type consistency is not verified because the postconditions are weaker than those inherited:

```
with P; use P;
package Q with SPARK_Mode is
   pragma Elaborate_Body;
   type Square is new Rectangle with private;

   overriding
   procedure Set_Width (This  : in out Square;
                        Value : Positive)
   with
  Post'Class => Width (This) = Height (This);

   overriding
   procedure Set_Height (This  : in out Square;
                         Value : Positive)
   with
  Post'Class => Width (This) = Height (This);

private
   type Square is new Rectangle with null record;
end Q;
```

98.7.7 Notes

Verification can be achieved dynamically with the GNATtest tool, using the `--validate-type-extensions` switch. SPARK enforces this rule.

99.1.1 Reference

SPARK User's Guide, section 8: "Applying SPARK in Practice"[432]

99.1.2 Description

SPARK has proven itself highly effective, both in terms of low defects, low development costs, and high productivity. The guideline advises extensive use of SPARK, especially for the sake of formally proving the most critical parts of the source code. The rest of the code can be in SPARK as well, even if formal proof is not intended, with some parts in Ada when features outside the SPARK subset are essential.

99.1.3 Applicable Vulnerability within ISO TR 24772-2

Reliability
✓

Portability
Performance
Security
✓

Remediation → Low

Verification Method → Compiler restrictions

99.2.1 Reference

Power of 10 rule #10: "All code must be compiled, from the first day of development, with all compiler warnings enabled at the most pedantic setting available. All code must compile without warnings."

99.2.2 Description

The Ada compiler does a degree of static analysis itself, and generates many warnings when they are enabled. These warnings likely indicate very real problems so they should be examined and addressed, either by changing the code or disabling the warning for the specific occurrence flagged in the source code.

To ensure that warnings are examined and addressed one way or the other, the compiler must be configured to treat warnings as errors, i.e., preventing object code generation.

Note that warnings will occasionally be given for code usage that is intentional. In those cases the warnings should be disabled by using `pragma Warnings` with the parameter `Off`, and a string indicating the error message to be disabled. In other cases, a different mechanism might be appropriate, such as aspect (or pragma) `Unreferenced`.

99.2.3 Applicable Vulnerability within ISO TR 24772-2

- 6.18 Dead Store [WXQ]
- 6.19 Unused variable [YZS]
- 6.20 Identifier name reuse [YOW]
- 6.22 Initialization of variables [LAV]

99.2.4 Applicable Common Weakness Enumeration

- CWE-1127 - Compilation with Insufficient Warnings or Errors[435]

99.2.5 Noncompliant Code Example

```
procedure P (This : Obj) is
begin
   ... code not referencing This
end P;
```

The formal parameter controls dispatching for the sake of selecting the subprogram to be called but does not participate in the implementation of the body.

99.2.6 Compliant Code Example

```
procedure P (This : Obj) is
   pragma Unreferenced (This);
begin
   ... code not referencing This
end P;
```

The compiler will no longer issue a warning that the formal parameter `This` is not referenced. Of course, if that changes and `This` becomes referenced, the compiler will flag the **`pragma`**.

99.2.7 Notes

This rule can be applied via the GNAT `-gnatwae` compiler switch, which both enables warnings and treats them as errors. Note that the switch enables almost all optional warnings, but not all. Some optional warnings correspond to very specific circumstances, and would otherwise generate too much noise for their value.

Verification Method → Static analysis tools

99.3.1 Reference

Power of 10 rule #10: "All code must also be checked daily with at least one, but preferably more than one, strong static source code analyzer and should pass all analyses with zero warnings."

99.3.2 Description

If not using SPARK for regular development, use a static analyzer, such as CodePeer, extensively. No warnings or errors should remain unresolved at the given level adopted for analysis (which can be selected to adjust the false positive ratio).

Specifically, any code checked into the configuration management system must be checked by the analyzer and be error-free prior to check-in. Similarly, each nightly build should produce a CodePeer baseline for the project.

99.3.3 Applicable Vulnerability within ISO TR 24772-2

- 6.6 Conversion errors [FLC]
- 6.18 Dead store [WXQ]
- 6.19 Unused variable [YZS]
- 6.20 Identifier name reuse [YOW]
- 6.24 Side-effects and order of evaluation [SAM]
- 6.25 Likely incorrect expression [KOA]

99.3.4 Applicable Common Weakness Enumeration

N/A

99.3.5 Noncompliant Code Example

N/A

99.3.6 Compliant Code Example

N/A

99.3.7 Notes

CodePeer is the recommended static analyzer. Note that CodePeer can detect GNATcheck rule violations (via the `--gnatcheck` CodePeer switch and a rules file).

99.4 Hide Implementation Artifacts (SWE04)

Level → Advisory

Category

Safety

Cyber
✓

Goal

Maintainability
✓

Reliability
✓

Portability
Performance
Security
✓

Remediation → High, as retrofit can be extensive

Verification Method → GNATcheck rule: `Visible_Components`

99.4.1 Reference

MISRA C Rule 8.7: "Functions and objects should not be defined with external linkage if they are referenced in only one translation unit."

99.4.2 Description

Do not make implementation artifacts compile-time visible to clients. Only make available those declarations that define the abstraction presented to clients by the component. In other words, define Abstract Data Types and use the language to enforce the abstraction. This is a fundamental Object-Oriented Design principle.

This guideline minimizes client dependencies and thus allows the maximum flexibility for changes in the underlying implementation. It minimizes the editing changes required for client code when implementation changes are made.

This guideline also limits the region of code required to find any bugs to the package and child packages, if any, defining the abstraction.

This guideline is to be followed extensively as the design default for components. Once the application code size becomes non-trivial, the cost of retrofit is extremely high.

99.4.3 Applicable Vulnerability within ISO TR 24772-2

N/A

99.4.4 Applicable Common Weakness Enumeration

- CWE-1061 - Insufficient Encapsulation[436]
- CWE-496 - Public Data Assigned to Private Array-Typed Field[437]

99.4.5 Noncompliant Code Example

```
package Noncompliant is
   type Content_T is array (Capacity_T range <>) of Integer;
   type Stack_T (Capacity : Capacity_T) is tagged record
      Content : Content_T (1 .. Capacity);
      Top     : Capacity_T := 0;
   end record;
   procedure Push
     (Stack : in out Stack_T;
      Item  :        Integer);
   procedure Pop
     (Stack : in out Stack_T;
      Item  :    out Integer);
end Noncompliant;
```

[436] https://cwe.mitre.org/data/definitions/1061.html
[437] https://cwe.mitre.org/data/definitions/496.html

Note that both type Content_T, as well as the record type components of type Stack_T, are visible to clients. Client code may declare variables of type Content_T and may directly access and modify the record components. Bugs introduced via this access could be anywhere in the entire client codebase.

99.4.6 Compliant Code Example

```
package Compliant is
   type Stack_T (Capacity : Capacity_T) is tagged private;
   procedure Push
     (Stack : in out Stack_T;
      Item  :        Integer);
   procedure Pop
     (Stack : in out Stack_T;
      Item  :    out Integer);
private
   type Content_T is array (Capacity_T range <>) of Integer;
   type Stack_T (Capacity : Capacity_T) is tagged record
      Content : Content_T (1 .. Capacity);
      Top     : Capacity_T := 0;
   end record;
end Compliant;
```

Type Content_T, as well as the record type components of type Stack_T, are no longer visible to clients. Any bugs in the stack processing code must be in this package, or its child packages, if any.

99.4.7 Notes

The GNATcheck rule specified above is not exhaustive.

RESOURCE MANAGEMENT

101.1 Controlled Types

101.1.1 Overview

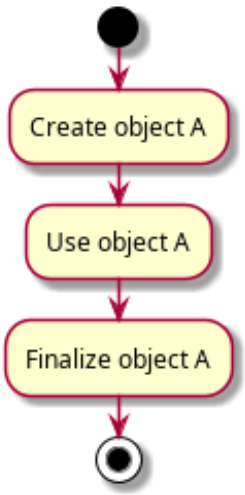
In this section, we introduce the concept of controlled types. We start with a review of lifetime of objects and discuss how controlled types allow us to control the initialization, post-copy (e.g. assignment) adjustment and finalization of objects.

Relevant topics

- Assignment and Finalization[443]

Lifetime of objects

We already talked about the lifetime of objects[444] previously in the context of *access types* (page 788). Again, we assume you understand the concept. In any case, let's quickly review the typical lifetime of an object:



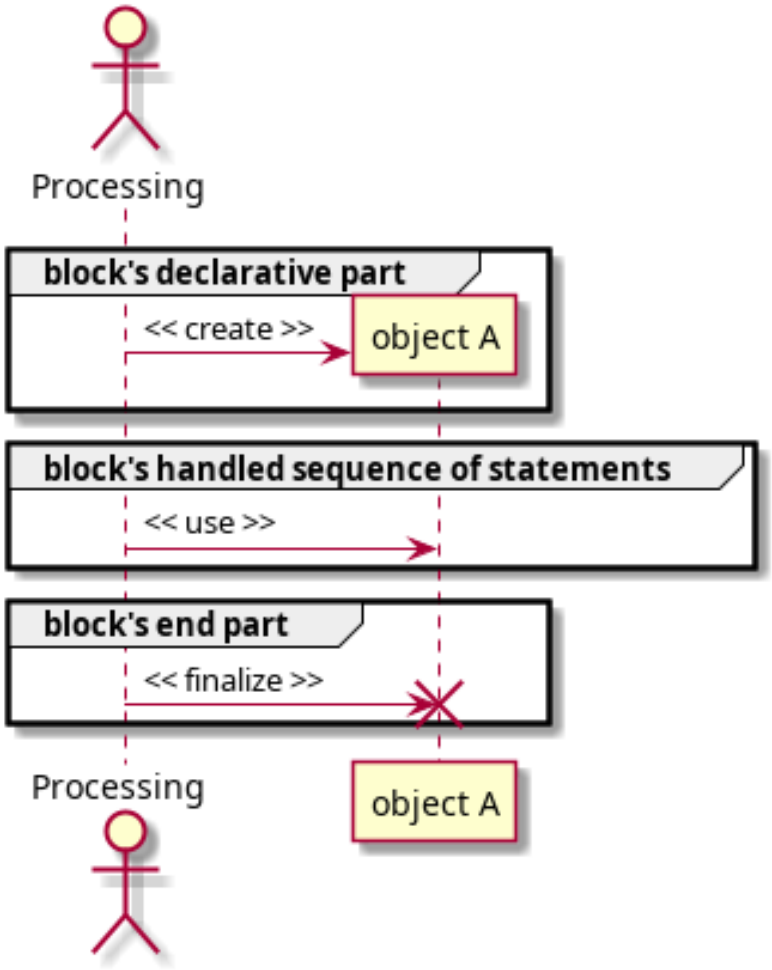
In simple terms, an object A is first created before we can make use of it. When object A is about to get out of scope, it is finalized. Note that finalization might not entail any actual code execution — but it often does.

[443] http://www.ada-auth.org/standards/22rm/html/RM-7-6.html
[444] https://en.wikipedia.org/wiki/Variable_(computer_science)#Scope_and_extent

Let's analyze the lifetime of object A in a procedure P:

```
procedure P is
   A : T;
begin
   P2 (A);
end P;
```

We could visualize the lifetime as follows:



In other words, object A is created in the declarative part of P and then it's used in P's sequence of statements. Finally, A is finalized when P ends.

Initialization of objects

Typically, right after an object A is created, it is still uninitialized. Therefore, we have to explicitly initialize it with a meaningful initial value — or with the value returned by a function call, for example. Similarly, when an object A is about to get out of scope, it is going to be finalized (i.e. destroyed) and its contents are then lost forever.

As we know, for some standard Ada types, objects are initialized by default. For example, objects of access types are initialized by default to `null`. Likewise, we can declare *types with default initial value* (page 334):

Listing 1: main.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
   type Int is new Integer
     with Default_Value => 42;

   I  : Int;
   AI : access Int;
begin
   Put_Line ("I : "
             & I'Image);
   Put_Line ("AI : "
             & AI'Image);
end Main;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Overview.
 ↪Default_Initialization
MD5: 540dcbb3134d774f31dfb3e61a180d41
```

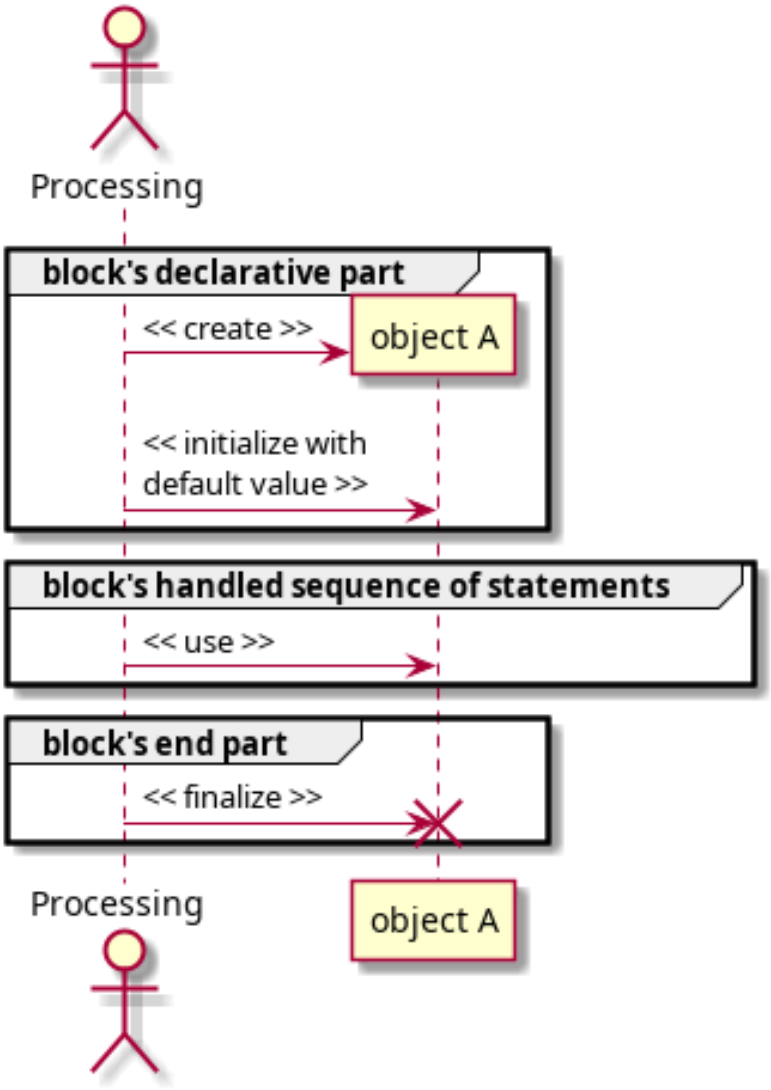
Build output

```
main.adb:10:04: warning: variable "AI" is read but never assigned [-gnatwv]
```

Runtime output

```
I :  42
AI : null
```

In this case, we can visualize the lifetime of those objects as follows:



Even though these default initialization methods provide some control over the objects, they might not be enough in certain situations. Also, we don't have any means to perform useful operations right before an object gets out of scope.

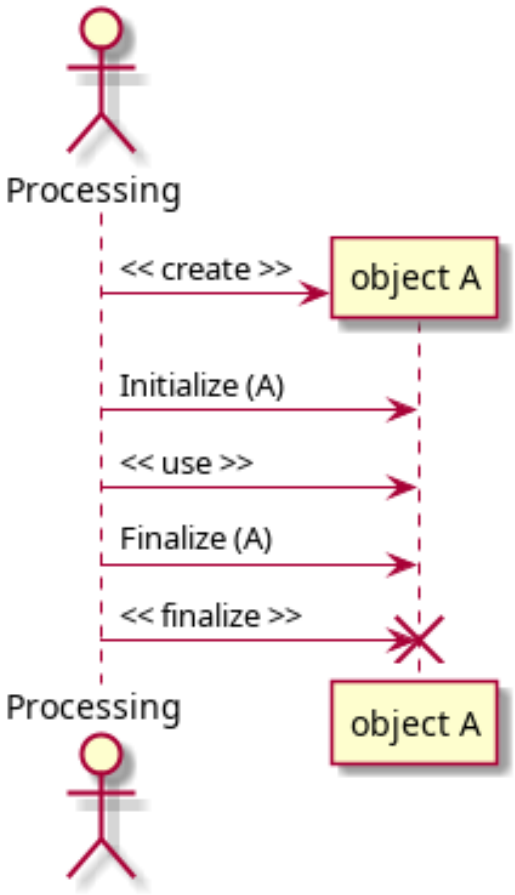
For further reading...

In general, record types have a very good default initialization capability. They're the most common completion for private types, so the facility is often used. In this sense, default initialization is the first choice, as it's guaranteed and requires nothing of the client. In addition, it's cheap at run-time compared to controlled types.

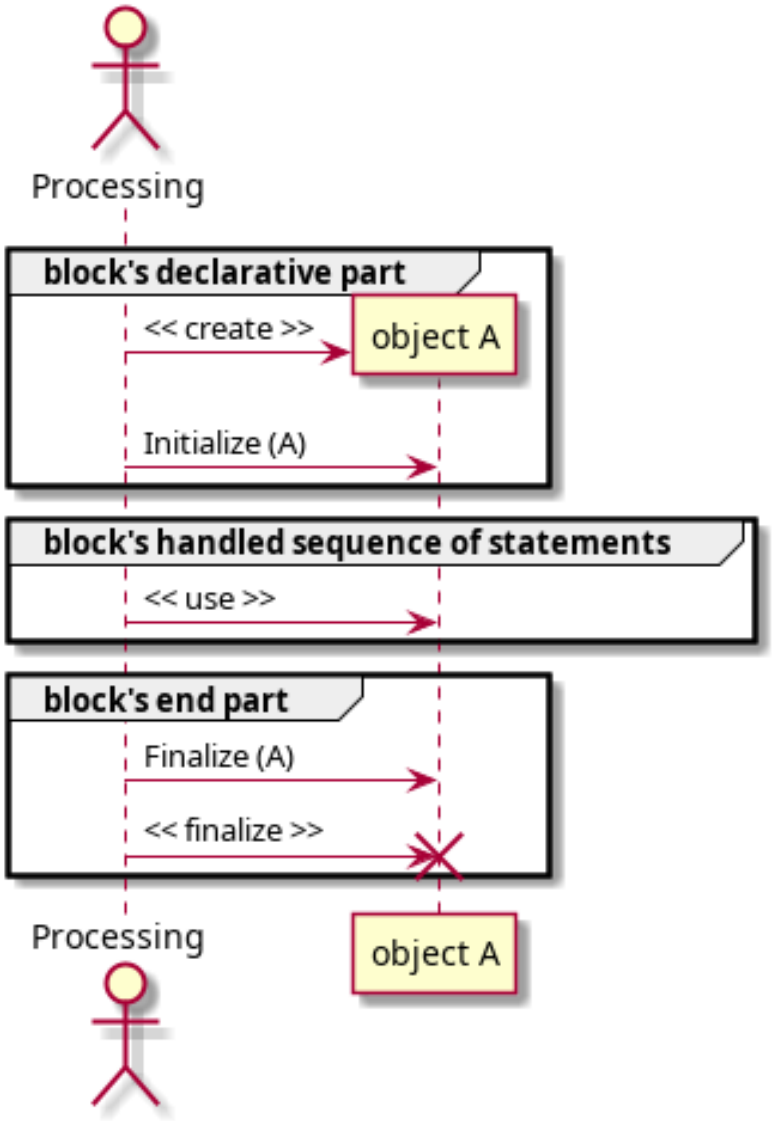
Controlled objects

Controlled objects allow us to better control the initialization and finalization of an object. For any controlled object `A`, an `Initialize (A)` procedure is called right *after* the object is created, and a `Finalize (A)` procedure is called right *before* the object is actually finalized.

We can visualize the lifetime of controlled objects as follows:



In the context of a block statement, the lifetime becomes:



Let's look at a simple example:

Listing 2: simple_controlled_types.ads

```
with Ada.Finalization;

package Simple_Controlled_Types is

   type T is tagged private;

   procedure Dummy (E : T);

private

   type T is new
     Ada.Finalization.Controlled
       with null record;

   overriding
   procedure Initialize (E : in out T);

   overriding
```

(continues on next page)

(continued from previous page)

```
19    procedure Finalize (E : in out T);
20
21 end Simple_Controlled_Types;
```

Listing 3: simple_controlled_types.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Simple_Controlled_Types is
4
5     procedure Dummy (E : T) is
6     begin
7        Put_Line ("(Dummy...)");
8     end Dummy;
9
10    procedure Initialize (E : in out T) is
11    begin
12       Put_Line ("Initialize...");
13    end Initialize;
14
15    procedure Finalize (E : in out T) is
16    begin
17       Put_Line ("Finalize...");
18    end Finalize;
19
20 end Simple_Controlled_Types;
```

Listing 4: show_controlled_types.adb

```
1  with Simple_Controlled_Types;
2  use  Simple_Controlled_Types;
3
4  procedure Show_Controlled_Types is
5     A : T;
6     --
7     --  This declaration roughly
8     --  corresponds to:
9     --
10    --     A : T;
11    --  begin
12    --     Initialize (A);
13    --
14 begin
15    Dummy (A);
16
17    --  When A is about to get out of
18    --  scope:
19    --
20    --  Finalize (A);
21    --
22 end Show_Controlled_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Overview.Simple_
 ↪Example
MD5: 24f95418bb8c439648ab9dba9f0c953a
```

Runtime output

```
Initialize...
(Dummy...)
Finalize...
```

When we run this application, we see the user messages indicating the calls to `Initialize` and `Finalize`.

For further reading...

Note that if a controlled object isn't used in the application, the compiler might optimize it out. In this case, procedures `Initialize` and `Finalize` won't be called for this object, as it doesn't actually exist. You can see this effect by replacing the call to `Dummy (A)` in the `Show_Controlled_Types` procedure by a null statement (`null`).

Adjustment of controlled objects

An assignment is a full bit-wise copy of the entire right-hand side to the entire left-hand side. When copying controlled objects, however, we might need to adjust the target object. This is made possible by overriding the `Adjust` procedure, which is called right after the copy to an object has been performed. (As we'll see later on, *limited controlled types* (page 1824) do not offer an `Adjust` procedure.)

The deep copy[445] of objects is a typical example where adjustments are necessary. When we assign an object B to an object A, we're essentially doing a shallow copy. If we have references to other objects in the source object B, those references will be copied as well, so both target A and source B will be referring to the same objects. When performing a deep copy, however, we want the information from the dereferenced objects to be copied, not the references themselves. Therefore, we have to first allocate new objects for the target object A and copy the information from the original references — the ones we copied from the source object B — to the new objects. This kind of processing can be performed in the `Adjust` procedure.

As an example, let's extend the previous code example and override the `Adjust` procedure:

Listing 5: simple_controlled_types.ads

```

When running this application, we see that the `Adjust` procedure is called for object `A` — right after `B` is copied to `A` as part of the `A := B` assignment. We discuss more about this procedure *later on* (page 1838).

Limited controlled types

Ada offers controlled types in two flavors: nonlimited controlled types — such as the ones we've seen so far — and limited controlled types. Both types are declared in the `Ada.Finalization` package.

The only difference between these types is that limited controlled types don't have an `Adjust` procedure that could be overridden, as limited types *do not permit direct copies of objects to be made via assignments* (page 923). (Obviously, both controlled and limited controlled types provide `Initialize` and `Finalize` procedures.)

The following table summarizes the information:

Type	Name	Initialize	Finalize	Adjust
Nonlimited Controlled	**`Controlled`**	Yes	Yes	Yes
Limited controlled	`Limited_Controlled`	Yes	Yes	Not available

Simple Example with ID

Although the previous code examples indicated that `Initialize`, `Finalize` and `Adjust` are called as we expect for controlled objects, they didn't show us exactly how those objects are actually handled. In this section, we discuss this by analyzing a code example that assigns a unique ID to each controlled object.

Let's start with the complete code example:

Listing 8: simple_controlled_types.ads

```
1  with Ada.Finalization;
2
3  package Simple_Controlled_Types is
4
5     type T is tagged private;
6
7     procedure Show (E    : T;
8                     Name : String);
9
10 private
11
12    protected Id_Gen is
13       procedure New_Id (Id_Out : out Positive);
14    private
15       Id : Natural := 0;
16    end Id_Gen;
```

(continues on next page)

25    procedure Initialize (E : in out T);
26
27    overriding
28    procedure Adjust (E : in out T);
29
30    overriding
31    procedure Finalize (E : in out T);
32
33 end Simple_Controlled_Types;
```

Listing 9: simple_controlled_types.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Simple_Controlled_Types is
4
5     protected body Id_Gen is
6
7        procedure New_Id (Id_Out : out Positive) is
8        begin
9           Id := Id + 1;
10          Id_Out := Id;
11       end New_Id;
12
13    end Id_Gen;
14
15    procedure Initialize (E : in out T) is
16    begin
17       Id_Gen.New_Id (E.Id);
18       Put_Line ("Initialize: ID => "
19                 & E.Id'Image);
20    end Initialize;
21
22    procedure Adjust (E : in out T) is
23       Prev_Id : constant Positive := E.Id;
24    begin
25       Id_Gen.New_Id (E.Id);
26       Put_Line ("Adjust:     ID => "
27                 & E.Id'Image);
28       Put_Line ("    (Previous ID => "
29                 & Prev_Id'Image
30                 & ")");
31    end Adjust;
32
33    procedure Finalize (E : in out T) is
34    begin
35       Put_Line ("Finalize:   ID => "
36                 & E.Id'Image);
37    end Finalize;
38
39    procedure Show (E    : T;

--------
Finalize:   ID =>  2
Finalize:   ID =>  3
```

In contrast to the previous versions of the `Simple_Controlled_Types` package, type `T` now has an `Id` component. Moreover, we use a protected object `Id_Gen` that provides us with a unique ID to keep track of each controlled object. Basically, we assign an ID to each controlled object (right after it is created) via the call to `Initialize`. Similarly, this ID is updated via the calls to `Adjust`. Besides, we now have a `Show` procedure that displays the ID of a controlled object.

When running the application, we see that the calls to `Initialize`, `Adjust` and `Finalize` happen as expected. In addition, we see the objects' ID, which we will now analyze in order to understand how each object is actually handled.

First, we see the two calls to `Initialize` for objects `A` and `B`. Object `A`'s ID is 1, and object `B`'s ID is 2. This is later confirmed by the calls to `Show`.

The `A := B` assignment triggers two procedure calls: a call to `Finalize (A)` and a call to `Adjust (A)`. In fact, this assignment can be described as follows:

1. `Finalize (A)` is called before the actual copy;
2. `B`'s data is copied to object `A`;
3. `Adjust (A)` is called after that copy.

We can confirm this via the object ID: the object we handle in the call to `Finalize (A)` has an ID of 1, and the object we handle in the call to `Adjust (A)` has an ID of 2 (which originates from the copy of `B` to `A`) and is later changed (*adjusted*) to 3. Again, we can verify the correct IDs by looking at the output of the calls to `Show`.

Note that the call to `Finalize (A)` (before the copy of `B`'s data) indicates that the previous version of object `A` is being finalized, i.e. it's as though the original object `A` is going to be destroyed and its contents are going to be lost. Actually, the object's contents are just overwritten, but the call to `Finalize` allows us to make proper adjustments to the object before the previous information is lost.

Finally, the new version of object `A` (the one whose ID is 3) and object `B` are finalized via the calls to `Finalize (A)` and `Finalize (B)` before the `Show_Controlled_Types` procedure ends.

101.1.2 Initialization

In this section, we cover some details about the initialization of controlled types. Most of those details are related to the initialization order. In principle, as stated in the Ada Reference Manual, "`Initialize` and other initialization operations are done in an arbitrary order," except in the situations that we describe later on.

Relevant topics

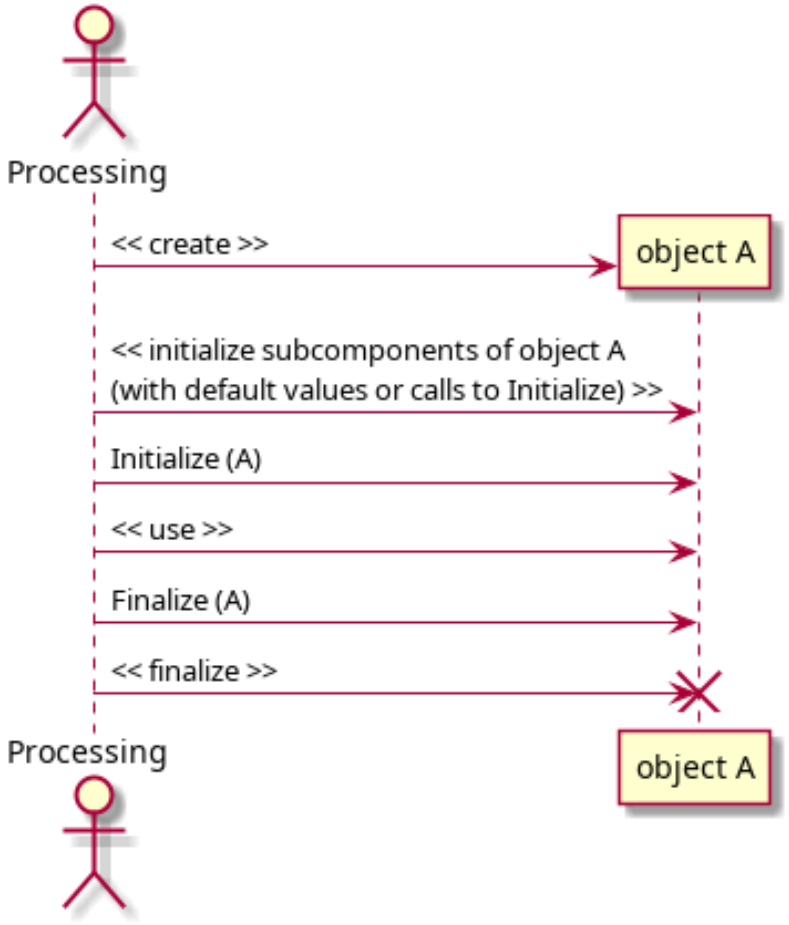
- Assignment and Finalization[446]

Subcomponents

We've seen before that default initialization is a way of controlling the initialization of arbitrary types. In the case of controlled types, the default initialization of its subcomponents always takes places before the call to `Initialize`.

Similarly, a controlled type might have subcomponents of controlled types. These subcomponents are initialized by a call to the `Initialize` procedure of each of those controlled types.

We can visualize the lifetime as follows:



In order to see this effect, let's start by implementing two controlled types: Sub_1 and Sub_2:

[446] http://www.ada-auth.org/standards/22rm/html/RM-7-6.html

Listing 11: subs.ads

```
with Ada.Finalization;

package Subs is

   type Sub_1 is tagged private;

   type Sub_2 is tagged private;

private

   type Sub_1 is new
     Ada.Finalization.Controlled
       with null record;

   overriding
   procedure Initialize (E : in out Sub_1);

   type Sub_2 is new
     Ada.Finalization.Controlled
       with null record;

   overriding
   procedure Initialize (E : in out Sub_2);

end Subs;
```

Listing 12: subs.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Subs is

   procedure Initialize (E : in out Sub_1) is
   begin
      Put_Line ("Initialize: Sub_1...");
   end Initialize;

   procedure Initialize (E : in out Sub_2) is
   begin
      Put_Line ("Initialize: Sub_2...");
   end Initialize;

end Subs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Initialization.
 ↪Controlled_Initialization
MD5: f6a7676e82294a62965157d2ffd4ae3b
```

Now, let's use those controlled types as components of a type T. In addition, let's declare an integer component I with default initialization. This is how the complete code looks like:

Listing 13: simple_controlled_types.ads

```
with Ada.Finalization;

with Subs; use Subs;

```

(continues on next page)

(continued from previous page)

```
package Simple_Controlled_Types is

   type T is tagged private;

   procedure Dummy (E : T);

private

   function Default_Init return Integer;

   type T is new
     Ada.Finalization.Controlled with
   record
      S1 : Sub_1;
      S2 : Sub_2;
      I  : Integer := Default_Init;
   end record;

   overriding
   procedure Initialize (E : in out T);

end Simple_Controlled_Types;
```

Listing 14: simple_controlled_types.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Simple_Controlled_Types is

   function Default_Init return Integer is
   begin
      Put_Line ("Default_Init: Integer...");
      return 42;
   end Default_Init;

   procedure Dummy (E : T) is
   begin
      Put_Line ("(Dummy: T...)");
   end Dummy;

   procedure Initialize (E : in out T) is
   begin
      Put_Line ("Initialize: T...");
   end Initialize;

end Simple_Controlled_Types;
```

Listing 15: show_controlled_types.adb

```
with Simple_Controlled_Types;
use  Simple_Controlled_Types;

procedure Show_Controlled_Types is
   A : T;
begin
   Dummy (A);
end Show_Controlled_Types;
```

Code block metadata

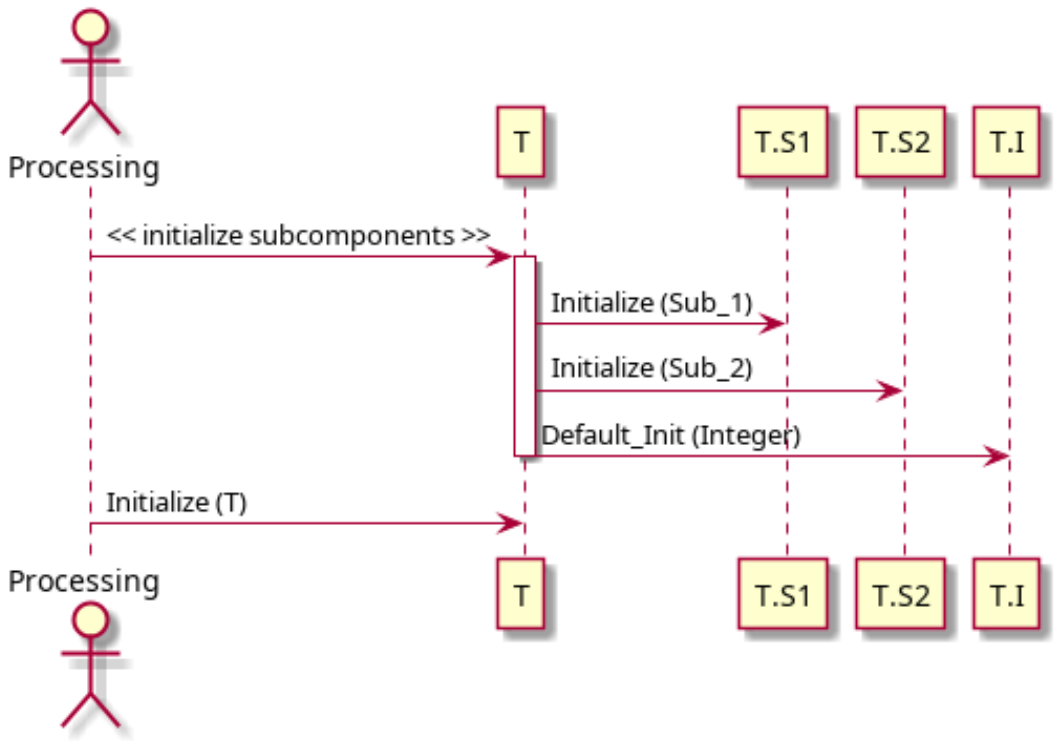
```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Initialization.
 ↪Controlled_Initialization
MD5: 39d0efa76c056ac8190573c86f17c890
```

Runtime output

```
Initialize: Sub_1...
Initialize: Sub_2...
Default_Init: Integer...
Initialize: T...
(Dummy: T...)
```

When we run this application, we see that the Sub_1 and Sub_2 components are initialized by calls to their respective `Initialize` procedures, and the `I` component is initialized with its default value (via a call to the `Default_Init` function). Finally, after all subcomponents of type T have been initialized, the `Initialize` procedure is called for the type T itself.

This diagram shows the initialization sequence:



Components with access discriminants

Record types with access discriminants are a special case. In fact, according to the Ada Reference Manual, "if an object has a component with an access discriminant constrained by a *per-object expression* (page 429), `Initialize` is applied to this component after any components that do not have such discriminants. For an object with several components with such a discriminant, `Initialize` is applied to them in order of their component declarations."

Let's see a code example. First, we implement another package with controlled types:

Listing 16: selections.ads

```
with Ada.Finalization;

package Selections is

   type Selection is private;

   type Selection_1 (S : access Selection) is
     tagged private;

   type Selection_2 (S : access Selection) is
     tagged private;

private

   type Selection is null record;

   type Selection_1 (S : access Selection) is new
     Ada.Finalization.Controlled
       with null record;

   overriding
   procedure Initialize
     (E : in out Selection_1);

   type Selection_2 (S : access Selection) is new
     Ada.Finalization.Controlled
       with null record;

   overriding
   procedure Initialize
     (E : in out Selection_2);

end Selections;
```

Listing 17: selections.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Selections is

   procedure Initialize
     (E : in out Selection_1) is
   begin
      Put_Line ("Initialize: Selection_1...");
   end Initialize;

   procedure Initialize
     (E : in out Selection_2) is
   begin
```

(continues on next page)

(continued from previous page)

```
      Put_Line ("Initialize: Selection_2...");
   end Initialize;

end Selections;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Initialization.
 ↪Controlled_Initialization
MD5: 01c3639ebd52d37856e77ccfeb057d1b
```

In this example, we see the declaration of the Selection_1 and Selection_2 types, which are controlled types with an access discriminant of Selection type. Now, let's use these types in the declaration of the T type from the *previous example* (page 1828) and add two new components (Sel_1 and Sel_2):

Listing 18: simple_controlled_types.ads

```
with Ada.Finalization;

with Subs;       use Subs;
with Selections; use Selections;

package Simple_Controlled_Types is

   type T (S1 : access Selection;
           S2 : access Selection) is
     tagged private;

   procedure Dummy (E : T);

private

   function Default_Init return Integer;

   type T (S1 : access Selection;
           S2 : access Selection) is new
     Ada.Finalization.Controlled with
   record
      Sel_1 : Selection_1 (S1);
      Sel_2 : Selection_2 (S2);
      S_1   : Sub_1;
      I     : Integer := Default_Init;
   end record;

   overriding
   procedure Initialize (E : in out T);

end Simple_Controlled_Types;
```

Listing 19: simple_controlled_types.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Simple_Controlled_Types is

   function Default_Init return Integer is
   begin
      Put_Line ("Default_Init: Integer...");
      return 42;
```

(continues on next page)

(continued from previous page)

```
   end Default_Init;

   procedure Dummy (E : T) is
   begin
      Put_Line ("(Dummy: T...)");
   end Dummy;

   procedure Initialize (E : in out T) is
   begin
      Put_Line ("Initialize: T...");
   end Initialize;

end Simple_Controlled_Types;
```

Listing 20: show_controlled_types.adb

```
with Simple_Controlled_Types;
use  Simple_Controlled_Types;

with Selections;
use  Selections;

procedure Show_Controlled_Types is
   S1, S2 : aliased Selection;
   A : T (S1'Access, S2'Access);
begin
   Dummy (A);
end Show_Controlled_Types;
```

Code block metadata

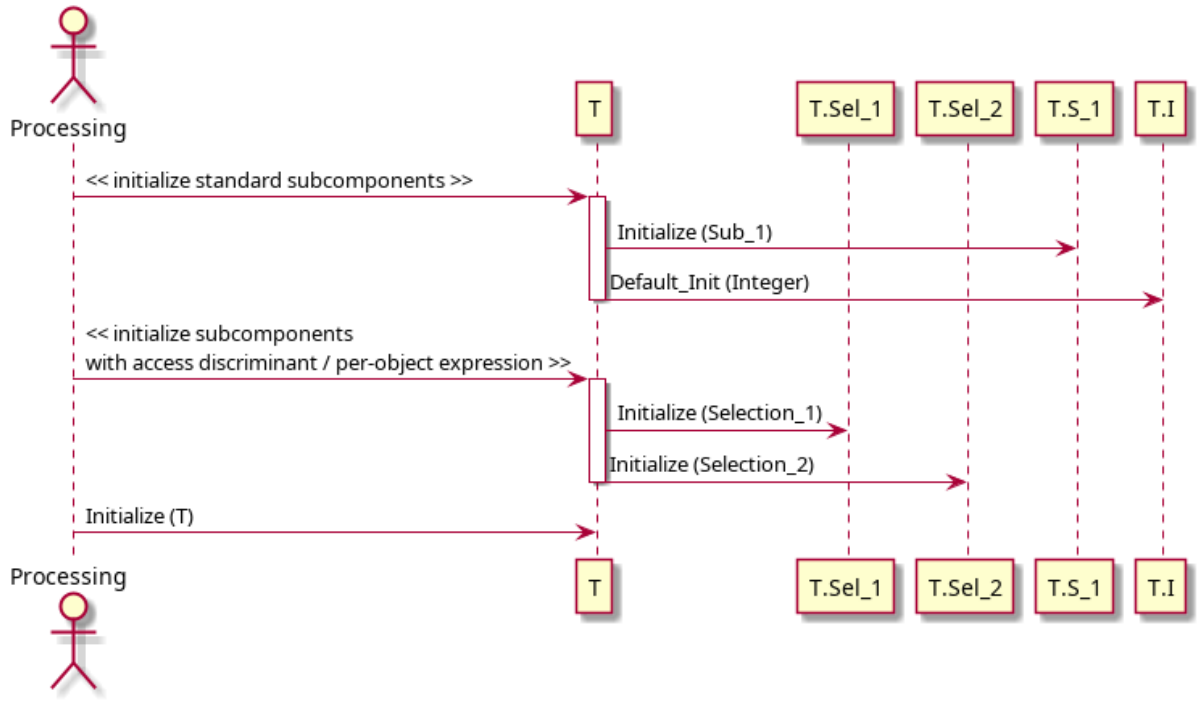
```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Initialization.
 ↪Controlled_Initialization
MD5: 74f507b912ab746b70aec451a9bc8f74
```

Runtime output

```
Initialize: Sub_1...
Default_Init: Integer...
Initialize: Selection_1...
Initialize: Selection_2...
Initialize: T...
(Dummy: T...)
```

When running this example, we see that all other subcomponents — to be more precise, those subcomponents that require initialization — are initialized before the Sub_1 and Sub_2 components are initialized via calls to their corresponding `Initialize` procedure. Note that, although Sub_1 and Sub_2 are the last components to be initialized, they are still initialized before the call to the `Initialize` procedure of type T.

This diagram shows the initialization sequence:



Task activation

Components of task types also require special treatment. According to the Ada Reference Manual, "for an allocator, any task activations follow all calls on `Initialize`."

As always, let's analyze an example that illustrates this. First, we implement another package called `Workers` with a simple task type:

Listing 21: workers.ads

```
1  package Workers is
2
3     task type Worker is
4        entry Start;
5        entry Stop;
6     end Worker;
7
8  end Workers;
```

Listing 22: workers.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Workers is
4
5     task body Worker is
6
7        function Init return Integer is
8        begin
9           Put_Line ("Activating Worker task...");
10          return 0;
11       end Init;
12
13       I : Integer := Init;
14    begin
15
```

(continues on next page)

(continued from previous page)

```
      accept Start do
        Put_Line ("Worker.Start accepted...");
         I := I + 1;
      end Start;

      accept Stop do
        Put_Line ("Worker.Stop accepted...");
         I := I - 1;
      end Stop;
   end Worker;

end Workers;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Initialization.
↪Controlled_Initialization
MD5: 1d48a78f14a496c8cdadeab9d1bc9070
```

Let's extend the declaration of the T type from the *previous example* (page 1832) and declare a new component of `Worker` type. Note that we have to change T to a limited controlled type because of this new component of task type. This is the updated code:

Listing 23: simple_controlled_types.ads

```
with Ada.Finalization;

with Subs;       use Subs;
with Selections; use Selections;
with Workers;    use Workers;

package Simple_Controlled_Types is

   type T (S : access Selection) is
     tagged limited private;

   procedure Start_Work (E : T);
   procedure Stop_Work (E : T);

private

   function Default_Init return Integer;

   type T (S : access Selection) is new
     Ada.Finalization.Limited_Controlled with
   record
      W     : Worker;
      Sel_1 : Selection_1 (S);
      S1    : Sub_1;
      I     : Integer := Default_Init;
   end record;

   overriding
   procedure Initialize (E : in out T);

end Simple_Controlled_Types;
```

Listing 24: simple_controlled_types.adb

```
with Ada.Text_IO; use Ada.Text_IO;
```

(continues on next page)

(continued from previous page)

```

package body Simple_Controlled_Types is

   function Default_Init return Integer is
   begin
      Put_Line ("Default_Init: Integer...");
      return 42;
   end Default_Init;

   procedure Start_Work (E : T) is
   begin
      --  Starting Worker task:
      E.W.Start;

   end Start_Work;

   procedure Stop_Work (E : T) is
   begin
      --  Stopping Worker task:
      E.W.Stop;
   end Stop_Work;

   procedure Initialize (E : in out T) is
   begin
      Put_Line ("Initialize: T...");
   end Initialize;

end Simple_Controlled_Types;
```

Listing 25: show_controlled_types.adb

```
with Simple_Controlled_Types;
use  Simple_Controlled_Types;

with Selections; use Selections;

procedure Show_Controlled_Types is
   type T_Access is access T;

   S : aliased Selection;
   A : constant T_Access := new T (S'Access);
begin
   Start_Work (A.all);
   Stop_Work (A.all);
end Show_Controlled_Types;
```

Code block metadata

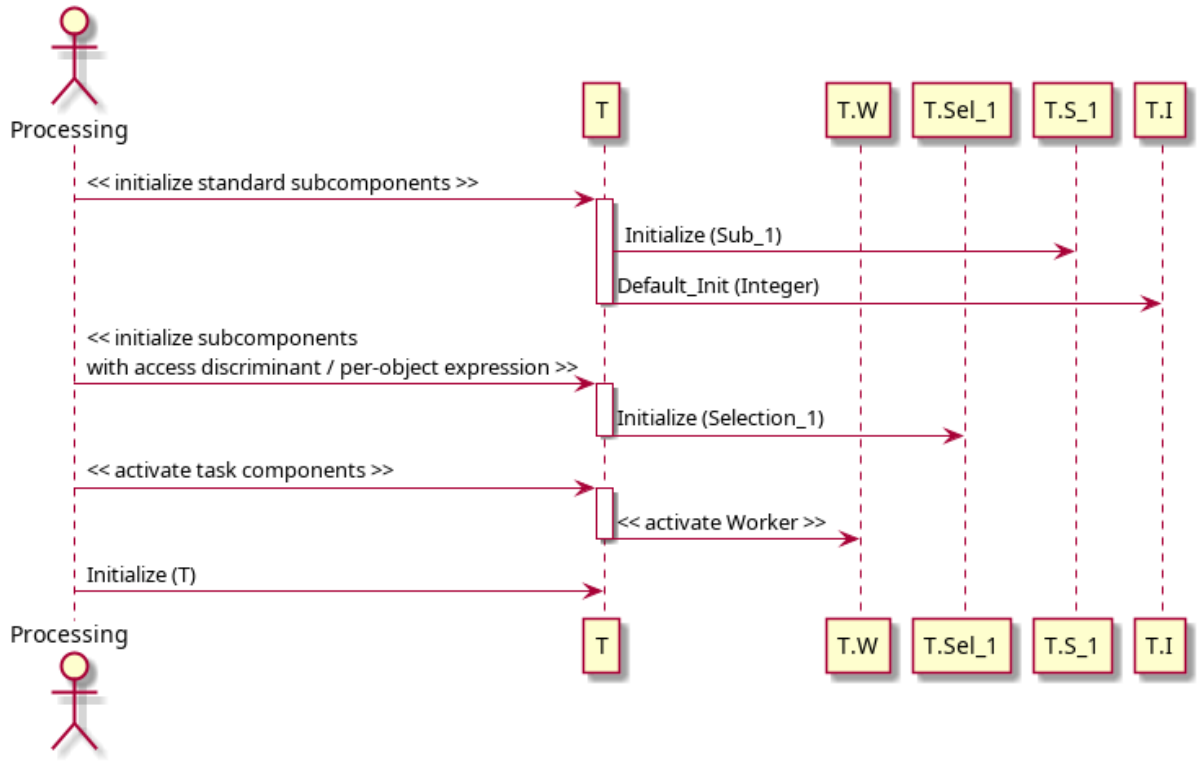
```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Initialization.
 ↪Controlled_Initialization
MD5: f87adac74205d590ee66ce971918e642
```

Runtime output

```
Initialize: Sub_1...
Default_Init: Integer...
Initialize: Selection_1...
Activating Worker task...
Initialize: T...
Worker.Start accepted...
Worker.Stop accepted...
```

When we run this application, we see that the `W` component is activated only after all other subcomponents of type `T` have been initialized.

This diagram shows the initialization sequence:



101.1.3 Assignment

We already talked about *adjustments* (page 1822) previously. As we already mentioned, an actual assignment is a full bit-wise copy of the entire right-hand side to the entire left-hand side, so the adjustment (via a call to `Adjust`) is a way to "work around" that, when necessary. In this section, we'll look into some details about the adjustment of controlled types.

Relevant topics

- Assignment and Finalization[447]

Assignment using anonymous object

The Ada Reference Manual[448] mentions that an anonymous object is created during the assignment of objects of controlled type. A simple `A := B` operation for nonlimited controlled types can be expanded to the following illustrative code:

```
procedure P is
   A, B: Some_Controlled_Type;
begin
   --
```

(continues on next page)

[447] http://www.ada-auth.org/standards/22rm/html/RM-7-6.html
[448] http://www.ada-auth.org/standards/22rm/html/RM-7-6.html

(continued from previous page)

```
   --  A := B;
   --
   B_To_A_Assignment : declare
      Anon_Obj : Some_Controlled_Type;
   begin
      Anon_Obj := B;
      Adjust (Anon_Obj);
      Finalize (A);
      A := Anon_Obj;
      Finalize (Anon_Obj);
   end B_To_A_Assignment;
end P;
```

The first assignment happens to the anonymous object `Anon_Obj`. After the adjustment of `Anon_Obj` and the finalization of the original version of `A`, the actual assignment to `A` can take place — and `Anon_Obj` can be discarded after it has been properly finalized. With this strategy, we have a chance to finalize the original version of `A` before the assignment overwrites the object.

Of course, this expanded code isn't really efficient, and the compiler has some freedom to improve the performance of the generated machine code. Whenever possible, it'll typically optimize the anonymous object out and build the object in place. (The Ada Reference Manual[449] describes the rules when this is possible or not.)

Also, the `A := Anon_Obj` statement in the code above doesn't necessarily translate to an actual assignment in the generated machine code. Typically, a compiler may treat `Anon_Obj` as the new `A` and destroy the original version of `A` (i.e. the object that used to be `A`). In this case, the code becomes something like this:

```
procedure P is
   A, B: Some_Controlled_Type;
begin
   --
   --  A := B;
   --
   B_To_A_Assignment : declare
      Anon_Obj : Some_Controlled_Type;
   begin
      Anon_Obj := B;
      Finalize (A);
      Adjust (Anon_Obj);
      declare
         A : Some_Controlled_Type renames Anon_Obj;
      begin
         --  Now, we treat Anon_Obj as the new A.
         --  Further processing continues here...

      end;
   end B_To_A_Assignment;
end P;
```

In some cases, the compiler is required to build the object in place. A typical example is when an object of controlled type is initialized by assigning an aggregate to it:

```
C: constant Some_Controlled_Type :=
    (Ada.Finalization.Controlled with ...);
--  C is built in place,
--  no anonymous object is used here.
```

Also, it's possible that `Adjust` and `Finalize` aren't called at all. Consider an assignment

[449] http://www.ada-auth.org/standards/22rm/html/RM-7-6.html

like this: `A := A;`. In this case, since the object on both sides is the same, the compiler is allowed to simply skip the assignment and not do anything.

For more details about possible optimizations and compiler behavior, please refer to the Ada Reference Manual[450] .

In general, the advice is simply: use `Adjust` and `Finalize` solely for their intended purposes. In other words, don't implement extraneous side-effects into those procedures, as they might not be called at run-time.

Adjustment of subcomponents

In principle, the order in which components are adjusted is arbitrary. However, adjustments of subcomponents will happen before the adjustment of the component itself. The subcomponents must be adjusted before the enclosing object because the semantics of the adjustment of the whole might depend on the states of the parts (the subcomponents), so those states must already be in place.

Let's revisit a *previous code example* (page 1828). First, we override the `Adjust` procedure of the Sub_1 and Sub_2 types from the Subs package.

Listing 26: subs.ads

```
with Ada.Finalization;

package Subs is

   type Sub_1 is tagged private;

   type Sub_2 is tagged private;

private

   type Sub_1 is new
     Ada.Finalization.Controlled
       with null record;

   overriding
   procedure Initialize (E : in out Sub_1);

   overriding
   procedure Adjust (E : in out Sub_1);

   overriding
   procedure Finalize (E : in out Sub_1);

   type Sub_2 is new
     Ada.Finalization.Controlled
       with null record;

   overriding
   procedure Initialize (E : in out Sub_2);

   overriding
   procedure Adjust (E : in out Sub_2);

   overriding
   procedure Finalize (E : in out Sub_2);

end Subs;
```

[450] http://www.ada-auth.org/standards/22rm/html/RM-7-6.html

Listing 27: subs.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Subs is

   procedure Initialize (E : in out Sub_1) is
   begin
      Put_Line ("Initialize: Sub_1...");
   end Initialize;

   procedure Adjust (E : in out Sub_1) is
   begin
      Put_Line ("Adjust: Sub_1...");
   end Adjust;

   procedure Finalize (E : in out Sub_1) is
   begin
      Put_Line ("Finalize: Sub_1...");
   end Finalize;

   procedure Initialize (E : in out Sub_2) is
   begin
      Put_Line ("Initialize: Sub_2...");
   end Initialize;

   procedure Adjust (E : in out Sub_2) is
   begin
      Put_Line ("Adjust: Sub_2...");
   end Adjust;

   procedure Finalize (E : in out Sub_2) is
   begin
      Put_Line ("Finalize: Sub_2...");
   end Finalize;

end Subs;
```

 ↪Controlled_Initialization
MD5: 110d88543a7a897ba433c90f6c2a881c
```

Next, we override the `Adjust` procedure of the T type from the `Simple_Controlled_Types` package:

Listing 28: simple_controlled_types.ads

```
with Ada.Finalization;

with Subs; use Subs;

package Simple_Controlled_Types is

   type T is tagged private;

   procedure Dummy (E : T);

private

```

(continues on next page)

(continued from previous page)

```
13    function Default_Init return Integer;
14
15    type T is new
16      Ada.Finalization.Controlled with
17    record
18       S1 : Sub_1;
19       S2 : Sub_2;
20       I  : Integer := Default_Init;
21    end record;
22
23    overriding
24    procedure Initialize (E : in out T);
25
26    overriding
27    procedure Adjust (E : in out T);
28
29    overriding
30    procedure Finalize (E : in out T);
31
32 end Simple_Controlled_Types;
```

Listing 29: simple_controlled_types.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Simple_Controlled_Types is
4
5     function Default_Init return Integer is
6     begin
7        Put_Line ("Default_Init: Integer...");
8        return 42;
9     end Default_Init;
10
11    procedure Dummy (E : T) is
12    begin
13       Put_Line ("(Dummy: T...)");
14    end Dummy;
15
16    procedure Initialize (E : in out T) is
17    begin
18       Put_Line ("Initialize: T...");
19    end Initialize;
20
21    procedure Adjust (E : in out T) is
22    begin
23       Put_Line ("Adjust: T...");
24    end Adjust;
25
26    procedure Finalize (E : in out T) is
27    begin
28       Put_Line ("Finalize: T...");
29    end Finalize;
30
31 end Simple_Controlled_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Adjustment.
 ↪Controlled_Initialization
MD5: 9fb392305df70734994cffe612cb3869
```

Finally, this is the main application:

Listing 30: show_controlled_types.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Simple_Controlled_Types;
use  Simple_Controlled_Types;

procedure Show_Controlled_Types is
   A, B : T;
begin
   Dummy (A);

   Put_Line ("----------");
   Put_Line ("A := B");
   A := B;
   Put_Line ("----------");
end Show_Controlled_Types;
```

Code block metadata

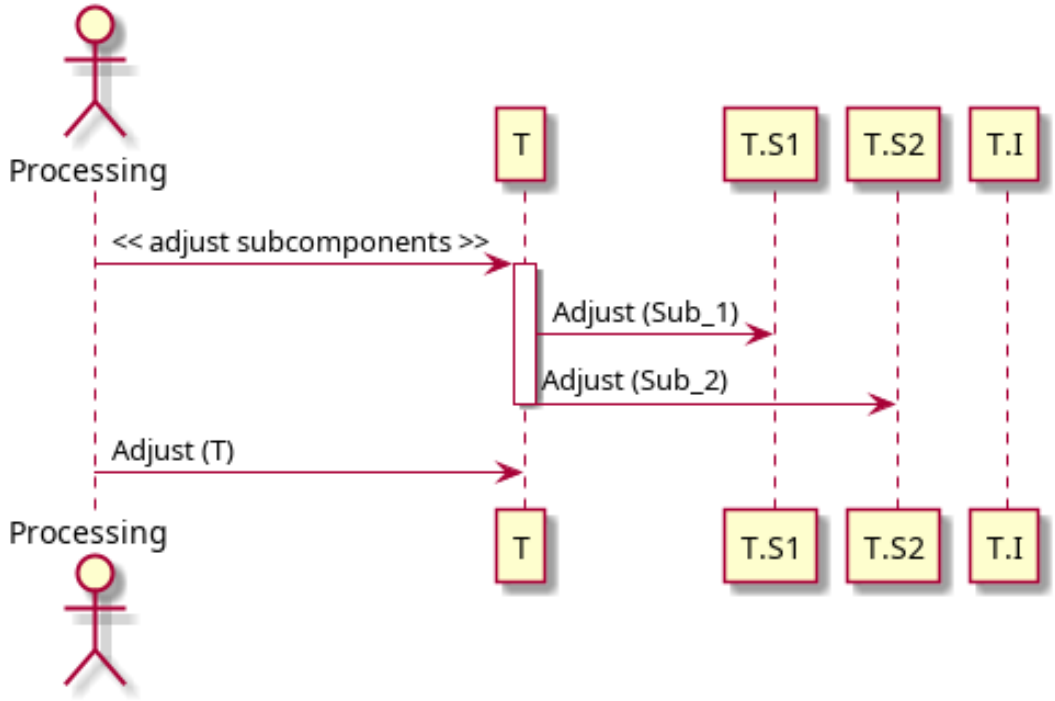
```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Adjustment.
 ↪Controlled_Initialization
MD5: 1ceaa50cbb18b9f1f997246a614e3a90
```

Runtime output

```
Initialize: Sub_1...
Initialize: Sub_2...
Default_Init: Integer...
Initialize: T...
Initialize: Sub_1...
Initialize: Sub_2...
Default_Init: Integer...
Initialize: T...
(Dummy: T...)
----------
A := B
Finalize: T...
Finalize: Sub_2...
Finalize: Sub_1...
Adjust: Sub_1...
Adjust: Sub_2...
Adjust: T...
----------
Finalize: T...
Finalize: Sub_2...
Finalize: Sub_1...
Finalize: T...
Finalize: Sub_2...
Finalize: Sub_1...
```

When running this code, we see that the S1 and S2 components are adjusted before the adjustment of the parent type T takes place.

This diagram shows the adjustment sequence:



101.1.4 Finalization

We mentioned finalization — and the `Finalize` procedure — at the *beginning of the chapter* (page 1819). In this section, we discuss the topic in more detail.

Relevant topics

- Assignment and Finalization[451]
- Completion and Finalization[452]

Normal and abnormal completion

When a subprogram has just executed its last statement, normal completion of this subprogram has been reached. At this point, finalization starts. In the case of controlled objects, this means that the `Finalize` procedure is called for those objects. (As we've already seen *an example of normal completion* (page 1820) at the beginning of the chapter, we won't repeat it here, as we assume you are already familiar with the concept.)

When an exception is raised or due to an abort, however, a subprogram has an abnormal completion. We discuss more about exception handling and finalization *later on* (page 1853).

[451] http://www.ada-auth.org/standards/22rm/html/RM-7-6.html
[452] http://www.ada-auth.org/standards/22rm/html/RM-7-6-1.html

Finalization via unchecked deallocation

When performing unchecked deallocation of a controlled type, the `Finalize` procedure is called right before the actual memory for the controlled object is deallocated.

Let's see a simple example:

Listing 31: simple_controlled_types.ads

```
with Ada.Finalization;
with Ada.Unchecked_Deallocation;

package Simple_Controlled_Types is

   type T is tagged private;

   procedure Dummy (E : T);

   type T_Access is access T;

   procedure Free (A : in out T_Access);

private

   type T is new
     Ada.Finalization.Controlled
       with null record;

   overriding
   procedure Finalize (E : in out T);

   procedure Free_T_Access is
     new Ada.Unchecked_Deallocation
       (Object => T,
        Name   => T_Access);

   procedure Free (A : in out T_Access)
     renames Free_T_Access;

end Simple_Controlled_Types;
```

Listing 32: simple_controlled_types.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Simple_Controlled_Types is

   procedure Dummy (E : T) is
   begin
      Put_Line ("(Dummy T...)");
   end Dummy;

   procedure Finalize (E : in out T) is
   begin
      Put_Line ("Finalize T...");
   end Finalize;

end Simple_Controlled_Types;
```

Listing 33: show_controlled_types.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Simple_Controlled_Types;
use  Simple_Controlled_Types;

procedure Show_Controlled_Types is
   A : T_Access := new T;
begin
   Dummy (A.all);

   Free (A);
   --  At this point, Finalize (A.all)
   --  will be called before the actual
   --  deallocation.

   Put_Line ("We've just freed A.");
end Show_Controlled_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Finalization.
 ↪Unchecked_Deallocation
MD5: b9388699ee396430f689fe88df41fc32
```

Runtime output

```
(Dummy T...)
Finalize T...
We've just freed A.
```

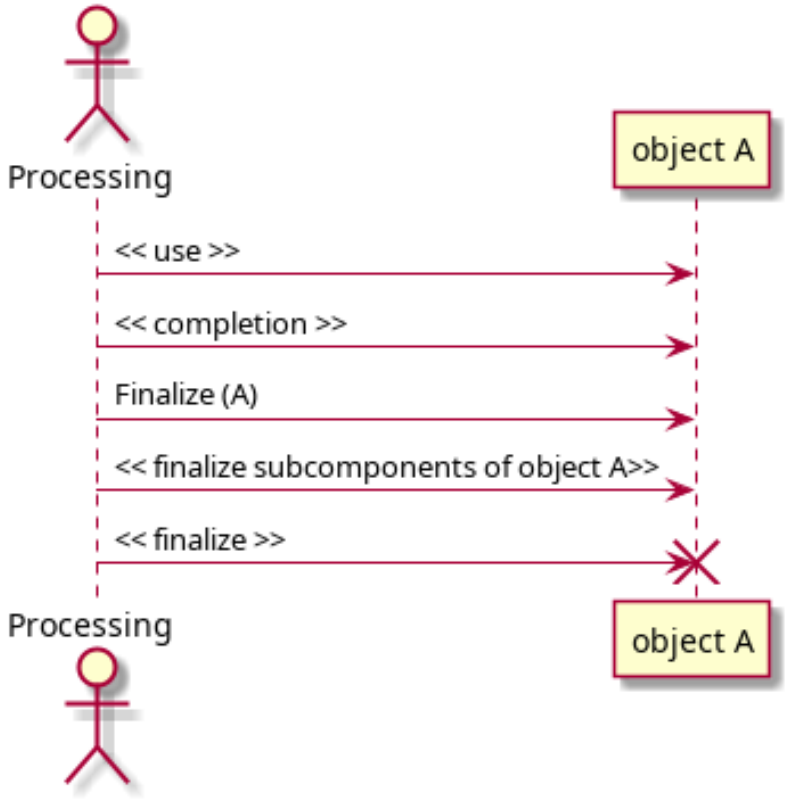
In this example, we see that a call to `Finalize` (for type `T`) is triggered by the call to `Free` for the `A` object — at this point, we haven't reached the end of the main procedure (`Show_Controlled_Types`) yet. After the call to `Free`, the object originally referenced by `A` has been completely finalized — and deallocated.

When the main procedure completes (after the call to `Put_Line` in that procedure), we would normally see the calls to `Finalize` for controlled objects. However, at this point, we obviously don't have a second call to the `Finalize` procedure for type `T`, as the object referenced by `A` has already been finalized and freed.

Subcomponents

As we've seen in the section about *initialization of subcomponents* (page 1828), subcomponents of a controlled type are initialized by a call to their corresponding `Initialize` procedure before the call to `Initialize` for the parent controlled type. In the case of finalization, the reverse order is applied: first, finalization of the parent type takes place, and then the finalization of the subcomponents.

We can visualize the lifetime as follows:



Let's show a code example by revisiting the previous implementation of the controlled types Sub_1 and Sub_2, and adapting it:

Listing 34: subs.ads

```
with Ada.Finalization;

package Subs is

   type Sub_1 is tagged private;

   type Sub_2 is tagged private;

private

   type Sub_1 is new
     Ada.Finalization.Controlled
       with null record;

   overriding
   procedure Finalize (E : in out Sub_1);

   type Sub_2 is new
     Ada.Finalization.Controlled
       with null record;

   overriding
   procedure Finalize (E : in out Sub_2);

end Subs;
```

Listing 35: subs.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Subs is

   procedure Finalize (E : in out Sub_1) is
   begin
      Put_Line ("Finalize: Sub_1...");
   end Finalize;

   procedure Finalize (E : in out Sub_2) is
   begin
      Put_Line ("Finalize: Sub_2...");
   end Finalize;

end Subs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Finalization.
 ↪Controlled_Initialization
MD5: 565f0b13586c08e0cdfdc119bcb28780
```

Now, let's use those controlled types as components of a type T:

Listing 36: simple_controlled_types.ads

```
with Ada.Finalization;

with Subs; use Subs;

package Simple_Controlled_Types is

   type T is tagged private;

   procedure Dummy (E : T);

private

   type T is new
     Ada.Finalization.Controlled with
   record
      S1 : Sub_1;
      S2 : Sub_2;
   end record;

   overriding
   procedure Finalize (E : in out T);

end Simple_Controlled_Types;
```

Listing 37: simple_controlled_types.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Simple_Controlled_Types is

   procedure Dummy (E : T) is
   begin
      Put_Line ("(Dummy: T...)");
```

(continues on next page)

(continued from previous page)

```
   end Dummy;

   procedure Finalize (E : in out T) is
   begin
      Put_Line ("Finalize: T...");
   end Finalize;

end Simple_Controlled_Types;
```

Listing 38: show_controlled_types.adb

```
with Simple_Controlled_Types;
use  Simple_Controlled_Types;

procedure Show_Controlled_Types is
   A : T;
begin
   Dummy (A);
end Show_Controlled_Types;
```

Code block metadata

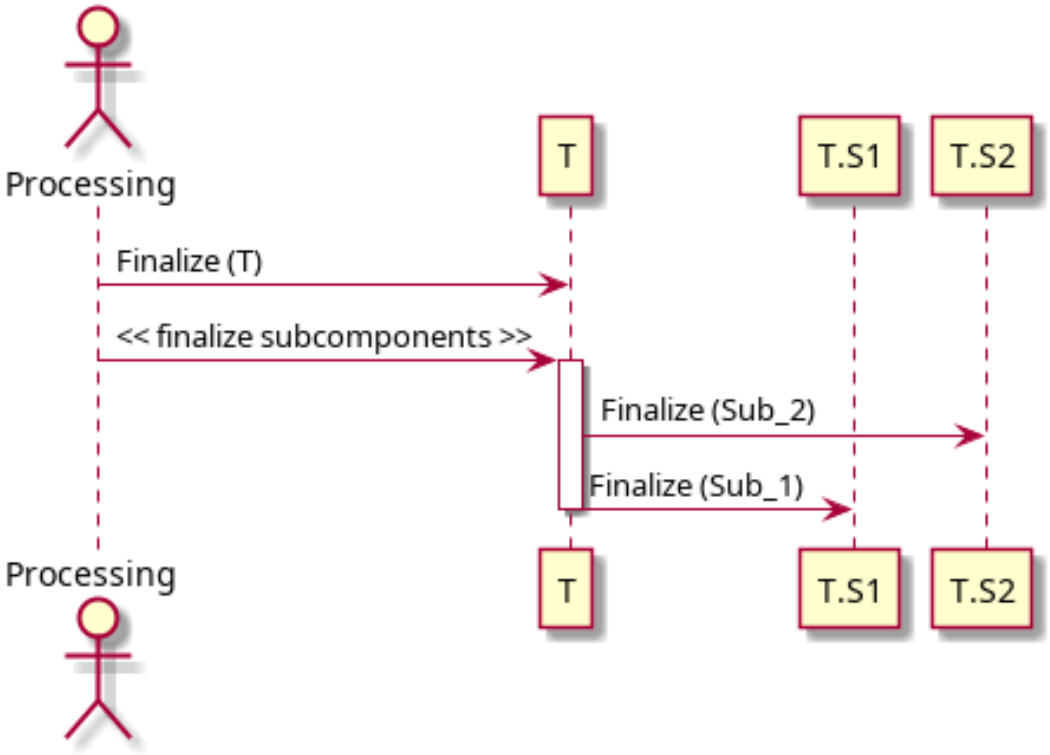
```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Finalization.
 ↪Controlled_Initialization
MD5: 6feecb7c544f340bf4841034d7ab5f71
```

Runtime output

```
(Dummy: T...)
Finalize: T...
Finalize: Sub_2...
Finalize: Sub_1...
```

When we run this application, we see that the `Finalize` procedure is called for the type T itself — as the first step of the finalization of type T. Then, the Sub_2 and Sub_1 components are finalized by calls to their respective `Finalize` procedures.

This diagram shows the finalization sequence:



Components with access discriminants

We already discussed the *initialization of components with access discriminants constrained by a per-object expression* (page 1832). In the case of the finalization of such components, they are finalized before any components that do not fall into this category — in the reverse order of their component declarations — but after the finalization of the parent type.

Let's revisit a *previous code example* (page 1832) and adapt it to demonstrate the finalization of components with access discriminants. First, we implement another package with controlled types:

Listing 39: selections.ads

```
with Ada.Finalization;

package Selections is

   type Selection is private;

   type Selection_1 (S : access Selection) is
     tagged private;

   type Selection_2 (S : access Selection) is
     tagged private;

private

   type Selection is null record;

   type Selection_1 (S : access Selection) is new
     Ada.Finalization.Controlled
       with null record;

   overriding
```

(continues on next page)

(continued from previous page)

```
   procedure Finalize
      (E : in out Selection_1);

   type Selection_2 (S : access Selection) is new
     Ada.Finalization.Controlled
       with null record;

   overriding
   procedure Finalize
     (E : in out Selection_2);

end Selections;
```

Listing 40: selections.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Selections is

   procedure Finalize
     (E : in out Selection_1) is
   begin
      Put_Line ("Finalize: Selection_1...");
   end Finalize;

   procedure Finalize
     (E : in out Selection_2) is
   begin
      Put_Line ("Finalize: Selection_2...");
   end Finalize;

end Selections;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Finalization.
 ↪Controlled_Initialization
MD5: d1d35eb7ea62742fb130fbf05d898989
```

In this example, we see the declaration of the `Selection_1` and `Selection_2` types, which are controlled types with an access discriminant of `Selection` type. Now, let's use these types in the declaration of a type T and add two new components — `Sel_1` and `Sel_2`:

Listing 41: simple_controlled_types.ads

```
with Ada.Finalization;

with Subs;       use Subs;
with Selections; use Selections;

package Simple_Controlled_Types is

   type T (S1 : access Selection;
           S2 : access Selection) is
     tagged private;

   procedure Dummy (E : T);

private

```

(continues on next page)

(continued from previous page)

```
16    type T (S1 : access Selection;
17            S2 : access Selection) is new
18      Ada.Finalization.Controlled with
19    record
20       Sel_1 : Selection_1 (S1);
21       Sel_2 : Selection_2 (S2);
22       S_1   : Sub_1;
23    end record;
24
25    overriding
26    procedure Finalize (E : in out T);
27
28 end Simple_Controlled_Types;
```

Listing 42: simple_controlled_types.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Simple_Controlled_Types is
4
5     procedure Dummy (E : T) is
6     begin
7        Put_Line ("(Dummy: T...)");
8     end Dummy;
9
10    procedure Finalize (E : in out T) is
11    begin
12       Put_Line ("Finalize: T...");
13    end Finalize;
14
15 end Simple_Controlled_Types;
```

Listing 43: show_controlled_types.adb

```
1  with Simple_Controlled_Types;
2  use  Simple_Controlled_Types;
3
4  with Selections;
5  use  Selections;
6
7  procedure Show_Controlled_Types is
8     S1, S2 : aliased Selection;
9     A : T (S1'Access, S2'Access);
10 begin
11    Dummy (A);
12 end Show_Controlled_Types;
```

Code block metadata

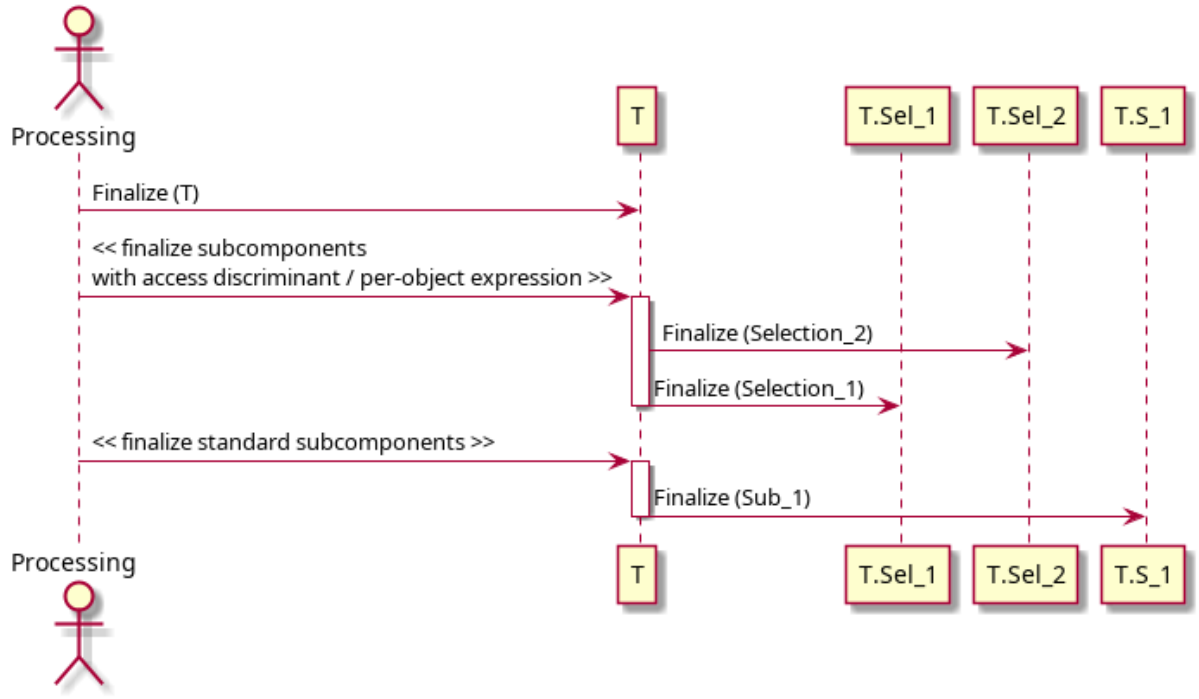
```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Finalization.
 ↪Controlled_Initialization
MD5: e421a750f11ade3b4df98569c71b904a
```

Runtime output

```
(Dummy: T...)
Finalize: T...
Finalize: Selection_2...
Finalize: Selection_1...
Finalize: Sub_1...
```

When we run this example, we see that the `Finalize` procedure of type `T` is called as the first step. Then, the `Finalize` procedure is called for the components with an access discriminant constrained by a *per-object expression* (page 429) — in this case, `Sel_2` and `Sel_1` (of `Selection_2` and `Selection_1` types, respectively). Finally, the `Sub_1` component is finalized.

This diagram shows the finalization sequence:



101.1.5 Controlled Types and Exception Handling

In the previous section, we mainly focused on the normal completion of controlled types. However, when control is transferred out of the normal execution path due to an abort or an exception being raised, we speak of abnormal completion. In this section, we focus on those cases.

Let's start with a simple example:

Listing 44: simple_controlled_types.ads

```
1  with Ada.Finalization;
2
3  package Simple_Controlled_Types is
4
5     type T is tagged private;
6
7     procedure Dummy (E : T);
8
9  private
10
11    type T is new
12      Ada.Finalization.Controlled
13        with null record;
14
15    overriding
16    procedure Initialize (E : in out T);
17
```

(continues on next page)

(continued from previous page)

```
   overriding
   procedure Finalize (E : in out T);

end Simple_Controlled_Types;
```

Listing 45: simple_controlled_types.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Simple_Controlled_Types is

   procedure Dummy (E : T) is
   begin
      Put_Line ("(Dummy...)");
   end Dummy;

   procedure Initialize (E : in out T) is
   begin
      Put_Line ("Initialize...");
   end Initialize;

   procedure Finalize (E : in out T) is
   begin
      Put_Line ("Finalize...");
   end Finalize;

end Simple_Controlled_Types;
```

Listing 46: show_simple_exception.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Simple_Controlled_Types;
use  Simple_Controlled_Types;

procedure Show_Simple_Exception is
   A : T;

   function Int_Last return Integer is
     (Integer'Last);

   Cnt : Positive := Int_Last;
begin
   Cnt := Cnt + 1;

   Dummy (A);

   Put_Line (Cnt'Image);

   --  When A is about to get out of
   --  scope:
   --
   --  Finalize (A);
   --
end Show_Simple_Exception;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Exception_
 ↪Handling.Simple_Exception
MD5: 9461f420f091f058e6ea1ee419b2a5c6
```

Runtime output

```
Initialize...
Finalize...

raised CONSTRAINT_ERROR : show_simple_exception.adb:14 overflow check failed
```

In this example, we're forcing an overflow to happen in the `Show_Simple_Exception` by adding one to the integer variable `Cnt`, which already has the value `Integer'Last`. The corresponding *overflow check* (page 667) raises the `Constraint_Error`.

However, *before* this exception is raised, the finalization of the controlled object `A` is performed. In this sense, we have normal completion of the controlled type — even though an exception is being raised.

For further reading...

We already talked about the *allocation check* (page 671), which may raise a `Program_Error` exception. In the code example for that section, we used controlled types. Feel free to revisit the example.

Relevant topics

- Completion and Finalization[453]

Exception raising in Initialize

If an exception is raised in the `Initialize` procedure, we have abnormal completion. Let's see an example:

Listing 47: ct_initialize_exception.ads

```
1  with Ada.Finalization;
2
3  package CT_Initialize_Exception is
4
5     type T is tagged private;
6
7     procedure Dummy (E : T);
8
9  private
10
11    type T is new
12      Ada.Finalization.Controlled
13        with null record;
14
15    overriding
16    procedure Initialize (E : in out T);
17
18    overriding
19    procedure Finalize (E : in out T);
20
21 end CT_Initialize_Exception;
```

[453] http://www.ada-auth.org/standards/22rm/html/RM-7-6-1.html

Listing 48: ct_initialize_exception.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body CT_Initialize_Exception is

   function Int_Last return Integer is
     (Integer'Last);

   Cnt : Positive := Int_Last;

   procedure Dummy (E : T) is
   begin
      Put_Line ("(Dummy...)");
   end Dummy;

   procedure Initialize (E : in out T) is
   begin
      Put_Line ("Initialize...");
      Cnt := Cnt + 1;
   end Initialize;

   procedure Finalize (E : in out T) is
   begin
      Put_Line ("Finalize...");
   end Finalize;

end CT_Initialize_Exception;
```

Listing 49: show_initialize_exception.adb

```
with CT_Initialize_Exception;
use  CT_Initialize_Exception;

procedure Show_Initialize_Exception is
   A : T;
begin
   Dummy (A);
end Show_Initialize_Exception;
```

Code block metadata

```

 ↪Handling.CT_Initialize_Exception
MD5: 189a5fafafb01eba31a73c9237fa7aff
```

Runtime output

```
Initialize...

raised CONSTRAINT_ERROR : ct_initialize_exception.adb:18 overflow check failed
```

In the Show_Initialize_Exception procedure, we declare an object A of controlled type T. As we know, this declaration triggers a call to the Initialize procedure that we've implemented in the body of the CT_Initialize_Exception package. In the Initialize procedure, we're forcing an overflow to happen — by adding one to the Cnt variable, which already has the `Integer'Last` value.

This is an example of abnormal completion, as the control is transferred out of the Initialize procedure, and the corresponding Finalize procedure is never called for object A.

Bounded errors of controlled types

Bounded errors are an important topic when talking about exception and controlled types. In general, if an exception is raised in the `Adjust` or `Finalize` procedure, this is considered a bounded error. If the bounded error is detected, the `Program_Error` exception is raised.

Note that the original exception raised in the `Adjust` or `Finalize` procedures could be any possible exception. For example, one of those procedures could raise a `Constraint_Error` exception. However, the actual exception that is raised at runtime is the `Program_Error` exception. This is because the bounded error, which raises the `Program_Error` exception, is more severe than the original exception coming from those procedures.

(The behavior is different when the `Adjust` or `Finalize` procedure is called explicitly, as we'll see later.)

Not every exception raised during an operation on controlled types is considered a bounded error. In fact, the case we've seen before, an *exception raised in the Initialize procedure* (page 1855) is not a bounded error.

Here's a code example of a `Constraint_Error` exception being raised in the `Finalize` procedure:

Listing 50: ct_finalize_exception.ads

```
with Ada.Finalization;

package CT_Finalize_Exception is

   type T is tagged private;

   procedure Dummy (E : T);

   procedure Reset_Counter;

private

   type T is new
     Ada.Finalization.Controlled
       with null record;

   overriding
   procedure Initialize (E : in out T);

   overriding
   procedure Adjust (E : in out T);

   overriding
   procedure Finalize (E : in out T);

end CT_Finalize_Exception;
```

Listing 51: ct_finalize_exception.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body CT_Finalize_Exception is

   Cnt : Integer := Integer'Last;

   procedure Dummy (E : T) is
   begin
      Put_Line ("(Dummy...)");
```

(continues on next page)

(continued from previous page)

```
   end Dummy;

   procedure Initialize (E : in out T) is
   begin
      Put_Line ("Initialize...");
   end Initialize;

   overriding
   procedure Adjust (E : in out T) is
   begin
      Put_Line ("Adjust...");
   end Adjust;

   procedure Finalize (E : in out T) is
   begin
      Put_Line ("Finalize...");
      Cnt := Cnt + 1;
   end Finalize;

   procedure Reset_Counter is
   begin
      Cnt := 0;
   end Reset_Counter;

end CT_Finalize_Exception;
```

Listing 52: show_finalize_exception.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with CT_Finalize_Exception;
use  CT_Finalize_Exception;

procedure Show_Finalize_Exception is
   A, B : T;
begin
   Dummy (A);

   --  When A is about to get out of
   --  scope:
   --
   --  Finalize (A);
   --
end Show_Finalize_Exception;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Exception_
 ↪Handling.CT_Finalize_Exception
MD5: eacb64b0a9d68ce3484a3bda9b633495
```

Runtime output

```
Initialize...
Initialize...
(Dummy...)
Finalize...
Finalize...

raised PROGRAM_ERROR : show_finalize_exception.adb:6 finalize/adjust raised␣
 ↪exception
```

In this example, we're again forcing an overflow to happen (by adding one to the integer variable `Cnt`), this time in the `Finalize` procedure. When this procedure is implicitly called — when object `A` is about to get out of scope in the `Show_Finalize_Exception` procedure — the `Constraint_Error` exception is raised.

As we've just seen, having an exception be raised during an implicit call to the `Finalize` procedure is a bounded error. Therefore, we see that the `Program_Error` exception is raised at runtime instead of the original `Constraint_Error` exception.

As we hinted in the beginning, when the `Adjust` or the `Finalize` procedure is called *explicitly*, the exception raised in that procedure is *not* considered a bounded error. In this case, the original exception is raised.

To show an example of such an explicit call, let's first move the overriden procedures for type `T` (`Initialize`, `Adjust` and `Finalize`) out of the private part of the package `CT_Finalize_Exception`, so they are now visible to clients. This allows us to call the `Finalize` procedure explicitly:

Listing 53: ct_finalize_exception.ads

```
with Ada.Finalization;

package CT_Finalize_Exception is

   type T is new
     Ada.Finalization.Controlled
   with null record;

   overriding
   procedure Initialize (E : in out T);

   overriding
   procedure Adjust (E : in out T);

   overriding
   procedure Finalize (E : in out T);

   procedure Dummy (E : T);

   procedure Reset_Counter;

end CT_Finalize_Exception;
```

Listing 54: show_finalize_exception.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with CT_Finalize_Exception;
use  CT_Finalize_Exception;

procedure Show_Finalize_Exception is
   A : T;
begin
   Dummy (A);

   Finalize (A);

   Put_Line ("After Finalize");
exception
   when Constraint_Error =>
      Put_Line
        ("Constraint_Error is being handled...");
```

(continues on next page)

(continued from previous page)

```
18       Reset_Counter;
19 end Show_Finalize_Exception;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Controlled_Types.Exception_
 ↪Handling.CT_Finalize_Exception
MD5: f43133c997076c491a20117960be8807
```

Runtime output

```
Initialize...
(Dummy...)
Finalize...
Constraint_Error is being handled...
Finalize...
```

Now, we're calling the `Finalize` procedure explicitly in the `Show_Finalize_Exception` procedure. As we know, due to the operation on `I` in the `Finalize` procedure, the `Constraint_Error` exception is raised in the procedure. Because we're handling this exception in the `Show_Finalize_Exception` procedure, we see the corresponding user message ("Constraint_Error is being handled...") at runtime.

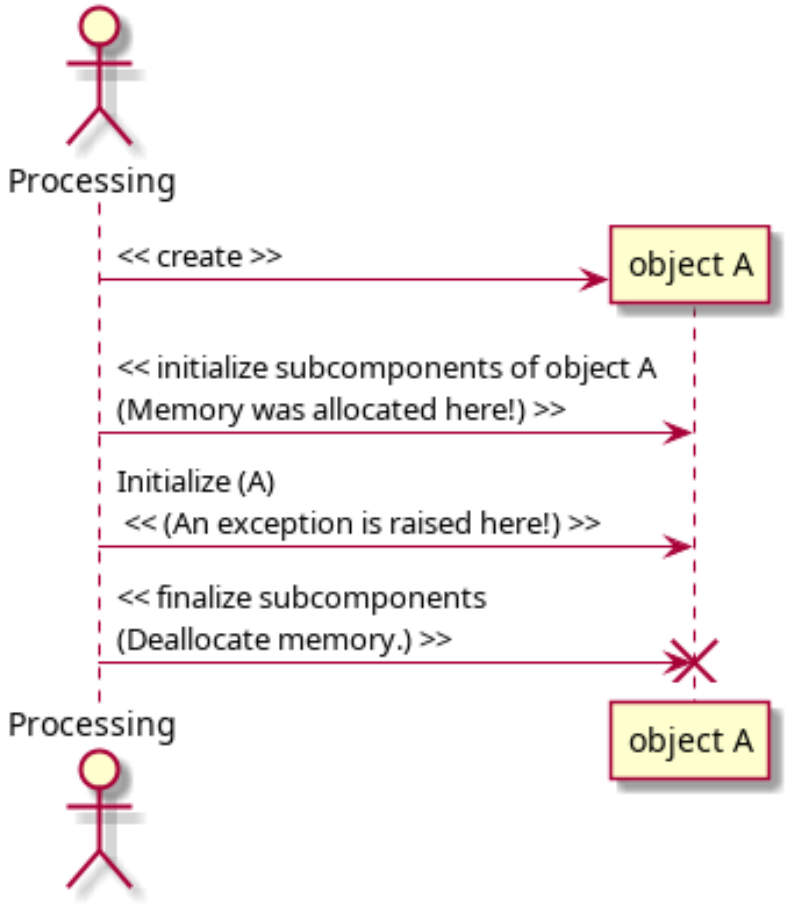
(Note that in the exception handling block, we're calling the `Reset_Counter` procedure. This prevents `Constraint_Error` from being raised in the next call to `Finalize`.)

Memory allocation and exceptions

When a memory block is allocated for controlled types and a bounded error occurs, there is no guarantee that this memory block will be deallocated. Roughly speaking, the compiler has the freedom — but not the obligation — to generate appropriate calls to `Finalize`, which may deallocate memory blocks.

For example, we've seen that *subcomponents of controlled type* (page 1828) of a controlled object `A` are initialized before the initialization of object `A` takes place. Because memory might have been allocated for the subcomponents, the compiler can insert code that attempts to finalize those subcomponents, which in turn deallocates the memory blocks (if they were allocated in the first place).

We can visualize this strategy in the following diagram:



This strategy (of finalizing subcomponents that haven't raised exceptions) prevents memory leaks. However, this behavior very much depends on the compiler implementation. The Ada Reference Manual[454] delineates (in the "Implementation Permissions" section) the cases where the compiler is allowed — but not required — to finalize objects when exceptions are raised.

Because the actual behavior isn't defined, custom implementation of `Adjust` and `Finalize` procedures for controlled types should be designed very carefully in order to avoid exceptions, especially when memory is allocated in the `Initialize` procedure.

101.1.6 Applications of Controlled Types

101.2 Memory Management

101.2.1 Maximum allocation size and alignment

We've seen details about the `Size` and `Object_Size` attributes in the section about *data representation* (page 349). *Later on* (page 353), we also mentioned the `Storage_Size` attribute.

In this section, we expand our discussion on sizes and talk about the `Max_Size_In_Storage_Elements` and the `Max_Alignment_For_Allocation` attributes. These attributes return values that are important in the allocation of *memory subpools* (page 1868) via the `Allocate` procedure from the `System.Storage_Pools` and the `System.Storage_Pools.Subpools` packages:

[454] http://www.ada-auth.org/standards/22rm/html/RM-7-6-1.html

```
procedure Allocate(
  Pool                     : in out Root_Storage_Pool;
  Storage_Address          :    out Address;
  Size_In_Storage_Elements :        Storage_Elements.Storage_Count;
  Alignment                :        Storage_Elements.Storage_Count);

procedure Allocate (
  Pool                     : in out Root_Storage_Pool_With_Subpools;
  Storage_Address          :    out Address;
  Size_In_Storage_Elements :        Storage_Elements.Storage_Count;
  Alignment                :        Storage_Elements.Storage_Count);
```

In fact, the `Max_Size_In_Storage_Elements` attribute indicates the maximum value that can be used for the actual `Size_In_Storage_Elements` parameter of the `Allocate` procedure . Likewise, the `Max_Alignment_For_Allocation` attribute indicates the maximum value for the actual `Alignment` parameter of the `Allocate` procedure. (We discuss more details about this procedure later on.)

The `Allocate` procedure is called when we allocate memory for access types. Therefore, the value returned by the `Max_Size_In_Storage_Elements` attribute for a subtype S indicates the maximum value of storage elements when allocating memory for an access type whose designated subtype is S, while the `Max_Alignment_For_Allocation` attribute indicates the maximum alignment that we can use when we allocate memory via the **new** allocator.

- 13.11.1 Storage Allocation Attributes[456]
- 13.11.4 Storage Subpools[457]

Code example with scalar type

Let's see a simple type T and two types based on it — an array and an access type:

Listing 55: custom_types.ads

```
1  package Custom_Types is
2
3     type T is new Integer;
4
5     type T_Array is
6       array (Positive range <>) of T;
7
8     type T_Access is access T;
9
10 end Custom_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Memory_Management.Max_Allocation_
 ↪Size_Alignment
MD5: cbe79faedd330bf7c3d1d75f8c1a5d7e
```

[455] http://www.ada-auth.org/standards/22rm/html/RM-13-11.html
[456] http://www.ada-auth.org/standards/22rm/html/RM-13-11-1.html
[457] http://www.ada-auth.org/standards/22rm/html/RM-13-11-4.html

The test procedure Show_Sizes shows the values returned by the Size, Max_Size_In_Storage_Elements, and Max_Alignment_For_Allocation attributes for the T type:

Listing 56: show_sizes.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with System;

with Custom_Types; use Custom_Types;

procedure Show_Sizes is
begin
   Put_Line
   ("T'Size:                                "
    & Integer'Image
        (T'Size
         / System.Storage_Unit)
    & " storage elements ("
    & T'Size'Image
    & " bits)");

   Put_Line
   ("T'Max_Size_In_Storage_Elements:        "
    & T'Max_Size_In_Storage_Elements'Image
    & " storage elements ("
    & Integer'Image
        (T'Max_Size_In_Storage_Elements
         * System.Storage_Unit)
    & " bits)");

   Put_Line
   ("T'Max_Alignment_For_Allocation:        "
    & T'Max_Alignment_For_Allocation'Image
    & " storage elements ("
    & Integer'Image
        (T'Max_Alignment_For_Allocation
         * System.Storage_Unit)
    & " bits)");

end Show_Sizes;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Memory_Management.Max_Allocation_
 ↪Size_Alignment
MD5: efefe17974e1feb04b1d32ff7d19db95
```

Runtime output

```
T'Size:                                4 storage elements ( 32 bits)
T'Max_Size_In_Storage_Elements:        4 storage elements ( 32 bits)
T'Max_Alignment_For_Allocation:        4 storage elements ( 32 bits)
```

On a typical desktop PC, you might get 4 storage elements (corresponding to 32 bits) as the value returned by these attributes.

In the original implementation of the Custom_Types package, we allowed the compiler to select the size of type T. We can be more specific in the type declarations and use the Size aspect for that type:

Listing 57: custom_types.ads

```
package Custom_Types is

   type T is new Integer
     with Size => 48;

   type T_Array is
     array (Positive range <>) of T;

   type T_Access is access T;

end Custom_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Memory_Management.Max_Allocation_
 ↪Size_Alignment
MD5: 1449cb6bf3a9c5863d999f354c6cea9b
```

Let's see how this change affects the `Size`, `Max_Size_In_Storage_Elements`, and `Max_Alignment_For_Allocation` attributes:

Listing 58: show_sizes.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with System;

with Custom_Types; use Custom_Types;

procedure Show_Sizes is
begin
   Put_Line
   ("T'Size:                                "
    & Integer'Image
        (T'Size
         / System.Storage_Unit)
    & " storage elements ("
    & T'Size'Image
    & " bits)");

   Put_Line
   ("T'Max_Size_In_Storage_Elements:        "
    & T'Max_Size_In_Storage_Elements'Image
    & " storage elements ("
    & Integer'Image
        (T'Max_Size_In_Storage_Elements
         * System.Storage_Unit)
    & " bits)");

   Put_Line
   ("T'Max_Alignment_For_Allocation:        "
    & T'Max_Alignment_For_Allocation'Image
    & " storage elements ("
    & Integer'Image
        (T'Max_Alignment_For_Allocation
         * System.Storage_Unit)
    & " bits)");

end Show_Sizes;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Memory_Management.Max_Allocation_
 ↪Size_Alignment
MD5: efefe17974e1feb04b1d32ff7d19db95
```

Runtime output

```
T'Size:                                 4 storage elements ( 32 bits)
T'Max_Size_In_Storage_Elements:         4 storage elements ( 32 bits)
T'Max_Alignment_For_Allocation:         4 storage elements ( 32 bits)
```

If the code compiles, you should see that T'Size now corresponds to 6 storage elements (i.e. 48 bits). On a typical desktop PC, the value of T'Max_Size_In_Storage_Elements and T'Max_Alignment_For_Allocation should have increased to 8 storage elements (64 bits).

Code example with array type

Note that using the Size and Max_Size_In_Storage_Elements attributes on array types can give you a potentially higher number:

Listing 59: show_sizes.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with System;

with Custom_Types; use Custom_Types;

procedure Show_Sizes is
begin
   Put_Line
   ("T_Array'Max_Size_In_Storage_Elements:  "
    & T_Array'Max_Size_In_Storage_Elements'Image
    & " storage elements ("
    & Long_Integer'Image
        (T_Array'Max_Size_In_Storage_Elements
         * System.Storage_Unit)
    & " bits)");

   Put_Line
   ("T_Array'Max_Alignment_For_Allocation:  "
    & T_Array'Max_Alignment_For_Allocation'Image
    & " storage elements ("
    & Integer'Image
        (T_Array'Max_Alignment_For_Allocation
         * System.Storage_Unit)
    & " bits)");

   Put_Line
   ("T_Array'Size:                         "
    & Long_Integer'Image
        (T_Array'Size
         / System.Storage_Unit)
    & " storage elements ("
    & T_Array'Size'Image
    & " bits)");

end Show_Sizes;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Memory_Management.Max_Allocation_
 ↪Size_Alignment
MD5: 1fa44ee368c280678b534efb74f2d14b
```

Runtime output

```
T_Array'Max_Size_In_Storage_Elements:   17179869184 storage elements (␣
 ↪137438953472 bits)
T_Array'Max_Alignment_For_Allocation:   16 storage elements ( 128 bits)
T_Array'Size:                           17179869176 storage elements (␣
 ↪137438953408 bits)
```

In this case, these values indicate the maximum amount of memory that is theoretically available for the array in the memory pool. This information allows us to calculate the (theoretical) maximum number of components for an array of this type:

Listing 60: show_sizes.adb

```
with Ada.Text_IO;  use Ada.Text_IO;
with System;

with Custom_Types; use Custom_Types;

procedure Show_Sizes is
begin

   Put_Line
   ("T_Array: Max. number of components:  "
    & Long_Integer'Image
        (T_Array'Max_Size_In_Storage_Elements /
          (T'Size
           / System.Storage_Unit))
    & " components");

end Show_Sizes;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Memory_Management.Max_Allocation_
 ↪Size_Alignment
MD5: 6461fb3e65486bbb92d4d63bff3baacd
```

Runtime output

```
T_Array: Max. number of components:   2863311530 components
```

By dividing the value returned by the `Max_Size_In_Storage_Elements` attribute with the size of each individual component, we can get the maximum number of components.

101.2.2 Storage elements

We saw parts of the `System.Storage_Elements` package while discussing *addresses* (page 401). However, we haven't discussed yet the main types from that package: `Storage_Element` and `Storage_Array`.

We defined *storage elements* (page 349) previously. In the `System.Storage_Elements` package, a storage element is represented by the `Storage_Element` type. Its size (`Storage_Element'Size`) is equal to `Storage_Unit` — which we also mentioned previously.

The `Storage_Array` type is an array type of storage elements. This is its definition:

```
type Storage_Array is
  array (Storage_Offset range <>) of
    aliased Storage_Element;
```

A storage array is used to represent a contiguous sequence of storage elements in memory. In other words, you can think of an object of `Storage_Array` type as a (memory) buffer.

Important

Note that arrays of `Storage_Array` type are guaranteed by the language to be contiguous. In contrast, storage pools are not required to be contiguous blocks of memory. However, each memory allocation in a storage pool returns a pointer to a contiguous block of memory.

Also, arrays in general are not guaranteed to be contiguous — apart from arrays of `Storage_Array` type, as we've just seen. In practice, however, if you're using a modern architecture, you most likely won't encounter an array that isn't allocated on a contiguous block. (You would perhaps see an array allocated on non-contiguous blocks when using an older architecture with segmented memory.)

For further reading

Note that the `Storage_Offset` is an integer type with a range defined by the compiler implementation. It's used not only in the definition of the `Storage_Array` but also in *address arithmetic* (page 407), which we discussed in an earlier chapter.

In fact, the `Storage_Array` is used in the generic `Storage_IO` package to define a memory buffer:

```
with System.Storage_Elements;
use  System.Storage_Elements;

subtype Buffer_Type is
  Storage_Array (1 .. Buffer_Size);
```

Let's see a simple example that makes use of the `Storage_IO` package:

Listing 61: show_storage_io.adb

```
1  pragma Ada_2022;
2
3  with Ada.Text_IO;    use Ada.Text_IO;
4  with Ada.Storage_IO;
5
6  procedure Show_Storage_IO is
7     type Rec is record
8        A, B : Integer;
9        C    : Float;
10    end record;
11
12    package Rec_Storage_IO is new
13      Ada.Storage_IO (Element_Type => Rec);
14    use Rec_Storage_IO;
15
16    Buf    : Buffer_Type;
17    R1, R2 : Rec;
18 begin
19    R1 := (1, 2, 3.0);
20    Put_Line ("R1 : " & R1'Image);
21
```

(continues on next page)

(continued from previous page)

```
22    --  Writing from R1 to the buffer Buf:
23    Write (Buf, R1);
24
25    --  Reading from the buffer Buf to R2:
26    Read (Buf, R2);
27
28    Put_Line ("R2 : " & R2'Image);
29 end Show_Storage_IO;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Resource_Management.Storage_Elements
MD5: b95cd5f7ce8175d527676f73c27c1bcc
```

Runtime output

```
R1 :
(A =>  1,
 B =>  2,
 C =>  3.00000E+00)
R2 :
(A =>  1,
 B =>  2,
 C =>  3.00000E+00)
```

In this example, we instantiate the `Storage_IO` package for the `Rec` type and declare a buffer `Buf` of `Buffer_Type` type. (Note that `Buf` is essentially an array of `Storage_Array` type.) We then use this buffer and write an element to it (via `Write`) and read from it (via `Read`).

101.3 Containers

101.3.1 `Aggregate` aspect

Note: This feature was introduced in Ada 2022.

In a previous chapter, we discussed *container aggregates* (page 435), which are commonly used with standard containers. If you look at the type declarations of the standard containers (in the `Ada.Containers` packages), you'll notice that some of them make use of the `Aggregate` aspect. This aspect is used to specify which subprograms are called to process a container aggregate for a data type, let's say a type named T. Suppose we declare an object `Obj` like this: `Obj : T := [1, 2, 3]`. In this case, the `Aggregate` aspect specifies which subprograms are going to be called to process the `[1, 2, 3]` aggregate.

The `Aggregate` aspect is used in many declarations of the `Ada.Containers` packages. However, this aspect isn't restricted to the standard containers: we may indeed use the `Aggregate` aspect to specify a custom container aggregate for any type other than an array. In this section, we discuss the elements of the `Aggregate` aspect and how to use this aspect to create your own container aggregates.

In the Ada Reference Manual

- Container Aggregates[464]

[462] http://www.ada-auth.org/standards/22rm/html/RM-13-11-4.html
[463] http://www.ada-auth.org/standards/22rm/html/RM-13-11-5.html
[464] http://www.ada-auth.org/standards/22rm/html/RM-4-3-5.html

Basic syntax

The Aggregate aspect has the following syntax:

```
type T is private
  with Aggregate =>
    (Empty          => Empty_Func,
     Add_Named      => Add_Named_Proc,
     Add_Unnamed    => Add_Unnamed_Proc,
     New_Indexed    => New_Indexed_Func,
     Assign_Indexed => Assign_Indexed_Proc);
```

Note that the order of the elements must be exactly as shown above.

Basically, there are three elements you can use in the Aggregate aspect to specify a procedure that is called when adding an element to the container: Add_Named, ada:*Add_Unnamed*, and Assign_Indexed.

Attention

Remember that an indexed aggregate has an index associated with each component. As discussed in the *section on container aggregates* (page 435),

- for indexed positional container aggregates, the index of each component is implied by its position;
- for indexed named container aggregates, the index of each component is explicitly indicated.

We discuss this topic later in more details.

Some restrictions apply to the Aggregate aspect. For example:

- we have to specify at least one of those elements (Add_Named, Add_Unnamed, or Assign_Indexed), and
- we cannot specify both Add_Named and Add_Unnamed elements at the same time.

We can, however, combine Add_Unnamed and Assign_Indexed in the same aspect declaration.

Classification

We can classify container aggregates in two categories:

- whether they are indexed or not; and
- whether they are positional or named.

This classification depends on the elements that were used in the declaration of the Aggregate aspect and whether a key is used in the aggregate. The following table presents the classification:

Indexed	Elements in Aggregate	Positional / named	Uses key	Container aggregate: example
No	Add_Named	Named	Yes	["Key_1" => "Hello", "Key_2" => "World"]
	Add_Unnamed	Positional	No	["Hello", "World"]
	Assign_Indexed Add_Unnamed			
Yes	Assign_Indexed Add_Unnamed	Named	Yes	[1 => "Hello", 2 => "World"]
	Assign_Indexed	Named	Yes	[1 => "Hello", 2 => "World"]
		Positional	No	["Hello", "World"]

The next table presents the typical use-cases:

Category	Typical use
Add_Named	Maps
Add_Unnamed	Lists, sets
Add_Unnamed Assign_Indexed	Vectors
Assign_Indexed	(none)

Before we discuss these approaches, let's first look at the Empty element.

Empty

The Empty element allows us to specify the behavior for an empty container, i.e. the simplest version of a container without any components.

Let's assume we a container type T for which we specify an Empty function in the Aggregate aspect, and we declare an object Obj : T. In this case, the Empty function is called in one of two scenarios:

- when we assign a null container to Obj — by writing Obj := []; — or
- when we assign a container with at least one component to Obj — for example: Obj := [1, 2];.

Let's see a complete code example:

Listing 62: custom_container_aggregates.ads

```
pragma Ada_2022;

package Custom_Container_Aggregates is

   type T is private
     with Aggregate =>
       (Empty     => Empty_Func,
        Add_Named => Add_Named_Proc);

   function Empty_Func return T;

   procedure Add_Named_Proc
     (Cont  : in out T;
      Key   :        String;
      Value :        String) is null;

```

(continues on next page)

(continued from previous page)

```
private

    type T is record
       Cnt : Natural;
    end record;

end Custom_Container_Aggregates;
```

Listing 63: custom_container_aggregates.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Custom_Container_Aggregates is

   function Empty_Func return T is
   begin
      Put_Line ("Calling Empty_Func");

      return (Cnt => 0);
   end Empty_Func;

end Custom_Container_Aggregates;
```

Listing 64: show_container_aggregate_empty.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

with Custom_Container_Aggregates;
use  Custom_Container_Aggregates;

procedure Show_Container_Aggregate_Empty is
   A : T;
begin
   Put_Line ("A := []");
   A := [];
end Show_Container_Aggregate_Empty;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Aggregates.Container_Aggregate_Empty
MD5: e80409d5a8e1f05f341e3ab39b0a79f3
```

Runtime output

```
A := []
Calling Empty_Func
```

In this example, we specify the `Empty` function for the `Aggregate` aspect of the container type T. (We also use the `Add_Unnamed` element. You can ignore it for the moment: we'll discuss it later on.)

The `A := []` statement in the `Show_Container_Aggregate_Empty` procedure calls `Empty_Func` — the function specified in the `Empty` element of the `Aggregate` aspect —, which returns an object of the container type T, which is then assigned to A. (You can confirm this by running this example and seeing the `Calling Empty_Func` message, which we included in the body of the `Empty_Func` function.)

We can also use a constant for the `Empty` element instead of a function:

Listing 65: custom_container_aggregates.ads

```
pragma Ada_2022;

package Custom_Container_Aggregates is

   type T is private
     with Aggregate =>
       (Empty     => Empty_Const,
        Add_Named => Add_Named_Proc);

   Empty_Const : constant T;

   procedure Add_Named_Proc
     (Cont  : in out T;
      Key   :        String;
      Value :        String) is null;

private

    type T is record
       Cnt : Natural;
    end record;

    Empty_Const : constant T := (Cnt => 0);

end Custom_Container_Aggregates;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Aggregates.Container_Aggregate_Empty_Const
MD5: 94033c4d5926065a0f23d57aca277ff5
```

Here, we simply assign `Empty_Const` when an actual `Empty` is needed.

In addition to this, we can specify a signed integer parameter — which indicates the number of components — for the `Empty` function:

Listing 66: custom_container_aggregates.ads

```
pragma Ada_2022;

package Custom_Container_Aggregates is

   type T is private
     with Aggregate =>
       (Empty       => Empty_Func,
        Add_Unnamed => Add_Unnamed_Proc);

   T_Len_Typical : constant := 10;

   function Empty_Func
     (Total : Integer := T_Len_Typical)
      return T;

   procedure Add_Unnamed_Proc
     (Cont : in out T;
      Item :        String) is null;

private

    type T is record
```

(continues on next page)

(continued from previous page)

```
       Cnt   : Natural;
       Total : Integer;
    end record;

end Custom_Container_Aggregates;
```

Listing 67: custom_container_aggregates.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Custom_Container_Aggregates is

   function Empty_Func
     (Total : Integer := T_Len_Typical)
      return T is
   begin
      Put_Line ("Calling Empty_Func ("
                & "Total => "
                & Total'Image & ")");

      return (Total => Total,
              Cnt   => 0);
   end Empty_Func;

end Custom_Container_Aggregates;
```

Listing 68: show_container_aggregate_empty.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

with Custom_Container_Aggregates;
use  Custom_Container_Aggregates;

procedure Show_Container_Aggregate_Empty is
   A : T;
begin
   Put_Line ("A := []");
   A := [];

   Put_Line ("A := [""Hello"", ""World""]");
   A := ["Hello", "World"];
end Show_Container_Aggregate_Empty;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Aggregates.Container_Aggregate_Empty
MD5: 7a1b49002b89ed524f09565984260e53
```

Runtime output

```
A := []
Calling Empty_Func (Total =>  0)
A := ["Hello", "World"]
Calling Empty_Func (Total =>  2)
```

In this example, we specify an Empty_Func function with an **Integer** parameter (for the Empty element of the Aggregate aspect).

The actual argument for the integer parameter of the Empty_Func function depends on the

number of elements we use in the container aggregate. In this specific example, when we write `A := []`, then `Empty_Func (0)` is called, whereas when we write `A := ["Hello", "World"]`, this results in a call to `Empty_Func (2)`.

Add_Named

The `Add_Named` element of the `Aggregate` aspect refers to a procedure that is called when we have a named container aggregate — i.e. a container aggregate with components in the `Key => Value` form — that doesn't use indexing.

Note that, when we specify the `Add_Named` element, we cannot specify any of these elements: `Add_Unnamed`, `New_Indexed` or `Assign_Indexed`. In other words, when we specify the `Add_Named` element, we can only use the `Empty` element in the same declaration.

Listing 69: custom_container_aggregates.ads

```
pragma Ada_2022;

package Custom_Container_Aggregates is

   type T is private
     with Aggregate =>
       (Empty     => Empty_Func,
        Add_Named => Add_Named_Proc);

   T_Len_Typical : constant := 10;

   function Empty_Func
     (Total : Integer := T_Len_Typical)
      return T;

   procedure Add_Named_Proc
     (Cont  : in out T;
      Key   :        String;
      Value :        String);

private

    type T is record
       Total : Integer;
       Cnt   : Natural;
    end record;

end Custom_Container_Aggregates;
```

Listing 70: custom_container_aggregates.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Custom_Container_Aggregates is

   function Empty_Func
     (Total : Integer := T_Len_Typical)
      return T is
   begin
      Put_Line ("Calling Empty_Func ("
                & "Total => "
                & Total'Image & ")");

      return (Total => Total,
```

(continues on next page)

(continued from previous page)

```
               Cnt   => 0);
   end Empty_Func;

   procedure Add_Named_Proc
     (Cont  : in out T;
      Key   :        String;
      Value :        String) is
   begin
      Put_Line ("Calling Add_Named_Proc (Anon, "
                & "Key => """
                & Key   & """, "
                & "Value => """
                & Value & """)");
   end Add_Named_Proc;

end Custom_Container_Aggregates;
```

Listing 71: show_named_container_aggregate.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

with Custom_Container_Aggregates;
use  Custom_Container_Aggregates;

procedure Show_Named_Container_Aggregate is
   A : T;
begin
   Put_Line ("A := []");
   A := [];

   Put_Line ("A := [""Key_1"" => ""Hello"", "
             &     """Key_2"" => ""World""]");
   A := ["Key_1" => "Hello",
         "Key_2" => "World"];

end Show_Named_Container_Aggregate;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Aggregates.Container_Aggregate_Named
MD5: c188cc332a81814b1e3d56119904f3f8
```

Runtime output

```
A := []
Calling Empty_Func (Total =>  0)
A := ["Key_1" => "Hello", "Key_2" => "World"]
Calling Empty_Func (Total =>  2)
Calling Add_Named_Proc (Anon, Key => "Key_1", Value => "Hello")
Calling Add_Named_Proc (Anon, Key => "Key_2", Value => "World")
```

When we write `A := []`, we're just calling `Empty_Func (0)` — as we're using a null container aggregate, there are no components to be added to the container. However, when we write `A := ["Key_1" => "Hello", "Key_2" => "World"]`, we see the following calls:

- a call to `Empty_Func (2)` that creates an empty container with two components;
- a call to `Add_Named_Proc (Anon, "Key_1", "Hello")` for the first component, and
- a call to `Add_Named_Proc (Anon, "Key_2", "World")` for the second component.

The Anon argument in the calls above indicates that an anonymous object is first created and then assigned to A.

Add_Unnamed

The Add_Unnamed element of the Aggregate aspect refers to a procedure that is called when we have a positional container aggregate.

Let's look at an example:

Listing 72: custom_container_aggregates.ads

```
pragma Ada_2022;

package Custom_Container_Aggregates is

   type T is private
     with Aggregate =>
       (Empty       => Empty_Func,
        Add_Unnamed => Add_Unnamed_Proc);

   T_Len_Typical : constant := 10;

   function Empty_Func
     (Total : Integer := T_Len_Typical)
      return T;

   procedure Add_Unnamed_Proc
     (Cont : in out T;
      Item :        String);

private

    type T is record
       Total : Integer;
       Cnt   : Natural;
    end record;

end Custom_Container_Aggregates;
```

Listing 73: custom_container_aggregates.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Custom_Container_Aggregates is

   function Empty_Func
     (Total : Integer := T_Len_Typical)
      return T is
   begin
      Put_Line ("Calling Empty_Func ("
                & "Total => "
                & Total'Image & ")");

      return (Total => Total,
              Cnt   => 0);
   end Empty_Func;

   procedure Add_Unnamed_Proc
     (Cont : in out T;
      Item :        String) is
```

(continues on next page)

(continued from previous page)

```
   begin
      Put_Line ("Calling Add_Unnamed_Proc (Anon, "
                & "Item => """
                & Item & """)");
   end Add_Unnamed_Proc;

end Custom_Container_Aggregates;
```

Listing 74: show_unnamed_container_aggregate.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

with Custom_Container_Aggregates;
use  Custom_Container_Aggregates;

procedure Show_Unnamed_Container_Aggregate is
   A : T;
begin
   Put_Line ("A := []");
   A := [];

   Put_Line ("A := [""Hello"", ""World""]");
   A := ["Hello", "World"];
end Show_Unnamed_Container_Aggregate;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Aggregates.Container_Aggregate_Unnamed
MD5: d1d7e67630d7b2831ebe07738f949be9
```

Runtime output

```
A := []
Calling Empty_Func (Total =>  0)
A := ["Hello", "World"]
Calling Empty_Func (Total =>  2)
Calling Add_Unnamed_Proc (Anon, Item => "Hello")
Calling Add_Unnamed_Proc (Anon, Item => "World")
```

The `A := ["Hello", "World"]` statement from the code above generates the following calls:

- a call to `Empty_Func (2)` that creates an empty container with two components;
- a call to `Add_Unnamed_Proc (Anon, "Hello")` for the first component, and
- a call to `Add_Unnamed_Proc (Anon, "World")` for the second component.

Assign_Indexed

The Assign_Indexed element of the Aggregate aspect refers to a procedure that is called when we have an indexed container aggregate. Note that, when we specify the Assign_Indexed element, we must also use the New_Indexed element in the same aspect declaration.

Let's look at an example:

Listing 75: custom_container_aggregates.ads

```
pragma Ada_2022;

package Custom_Container_Aggregates is

   type T is private
     with Aggregate =>
       (Empty          => Empty_Func,
        New_Indexed    => New_Indexed_Func,
        Assign_Indexed => Assign_Indexed_Proc);

   T_Len_Typical : constant := 10;

   function Empty_Func
     (Total : Integer := T_Len_Typical)
      return T;

   function New_Indexed_Func
     (First, Last : Positive)
      return T
     with Pre => First = Positive'First;

   procedure Assign_Indexed_Proc
     (Cont  : in out T;
      Index :        Positive;
      Item  :        String);

private

    type T is record
       Total : Integer;
       Cnt   : Natural;
    end record;

end Custom_Container_Aggregates;
```

Listing 76: custom_container_aggregates.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Custom_Container_Aggregates is

   function Empty_Func
     (Total : Integer := T_Len_Typical)
      return T is
   begin
      Put_Line
        ("Calling Empty_Func ("
         & "Total => " & Total'Image & ")");

      return (Total => Total,
              Cnt   => 0);
```

(continues on next page)

(continued from previous page)

```
   end Empty_Func;

   function New_Indexed_Func
     (First, Last : Positive)
      return T is
   begin
      Put_Line
        ("Calling New_Indexed_Func ("
         & "First => " & First'Image & ", "
         & "Last  => " & Last'Image & ")");

      return (Total => Last - First + 1,
              Cnt   => 0);
   end New_Indexed_Func;

   procedure Assign_Indexed_Proc
     (Cont  : in out T;
      Index :        Positive;
      Item  :        String)
   is
      pragma Unreferenced (Cont);
   begin
      Put_Line
        ("Calling Assign_Indexed_Proc (Anon, "
         & "Index => "   & Index'Image & ", "
         & "Item  => """ & Item & """)");

   end Assign_Indexed_Proc;

end Custom_Container_Aggregates;
```

Listing 77: show_indexed_container_aggregate.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

with Custom_Container_Aggregates;
use  Custom_Container_Aggregates;

procedure Show_Indexed_Container_Aggregate is
   A : T;
begin
   Put_Line ("A := []");
   A := [];

   Put_Line ("A := [""Hello"", ""World""]");
   A := ["Hello", "World"];

   Put_Line ("A := [1 => ""Hello"", "
             &     "2 => ""World""]");
   A := [1 => "Hello", 2 => "World"];

   Put_Line ("A := [1 => ""Hello"", "
             &     "2 => <>, "
             &     "3 => ""World""]");
   A := [1 => "Hello", 2 => <>, 3 => "World"];

end Show_Indexed_Container_Aggregate;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Aggregates.Container_Aggregate_Indexed
MD5: 62e341098594f4e4900efb2c44394002
```

Runtime output

```
A := []
Calling Empty_Func (Total =>  0)
A := ["Hello", "World"]
Calling Empty_Func (Total =>  2)
A := [1 => "Hello", 2 => "World"]
Calling New_Indexed_Func (First =>  1, Last  =>  2)
Calling Assign_Indexed_Proc (Anon, Index =>  1, Item  => "Hello")
Calling Assign_Indexed_Proc (Anon, Index =>  2, Item  => "World")
A := [1 => "Hello", 2 => <>, 3 => "World"]
Calling New_Indexed_Func (First =>  1, Last  =>  3)
Calling Assign_Indexed_Proc (Anon, Index =>  1, Item  => "Hello")
Calling Assign_Indexed_Proc (Anon, Index =>  3, Item  => "World")
```

The `A := [1 => "Hello", 2 => "World"]` statement from the code above generates the following calls:

- a call to `New_Indexed_Func (First => 1, Last => 2)` that creates an empty container with two components (where the first index of the container is 1 and the last index is 2);
- a call to `Assign_Indexed_Proc (Anon, 1, "Hello")` for the first component (which is stored at the position with index 1), and
- a call to `Assign_Indexed_Proc (Anon, 2, "World")` for the second component (which is stored at the position with index 2).

Note that, in the case of indexed aggregates, the `New_Indexed_Func` function is called instead of the `Empty` function.

For indexed aggregates, we can use the <> syntax for individual components. In the code above, we use it in the `A := [1 => "Hello", 2 => <>, 3 => "World"]` statement, which generates the following calls:

- a call to `New_Indexed_Func (First => 1, Last => 3)` that creates an empty container with three components (where the first index of the container is 1 and the last index is 3);
- a call to `Assign_Indexed_Proc (Anon, 1, "Hello")` for the first component, and
- a call to `Assign_Indexed_Proc (Anon, 3, "World")` for the third component.

In other words, the `2 => <>` element from the statement allows us to allocate a container with more components than we assign to. (There's no assignment happening at index 2 in the aggregate above: it'll have the default value or remain uninitialized.)

Combining `Add_Named` and `Assign_Indexed`

As mentioned previously, we may specify both `Add_Named` and `Assign_Indexed` elements together in the same aspect declaration. For example:

Listing 78: custom_container_aggregates.ads

```
1  pragma Ada_2022;
2
3  package Custom_Container_Aggregates is
4
5     type T is private
```

(continues on next page)

(continued from previous page)

```
     with Aggregate =>
       (Empty          => Empty_Func,
        Add_Unnamed    => Add_Unnamed_Proc,
        New_Indexed    => New_Indexed_Func,
        Assign_Indexed => Assign_Indexed_Proc);

   T_Len_Typical : constant := 10;

   function Empty_Func
     (Total : Integer := T_Len_Typical)
      return T;

   procedure Add_Unnamed_Proc
     (Cont : in out T;
      Item :        String);

   function New_Indexed_Func
     (First, Last : Positive)
      return T
     with Pre => First = Positive'First;

   procedure Assign_Indexed_Proc
     (Cont  : in out T;
      Index :        Positive;
      Item  :        String);

private

    type T is record
       Total : Integer;
       Cnt   : Natural;
    end record;

end Custom_Container_Aggregates;
```

Listing 79: custom_container_aggregates.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Custom_Container_Aggregates is

   function Empty_Func
     (Total : Integer := T_Len_Typical)
      return T is
   begin
      Put_Line ("Calling Empty_Func ("
                & "Total => "
                & Total'Image & ")");

      return (Total => Total,
              Cnt   => 0);
   end Empty_Func;

   procedure Add_Unnamed_Proc
     (Cont : in out T;
      Item :        String) is
   begin
      Put_Line ("Calling Add_Unnamed_Proc (Anon, "
                & "Item => """ & Item & """)");
   end Add_Unnamed_Proc;

```

(continues on next page)

(continued from previous page)

```
   function New_Indexed_Func
     (First, Last : Positive)
      return T is
   begin
      Put_Line
        ("Calling New_Indexed_Func ("
         & "First => " & First'Image & ", "
         & "Last  => " & Last'Image & ")");

      return (Total => Last - First + 1,
              Cnt   => 0);
   end New_Indexed_Func;

   procedure Assign_Indexed_Proc
     (Cont  : in out T;
      Index :        Positive;
      Item  :        String)
   is
      pragma Unreferenced (Cont);
   begin
      Put_Line
        ("Calling Assign_Indexed_Proc (Anon, "
         & "Index => "   & Index'Image & ", "
         & "Item  => """ & Item & """)");

   end Assign_Indexed_Proc;

end Custom_Container_Aggregates;
```

Listing 80: show_unnamed_indexed_container_aggregate.adb

```
pragma Ada_2022;

with Ada.Text_IO; use Ada.Text_IO;

with Custom_Container_Aggregates;
use  Custom_Container_Aggregates;

procedure Show_Unnamed_Indexed_Container_Aggregate
is
   A : T;
begin
   Put_Line ("A := []");
   A := [];

   Put_Line ("A := [""Hello"", ""World""]");
   A := ["Hello", "World"];

   Put_Line
     ("A := [1 => ""Hello"", 2 => ""World""]");
   A := [1 => "Hello", 2 => "World"];
end Show_Unnamed_Indexed_Container_Aggregate;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Aggregates.Container_Aggregate_Unnamed_Indexed
MD5: 91a2a40f752f1d7cb6f696c6925ed437
```

Runtime output

```
A := []
Calling Empty_Func (Total =>  0)
A := ["Hello", "World"]
Calling Empty_Func (Total =>  2)
Calling Add_Unnamed_Proc (Anon, Item => "Hello")
Calling Add_Unnamed_Proc (Anon, Item => "World")
A := [1 => "Hello", 2 => "World"]
Calling New_Indexed_Func (First =>  1, Last  =>  2)
Calling Assign_Indexed_Proc (Anon, Index =>  1, Item  => "Hello")
Calling Assign_Indexed_Proc (Anon, Index =>  2, Item  => "World")
```

Now, the subprogram calls depend on whether the container aggregate is positional or not:

- for positional aggregates (e.g.: `["Hello", "World"]`), the `Add_Unnamed` element is used; while
- for named aggregates (`[1 => "Hello", 2 => "World"]`), the `New_Indexed` / `Assign_Indexed` elements are used.

CHAPTER

TWO

ABSTRACTION-ORIENTED PROGRAMMING

102.1 Strong typing

In this chapter, we discuss the advantages of strong typing and how it can be used to avoid common implementation and maintenance issues.

102.1.1 Type-based security

Note: This section was originally written by Yannick Moy and published as Gem #82: Type-Based Security 1[480] and Gem #83: Type-Based Security 2[481].

The notions of tainted data and trusted data usually refer to data coming from the user vs. data coming from the application. Tainting is viral, in that any result of a computation where one of the operands is tainted becomes tainted too.

Various C/C++ static analyzers provide checkers for tainted data that help find bugs where data from the user serves to compute the size of an allocation, so that an attacker could use this to trigger a buffer overflow leading to an Elevation of Privilege (EoP) attack.

In Ada, the compiler can provide the guarantee that no such bugs have been introduced by accident (although you can still bypass the rule if you really want to, for example by using `Unchecked_Conversion` or address clause overlays), provided different types are used for tainted and trusted data, with no run-time penalty. This can be done with many types of data, including basic types like integers.

Let's say tainted data is of an integer type. The basic idea is to derive the trusted type from the tainted one, and to provide a function Value to get to the raw data inside a trusted value, like the following:

Listing 1: taint.ads

```
package Taint is

   type Trusted_Value is new Integer;

   function Value (V : Trusted_Value)
                   return Integer;
   pragma Inline (Value);

end Taint;
```

Code block metadata

[480] https://www.adacore.com/gems/gem-82
[481] https://www.adacore.com/gems/gem-83

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Type-Based_
 ↪Security.Taint
MD5: 5a46d00754a8f0a28d80e97a42743d08
```

Notice that the implementation of `Value` is just a type conversion:

Listing 2: taint.adb

```
package body Taint is

   function Value (V : Trusted_Value)
                   return Integer is
   begin
      return Integer (V);
   end Value;

end Taint;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Type-Based_
 ↪Security.Taint
MD5: 0392cf215f862eee3ce27a8ee0aaee10
```

Then, make sure the sensitive program uses trusted data:

Listing 3: sensitive.adb

```
with Taint; use Taint;

procedure Sensitive (X : Trusted_Value) is
begin
   null; --  Do something sensitive with value X
end Sensitive;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Type-Based_
 ↪Security.Taint
MD5: d92c7ff8cc73969c0e6c64c44e17992e
```

Let's try to pass in data from the user to the sensitive program:

Listing 4: main.adb

```
with Taint;
with Sensitive;

procedure Main is

   procedure Bad (Some_Value : Integer) is
   begin
      Sensitive (Some_Value);
   end Bad;

   A : Integer := 0;
begin
   Bad (A);
end Main;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Type-Based_
 ↪Security.Taint
MD5: d16afa87546274c5b097bd7927e5be08
```

Build output

```
main.adb:8:18: error: expected type "Trusted_Value" defined at taint.ads:3
main.adb:8:18: error: found type "Standard.Integer"
gprbuild: *** compilation phase failed
```

The compiler returns with a type error.

Now, this does not prevent us from doing useful computations on trusted data as easily as on tainted data, including initialization with literals, case statements, array indexing, etc.

Listing 5: main.adb

```
with Taint; use Taint;
with Sensitive;

procedure Main is
   Max_Value : constant := 100;
   X : Trusted_Value := Max_Value;
begin
   X := X + 1; --  Perform any computations on X
   Sensitive (X);
end Main;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Type-Based_
 ↪Security.Taint
MD5: 7b1616c22955890ecaa7ce2da32c27f8
```

Because `Trusted_Value` is a type derived from the tainted type (**`Integer`**), all operations allowed on tainted data are also allowed on trusted data, but operations mixing them are not allowed.

Be aware that nothing prevents the program itself from converting between tainted data and trusted data freely, but this requires inserting an explicit conversion, which can be spotted during code reviews.

To completely prevent such unintended conversions (say, to facilitate maintenance), the type used for trusted data must be made private, so that only the package which defines it can convert to and from it. With `Trusted_Value` being private, we should also provide a corresponding function for each literal which we used previously, as well as the operations that we'd like to allow on trusted values (note that for efficiency all operations could be inlined):

Listing 6: taint.ads

```
package Taint is

   type Trusted_Value is private;

   function Value (V : Trusted_Value)
                   return Integer;

   function Trusted_1 return Trusted_Value;
   function Trusted_100 return Trusted_Value;

   function "+" (V, W : Trusted_Value)
```

(continues on next page)

(continued from previous page)

```
                  return Trusted_Value;

private

   type Trusted_Value is new Integer;

end Taint;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Type-Based_
 ↪Security.Taint_2
MD5: bb77e6a30cc8e9c4a30414af02caa696
```

The new implementation is as expected:

Listing 7: taint.adb

```
package body Taint is

   function Value (V : Trusted_Value)
                   return Integer is
   begin
      return Integer (V);
   end Value;

   function Trusted_1 return Trusted_Value is
   begin
      return 1;
   end Trusted_1;

   function Trusted_100 return Trusted_Value is
   begin
      return 100;
   end Trusted_100;

   function "+" (V, W : Trusted_Value)
                  return Trusted_Value is
   begin
      return Trusted_Value (Integer (V) +
                            Integer (W));
   end "+";

end Taint;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Type-Based_
 ↪Security.Taint_2
MD5: a7eabc491583d0629ee81bdd647beee2
```

Of course, the client now needs to be adapted to this new interface:

Listing 8: sensitive.ads

```
with Taint; use Taint;
procedure Sensitive (X : Trusted_Value);
```

Listing 9: sensitive.adb

```
procedure Sensitive (X : Trusted_Value) is
begin
   --  Missing implementation!
   null;
end Sensitive;
```

Listing 10: good.adb

```
with Taint; use Taint;
with Sensitive;

procedure Good is
   X : Trusted_Value := Trusted_100;
begin
   X := X + Trusted_1;
   --  ^^^^^^^^^^^^^^^
   --  Perform any computations on X

   Sensitive (X);
end Good;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Type-Based_
 ↪Security.Taint_2
MD5: 683125f5583015950d5a132f52b6d765
```

That's it! No errors can result in tainted data being accidentally passed by the user where trusted data is expected, and future maintainers of the code won't be tempted to insert conversions when the compiler complains.

Input validation consists of checking a set of properties on the input which guarantee it is well-formed. This usually involves excluding a set of ill-formed inputs (black-list) or matching the input against an exhaustive set of well-formed patterns (white-list).

Here, we consider the task of validating an input for inclusion in an SQL command. This is a well-known defense against SQL injection attacks, where an attacker passes in a specially crafted string that is interpreted as a command rather than a plain string when executing the initial SQL command.

The basic idea is to define a new type `SQL_Input` derived from type **`String`**. Function `Validate` checks that the input is properly validated and fails if not. Function `Valid_String` returns the raw data inside a validated string, as follows:

Listing 11: inputs.ads

```
package Inputs is

   type SQL_Input is new String;

   function Validate (Input : String)
                      return SQL_Input;

   function Valid_String (Input : SQL_Input)
                          return String;

end Inputs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Type-Based_
 ↪Security.SQL_Input
MD5: aca2687ec652789bc1d2505710e4f50e
```

The implementation of `Validate` simply checks that the input string does not contain a dangerous character before returning it as an `SQL_Input`, while `Valid_String` is a simple type conversion:

Listing 12: inputs.adb

```
with Ada.Strings.Fixed; use Ada.Strings.Fixed;
with Ada.Strings.Maps;  use Ada.Strings.Maps;

package body Inputs is

   Dangerous_Characters : constant
     Character_Set := To_Set ("""*^';&><</");

   function Validate (Input : String)
                      return SQL_Input is
   begin
      if Index (Input,
                Dangerous_Characters) /= 0
      then
         raise Constraint_Error
           with "Invalid input "
                & Input
                & " for an SQL query ";
      else
         return SQL_Input (Input);
      end if;
   end Validate;

   function Valid_String (Input : SQL_Input)
                          return String is
   begin
      return String (Input);
   end Valid_String;

end Inputs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Type-Based_
 ↪Security.SQL_Input
MD5: c3ececc362deece290fb28490ae1a10b
```

Now, this does not prevent future uses of such type conversions in the program, whether malicious or unintended. To guard against such possibilities, we must make type `SQL_Input` private. To make sure we do not ourselves inadvertently convert an input string into a valid one in the implementation of package `Inputs`, we use this opportunity to make `SQL_Input` a discriminated record parameterized by the validation status.

Listing 13: inputs.ads

```
with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

package Inputs is

   type SQL_Input (<>) is private;
```

(continues on next page)

(continued from previous page)

```
7
8     function Validate (Input : String)
9                        return SQL_Input;
10
11    function Valid_String (Input : SQL_Input)
12                           return String;
13
14    function Is_Valid (Input : SQL_Input)
15                       return Boolean;
16
17 private
18
19    type SQL_Input (Validated : Boolean) is
20       record
21          case Validated is
22             when True =>
23                Valid_Input : Unbounded_String;
24             when False =>
25                Raw_Input   : Unbounded_String;
26          end case;
27       end record;
28
29 end Inputs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Type-Based_
 ↪Security.SQL_Input
MD5: 2a88112a61c5161ea30cbb0d4d4c13c0
```

Each time we access field `Valid_Input`, a discriminant check will be performed to ensure that the operand of type `SQL_Input` has been validated. Observe the use of `Unbounded_String` for the type of the input component, which is more convenient and flexible than using a constrained string.

Note in the implementation of `Validate`, that instead of raising an exception when the string cannot be validated, as in the first implementation, here we create corresponding validated or invalid input values based on the result of the check against dangerous characters. Also, an `Is_Valid` function has been added to allow clients to query validity of an `SQL_Input` value.

Listing 14: inputs.adb

```
1  with Ada.Strings.Fixed; use Ada.Strings.Fixed;
2  with Ada.Strings.Maps;  use Ada.Strings.Maps;
3
4  package body Inputs is
5
6     Dangerous_Characters : constant
7       Character_Set := To_Set ("""*^';&><</");
8
9     function Validate (Input : String)
10                       return SQL_Input is
11       Local_Input : constant Unbounded_String :=
12                       To_Unbounded_String (Input);
13    begin
14       if Index (Input,
15                 Dangerous_Characters) /= 0
16       then
17          return (Validated   => False,
18                  Raw_Input   => Local_Input);
```

(continues on next page)

(continued from previous page)

```
      else
         return (Validated   => True,
                 Valid_Input => Local_Input);
      end if;
   end Validate;

   function Valid_String (Input : SQL_Input)
                          return String is
   begin
      return To_String (Input.Valid_Input);
   end Valid_String;

   function Is_Valid (Input : SQL_Input)
                      return Boolean is
   begin
      return Input.Validated;
   end Is_Valid;

end Inputs;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Type-Based_
 ↪Security.SQL_Input
MD5: e2de53064d55ebf1de479991a5043e63
```

That's it! As long as this interface is used, no errors can result in improper input being interpreted as a command, while ensuring that future maintainers of the code won't inadvertently be able to insert inappropriate conversions.

Of course, this minimal interface does not really provide anything other than the validation of the input. Simply having an `Is_Valid` function to tell whether a string is valid input data would seem to give you much the same functionality. However, you can now safely extend this package with additional capabilities, such as transformations on valid SQL inputs (for example, to optimize queries before sending them to the database), or to resolve queries faster using a local cache, and so forth. By using the private encapsulation, you are guaranteed that no client package will tamper with the validity of the SQL inputs you are manipulating.

Incidentally, the similar but distinct problem of input sanitization, where possibly invalid data is transformed into something that is known valid prior to use, can be handled in the same way.

102.1.2 Example: Table access

In this section, we discuss an application that accesses a two-dimensional table. We first look into a typical implementation, and then discuss how to improve it with better use of strong typing.

Typical implementation

Let's look at an application that declares a two-dimensional lookup table, retrieves a value from it an displays this value.

Listing 15: show_tab_access.adb

```
with Ada.Text_IO; use  Ada.Text_IO;

procedure Show_Tab_Access is

   Tab : array (1 .. 5, 1 .. 10) of Float
     := ((0.50, 0.73, 0.22, 0.66, 0.64,
          0.20, 0.73, 0.22, 0.66, 0.64),
         (0.60, 0.23, 0.56, 0.27, 0.72,
          0.36, 0.27, 0.18, 0.18, 0.08),
         (0.20, 0.56, 0.74, 0.43, 0.72,
          0.19, 0.46, 0.45, 0.25, 0.49),
         (0.75, 0.88, 0.29, 0.08, 0.17,
          0.96, 0.23, 0.83, 0.89, 0.97),
         (0.18, 0.97, 0.82, 0.86, 0.96,
          0.24, 0.84, 0.83, 0.14, 0.26));

   X, Y : Positive;
   V    : Float;

begin
   X := 1;
   Y := 5;
   V := Tab (X, Y);

   Put_Line (Float'Image (V));
end Show_Tab_Access;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Example_
 ↪Table_Access.Table_Access_1
MD5: f0c5a6456c98568edcb89916da15dd3e
```

Runtime output

```
 6.40000E-01
```

In this application, we use X and Y as indices to access the Tab table. We store the value in V and display it.

In principle, there is nothing wrong with this implementation. Also, we're already making use of strong typing here, since accessing an invalid position of the array (say `Tab (6, 25)`) raises an exception. However, in this application, we're assuming that X always refers to the first dimension, while Y refers to the second dimension. What happens, however, if we write `Tab (Y, X)`? In the application above, this would still work because `Tab (5, 1)` is in the table's range. Even though this works fine here, it's not the expected behavior. In the next section, we'll look into strategies to make better use of strong typing to avoid this problem.

One could argue that the problem we've just described doesn't happen to competent developers, who are expected to be careful. While this might be true for the simple application we're discussing here, complex systems can be much more complicated to understand: they might include multiple tables and multiple indices for example. In this case, even competent developers might make use of wrong indices to access tables. Fortunately, Ada provides means to avoid this problem.

Using stronger typing

In the example above, we make use of the **Positive** type, which is already a constrained type: we're avoiding accessing the Tab table using an index with negative values or zero. But we still may use indices that are out-of-range in the positive range, or switch the indices, as in the `Tab (Y, X)` example we mentioned previously. These problems can be avoided by defining range types for each dimension. This is the updated implementation:

Listing 16: show_tab_access.adb

```
with Ada.Text_IO; use  Ada.Text_IO;

procedure Show_Tab_Access is

   type X_Range is range 1 .. 5;
   type Y_Range is range 1 .. 10;

   Tab : array (X_Range, Y_Range) of Float
     := ((0.50, 0.73, 0.22, 0.66, 0.64,
          0.20, 0.73, 0.22, 0.66, 0.64),
         (0.60, 0.23, 0.56, 0.27, 0.72,
          0.36, 0.27, 0.18, 0.18, 0.08),
         (0.20, 0.56, 0.74, 0.43, 0.72,
          0.19, 0.46, 0.45, 0.25, 0.49),
         (0.75, 0.88, 0.29, 0.08, 0.17,
          0.96, 0.23, 0.83, 0.89, 0.97),
         (0.18, 0.97, 0.82, 0.86, 0.96,
          0.24, 0.84, 0.83, 0.14, 0.26));

   X : X_Range;
   Y : Y_Range;
   V : Float;

begin
   X := 1;
   Y := 5;
   V := Tab (X, Y);

   Put_Line (Float'Image (V));
end Show_Tab_Access;
```

Code block metadata

```

```

Runtime output

```
 6.40000E-01
```

Now, we not only avoid mistakes like `Tab (Y, X)`, but we also detect them at compile time! This might decrease development time, since we don't need to run the application in order to check for those issues.

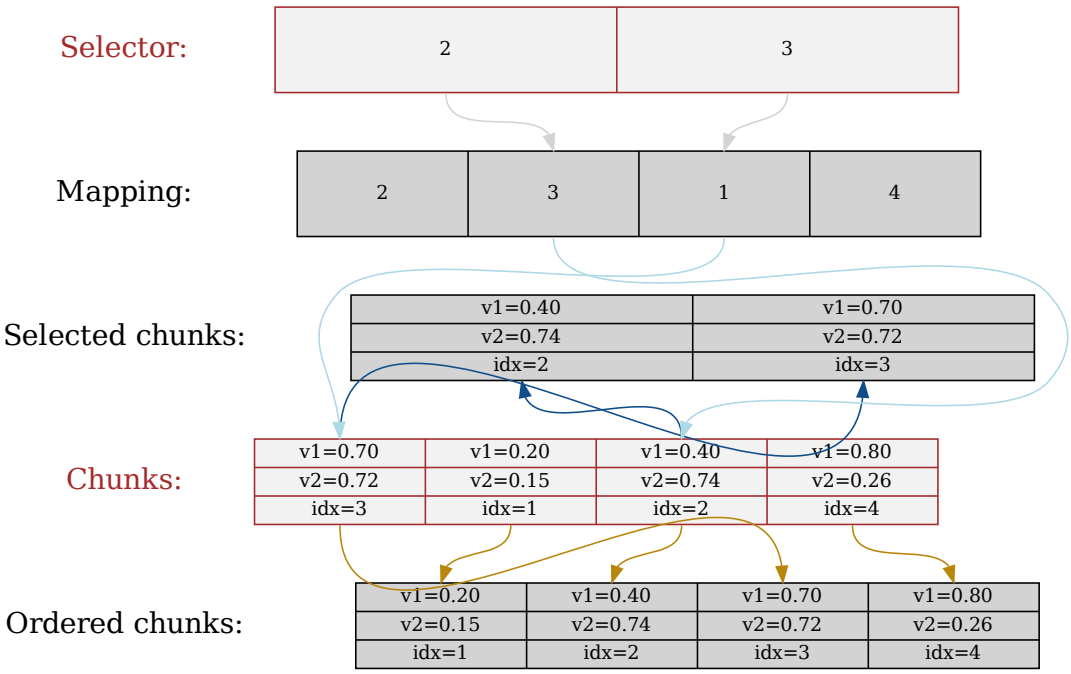
Also, maintenance becomes easier as well. Because we're explicitly stating the allowed ranges for X and Y, developers can know how to avoid constraint issues when accessing the Tab table. We're also formally indicating the expected behavior. For example, because we declare X to be of X_Range type, and that type is used in the first dimension of Tab, we're documenting — using the syntax of the Ada language — that X is supposed to be used to access the first dimension of Tab. Based on this information, developers that need to maintain this application can immediately identify the purpose of X and use the variable accordingly.

102.1.3 Example: Multiple indices

In this section, we discuss another example where the use of strong typing is relevant. Let's consider an application with the following requirements:

- The application receives the transmission of chunks of information.
  - Each chunk contains two floating-point coefficients.
  - Also, these chunks are received out of order, so that the chunk itself includes an index indicating its position in an ordered array.
- The application also receives a list of indices for the ordered array of chunks. This list — a so-called *selector* — is used to select two chunks from the array of ordered chunks.
- Due to external constraints, the application shall use the unordered array; creating an array of ordered chunks shall be avoided.
  - A function that returns an ordered array of chunks shall be available for testing purposes only.
  - A function that returns the selected chunks shall be available for testing purposes only.
  - A function that returns a mapping from the index of ordered chunks to the index of unordered chunks must be available.

For example, consider the following picture containing input chunks and a selector:



By using the mapping, we can select the correct chunks from the input (unordered) chunks. Also, we may create an array of ordered chunks for testing purposes.

Let's skip the discussion whether the design used in this application is good or not and assume that all requirements listed above are set on stone and can't be changed.

Typical implementation

This is a typical specification of the main package:

Listing 17: indirect_ordering.ads

```
package Indirect_Ordering is

   type Chunk is record
      V1  : Float;
      V2  : Float;
      Idx : Positive;
   end record;

   type Selector is
     array (1 .. 2) of Positive;

   type Mapping is
     array (Positive range <>) of Positive;

   type Chunks is
     array (Positive range <>) of Chunk;

   function Get_Mapping (C : Chunks)
                         return Mapping;

end Indirect_Ordering;
```

Listing 18: indirect_ordering.adb

```
package body Indirect_Ordering is

   function Get_Mapping (C : Chunks)
                         return Mapping is
   begin
      return Map : Mapping (C'Range) do
         for J in C'Range loop
            Map (C (J).Idx) := J;
         end loop;
      end return;
   end Get_Mapping;

end Indirect_Ordering;
```

Code block metadata

```

 ↪Multiple_Indices.Indirect_Ordering
MD5: c31c3617793d2143200550277b1fa630
```

And this is a typical specification of the Test child package:

Listing 19: indirect_ordering-test.ads

```
package Indirect_Ordering.Test is

   function Get_Ordered_Chunks (C : Chunks)
                                return Chunks;

   function Get_Selected_Chunks (C : Chunks;
                                 S : Selector)
                                 return Chunks;

end Indirect_Ordering.Test;
```

Listing 20: indirect_ordering-test.adb

```
package body Indirect_Ordering.Test is

   function Get_Ordered_Chunks (C : Chunks)
                                return Chunks
   is
      Map : constant Mapping := Get_Mapping (C);
   begin
      return OC : Chunks (C'Range) do
         for I in OC'Range loop
            OC (I) := C (Map (I));
         end loop;
      end return;
   end Get_Ordered_Chunks;

   function Get_Selected_Chunks (C : Chunks;
                                 S : Selector)
                                 return Chunks
   is
      Map : constant Mapping := Get_Mapping (C);
   begin
      return SC : Chunks (S'Range) do
         for I in S'Range loop
```

(continues on next page)

(continued from previous page)

```
            SC (I) := C (Map (S (I)));
         end loop;
      end return;
   end Get_Selected_Chunks;

end Indirect_Ordering.Test;
```

Code block metadata

```

 ↪Multiple_Indices.Indirect_Ordering
MD5: d1aefd70e995a610bc5eb3497a509032
```

Note that the information transmitted to the application might be inconsistent due to errors in the transmission channel. For example, the information from Idx (Chunk record) might be wrong. In a real-world application, we should deal with those transmission errors. However, for the discussion in this section, these problems are not crucial, so that we can simplify the implementation by skipping error handling.

Let's finally look at a test application that makes use of the package we've just implemented. In order to simplify the discussion, we'll initialize the array containing the unordered chunks and the selector directly in the application instead of receiving input data from an external source.

Listing 21: show_indirect_ordering.adb

```
with Indirect_Ordering; use Indirect_Ordering;

with Ada.Text_IO; use  Ada.Text_IO;

procedure Show_Indirect_Ordering is

   function Init_Chunks return Chunks is
      C : Chunks (1 .. 4);
   begin
      C (1) := (V1  => 0.70,
                V2  => 0.72,
                Idx => 3);
      C (2) := (V1  => 0.20,
                V2  => 0.15,
                Idx => 1);
      C (3) := (V1  => 0.40,
                V2  => 0.74,
                Idx => 2);
      C (4) := (V1  => 0.80,
                V2  => 0.26,
                Idx => 4);

      return C;
   end Init_Chunks;

   C  : Chunks            := Init_Chunks;
   S  : constant Selector := (2, 3);
   M  : constant Mapping  := Get_Mapping (C);

begin
   --  Loop over selector using original chunks
   for I in S'Range loop
      declare
         C1 : Chunk := C (M (S (I)));
      begin
```

(continues on next page)

(continued from previous page)

```
36          Put_Line ("Selector #"
37                    & Positive'Image (I)
38                    & ": V1 = "
39                    & Float'Image (C1.V1));
40       end;
41    end loop;
42    New_Line;
43
44 end Show_Indirect_Ordering;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Example_
 ↪Multiple_Indices.Indirect_Ordering
MD5: d09e1089f8e92bba43d00df8f35c4792
```

Runtime output

```
Selector # 1: V1 =  4.00000E-01
Selector # 2: V1 =  7.00000E-01
```

In this line of the test application, we retrieve the chunk using the index from the selector:

```
C1 : Chunk := C (M (S (I)));
```

Because C contains the unordered chunks and the index from S refers to the ordered chunks, we need to map between the *ordered index* and the *unordered index*. This is achieved by the mapping stored in M.

If we'd use the ordered array of chunks, we could use the index from S directly, as illustrated in the following procedure:

Listing 22: display_ordered_chunk.adb

```
1  with Indirect_Ordering;
2  use  Indirect_Ordering;
3
4  with Indirect_Ordering.Test;
5  use  Indirect_Ordering.Test;
6
7  with Ada.Text_IO; use Ada.Text_IO;
8
9  procedure Display_Ordered_Chunk (C : Chunks;
10                                  S : Selector)
11 is
12    OC : Chunks := Get_Ordered_Chunks (C);
13 begin
14    --  Loop over selector using ordered chunks
15    for I in S'Range loop
16       declare
17          C1 : Chunk := OC (S (I));
18       begin
19          Put_Line ("Selector #"
20                    & Positive'Image (I)
21                    & ": V1 = "
22                    & Float'Image (C1.V1));
23       end;
24    end loop;
25    New_Line;
26 end Display_Ordered_Chunk;
```

Code block metadata

```

 ↪Multiple_Indices.Indirect_Ordering
MD5: c2cf3942774379760d885f63d8200470
```

In this relatively simple application, we're already dealing with 3 indices:

- The index of the unordered chunks.
- The index of the ordered chunks.
- The index of the selector array.

The use of the wrong index to access an array can be a common source of issues. This becomes even more problematic when the application is extended and new features are implemented: the amount of arrays might increase and developers need to be especially careful not to use the wrong index.

For example, a mistake that developers can make when using the package above is to skip the mapping and access the array of unordered chunks directly with the index from the selector — i.e. `C (S (I))` in the test application above. Detecting this mistake requires extensive testing and debugging, since both the array of unordered chunks and the array of ordered chunks have the same range, so the corresponding indices can be used interchangeably without raising constraint exceptions, even though the behavior is not correct. Fortunately, we can use Ada's strong typing to detect such issues in an early stage of the development.

Using stronger typing

In the previous implementation, we basically used the **Positive** type for all indices. We can, however, declare individual types for each index of the application. This is the updated specification of the main package:

Listing 23: indirect_ordering.ads

```
1  package Indirect_Ordering is
2
3     type Chunk_Index     is new Positive;
4     type Ord_Chunk_Index is new Chunk_Index;
5
6     type Chunk is record
7        V1  : Float;
8        V2  : Float;
9        Idx : Ord_Chunk_Index;
10    end record;
11
12    type Selector_Index is range 1 .. 2;
13
14    type Selector is
15      array (Selector_Index) of Ord_Chunk_Index;
16
17    type Mapping is
18      array (Ord_Chunk_Index range <>) of
19        Chunk_Index;
20
21    type Chunks is
22      array (Chunk_Index range <>) of Chunk;
23
24    function Get_Mapping (C : Chunks)
25                          return Mapping;
```

(continues on next page)

(continued from previous page)

```
26
27 end Indirect_Ordering;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Example_
 ↪Multiple_Indices.Indirect_Ordering_2
MD5: 6cb8aa0d1d50d86bc87cfcc3f85b5203
```

By declaring these new types, we can avoid using the wrong index. Moreover, we're documenting — using the syntax provided by the language — which index is expected in each array or function from the package. This allows for better understanding of the package specification and makes maintenance easier, as well as it helps when implementing new features for the package.

This is the updated specification of the `Test` child package:

Listing 24: indirect_ordering-test.ads

```
1  package Indirect_Ordering.Test is
2
3     pragma Assertion_Policy
4       (Dynamic_Predicate => Check);
5
6     type Ord_Chunks is
7       array (Ord_Chunk_Index range <>) of Chunk
8         with Dynamic_Predicate =>
9           (for all I in Ord_Chunks'Range =>
10             Ord_Chunks (I).Idx = I);
11
12    type Sel_Chunks is
13      array (Selector_Index) of Chunk;
14
15    function Get_Ordered_Chunks
16      (C : Chunks)
17       return Ord_Chunks;
18
19    function Get_Selected_Chunks
20      (C : Chunks;
21       S : Selector)
22       return Sel_Chunks;
23
24 end Indirect_Ordering.Test;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Example_
 ↪Multiple_Indices.Indirect_Ordering_2
MD5: 184893bfc7fcb6015ed742e80fc6cdb1
```

Note that we also declared a separate type for the array of ordered chunks: `Ord_Chunks`. This is needed because the arrays uses a different index (`Ord_Chunk_Index`) and therefore can't be the same type as `Chunks`. For the same reason, we declared a separate type for the array of selected chunks: `Sel_Chunks`.

As a side note, we're now able to include a `Dynamic_Predicate` to `Ord_Chunks` that verifies that the index stored in the each chunk matches the corresponding index of its position in the ordered array.

We also had to add a new private package that includes a function that retrieves the range of an array of `Chunk` type — which are of `Chunk_Index` type — and converts the range using the `Ord_Chunk_Index` type.

Listing 25: indirect_ordering-cnvt.ads

```
private package Indirect_Ordering.Cnvt is

   type Ord_Chunk_Range is record
      First : Ord_Chunk_Index;
      Last  : Ord_Chunk_Index;
   end record;

   function Get_Ord_Chunk_Range
     (C : Chunks)
      return Ord_Chunk_Range is
        ((Ord_Chunk_Index (C'First),
          Ord_Chunk_Index (C'Last)));

end Indirect_Ordering.Cnvt;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Example_
 ↪Multiple_Indices.Indirect_Ordering_2
MD5: 0cdede9824fbfec60dd13da179b49916
```

This is needed for example in the Get_Mapping function, which has to deal with indices of these two types. Although this makes the code a little bit more verbose, it helps documenting the expected types in that function.

This is the corresponding update to the body of the main package:

Listing 26: indirect_ordering.adb

```
with Indirect_Ordering.Cnvt;
use  Indirect_Ordering.Cnvt;

package body Indirect_Ordering is

   function Get_Mapping (C : Chunks)
                         return Mapping is
      R : constant Ord_Chunk_Range :=
            Get_Ord_Chunk_Range (C);
   begin
      return Map : Mapping (R.First .. R.Last) do
         for J in C'Range loop
            Map (C (J).Idx) := J;
         end loop;
      end return;
   end Get_Mapping;

end Indirect_Ordering;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Example_
 ↪Multiple_Indices.Indirect_Ordering_2
MD5: 10315cebc721b1a9927e18ad64c877bc
```

This is the corresponding update to the body of the Test child package:

Listing 27: indirect_ordering-test.adb

```
with Indirect_Ordering.Cnvt;
use  Indirect_Ordering.Cnvt;
```

(continues on next page)

(continued from previous page)

```
3
4  package body Indirect_Ordering.Test is
5
6     function Get_Ordered_Chunks
7       (C : Chunks)
8        return Ord_Chunks
9     is
10       Map : constant Mapping := Get_Mapping (C);
11       R   : constant Ord_Chunk_Range :=
12                Get_Ord_Chunk_Range (C);
13    begin
14       return OC : Ord_Chunks (R.First .. R.Last)
15       do
16          for I in OC'Range loop
17             OC (I) := C (Map (I));
18          end loop;
19       end return;
20    end Get_Ordered_Chunks;
21
22    function Get_Selected_Chunks
23      (C : Chunks;
24       S : Selector)
25       return Sel_Chunks
26    is
27       Map : constant Mapping := Get_Mapping (C);
28    begin
29       return SC : Sel_Chunks do
30          for I in S'Range loop
31             SC (I) := C (Map (S (I)));
32          end loop;
33       end return;
34    end Get_Selected_Chunks;
35
36 end Indirect_Ordering.Test;
```

```

This is the updated test application:

Listing 28: show_indirect_ordering.adb

```
1  with Indirect_Ordering; use Indirect_Ordering;
2
3  with Ada.Text_IO; use  Ada.Text_IO;
4
5  procedure Show_Indirect_Ordering is
6
7     function Init_Chunks return Chunks is
8        C : Chunks (1 .. 4);
9     begin
10       C (1) := (V1  => 0.70,
11                 V2  => 0.72,
12                 Idx => 3);
13       C (2) := (V1  => 0.20,
14                 V2  => 0.15,
15                 Idx => 1);
16       C (3) := (V1  => 0.40,
```

(continues on next page)

(continued from previous page)

```
                V2  => 0.74,
                Idx => 2);
      C (4) := (V1  => 0.80,
                V2  => 0.26,
                Idx => 4);

      return C;
   end Init_Chunks;

   C  : Chunks            := Init_Chunks;
   S  : constant Selector := (2, 3);
   M  : constant Mapping  := Get_Mapping (C);

begin
   --  Loop over selector using original chunks
   for I in S'Range loop
      declare
         C1 : Chunk := C (M (S (I)));
      begin
         Put_Line ("Selector #"
                   & Selector_Index'Image (I)
                   & ": V1 = "
                   & Float'Image (C1.V1));
      end;
   end loop;
   New_Line;

end Show_Indirect_Ordering;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Strong_Typing.Example_
 ↪Multiple_Indices.Indirect_Ordering_2

```

Runtime output

```
Selector # 1: V1 =  4.00000E-01
Selector # 2: V1 =  7.00000E-01
```

Apart from minor changes, the test application is basically still the same. However, if we now change the following line:

```
C1 : Chunk := C (M (S (I)));
```

to

```
C1 : Chunk := C (S (I));
```

The compiler will gives us an error, telling us that it expected the `Chunk_Index` type, but found the `Ord_Chunk_Index` instead. By using Ada's strong typing, we're detecting issues at compile time instead of having to rely on extensive testing and debugging to detect them. Basically, this eliminates a whole category of potential bugs and reduces development time. At the same time, we're improving the documentation of the source-code and facilitating further improvements to the application.

102.1.4 Discriminants

Relevant topics

- discriminants in the context of strong typing

102.2 Object-Oriented Programming

102.2.1 Primitives

102.2.2 Overriding indicators

Relevant topics

- **Briefly** discuss `overriding` and `not overriding` mentioned in Overriding Indicators[482]
- Mention that `not overriding` is not recommended.

102.2.3 Abstract types and subprograms

102.2.4 Interfaces

Null records vs. interfaces

Earlier on (page 420) in the course, we discussed how to use null records to create a prototype. We could also consider using interfaces instead. However, as we've just learned, the consequences are that:

- we can only create an API for the package specification, but we cannot use that interface type in an application in the same way as we do with null records;
- we're forced to use object-oriented programming — which, depending on our goal, might be more complex than actually needed.

Let's revisit a previous example from the section on null records:

Listing 29: devices.ads

```
1  package Devices is
2
3     type Device is private;
4
5     function Create
6       (Active : Boolean)
7        return Device;
8
9     procedure Reset
10      (D : out Device) is null;
11
12    procedure Process
```

(continues on next page)

[482] http://www.ada-auth.org/standards/22rm/html/RM-8-3-1.html

(continued from previous page)

```
13       (D : in out Device) is null;
14
15    procedure Activate
16       (D : in out Device) is null;
17
18    procedure Deactivate
19       (D : in out Device) is null;
20
21 private
22
23    type Device is null record;
24
25    function Create
26       (Active : Boolean)
27        return Device is (null record);
28
29 end Devices;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.OO_Prog.Interfaces.Device
MD5: b4a604ba42af1a89943b0e12f5eefd80
```

We can easily rewrite this specification using interfaces:

Listing 30: devices.ads

```
1  package Devices is
2
3     type Device is interface;
4
5     function Create
6       (Active : Boolean)
7        return Device is abstract;
8
9     procedure Reset
10       (D : out Device) is null;
11
12    procedure Process
13       (D : in out Device) is null;
14
15    procedure Activate
16       (D : in out Device) is null;
17
18    procedure Deactivate

21 end Devices;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.OO_Prog.Interfaces.Device_
 ↪Interface
MD5: 0ef9e103a007921a9e6f2518f3b51ff1
```

These are the only changes we made:

- `Device` is now an interface, and
- `Create` is now an abstract function.

Keep in mind, however, that a null record isn't an abstract type, even though it *looks* abstract (as it doesn't store any information). This contrasts with interfaces, which are ab-

stract and therefore more restricted. For example, as indicated above, we cannot use the interface from the Devices package in an application, as we cannot declare objects of an abstract type. The following application — which works fine when Device is a null record — doesn't compile when Device is an interface:

Listing 31: show_device.adb

```
with Devices; use Devices;

procedure Show_Device is
   A : Device;
begin
   A := Create (Active => True);
   Process (A);
   Deactivate (A);
   Activate (A);
   Reset (A);
end Show_Device;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.OO_Prog.Interfaces.Device_
↪Interface
MD5: 9f35805d2ba8b8f68783dc8fd21e5d53
```

Build output

```
show_device.adb:4:08: error: type of object cannot be abstract
show_device.adb:6:04: error: target of assignment operation must not be abstract
show_device.adb:6:09: error: call to abstract function must be dispatching
gprbuild: *** compilation phase failed
```

A possible compromise is, of course, to reintroduce null records in our specification as a derived type. For example:

Listing 32: devices.ads

```
package Devices is

   type Abstract_Device is interface;

   function Create
     (Active : Boolean)
      return Abstract_Device is abstract;

   procedure Reset
     (D : out Abstract_Device) is null;

   procedure Process
     (D : in out Abstract_Device) is null;

   procedure Activate
     (D : in out Abstract_Device) is null;

   procedure Deactivate
     (D : in out Abstract_Device) is null;

   type Device is new
     Abstract_Device with private;

private

```

(continues on next page)

(continued from previous page)

```
   type Device is new
     Abstract_Device with null record;

   function Create
     (Active : Boolean)
      return Device is (null record);

end Devices;
```

Listing 33: show_device.adb

```
with Devices; use Devices;

procedure Show_Device is
   A : Device;
begin
   A := Create (Active => True);
   Process (A);
   Deactivate (A);
   Activate (A);
   Reset (A);
end Show_Device;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.OO_Prog.Interfaces.Device_
 ↪Interface
MD5: 9c9c34ec84a9831dfcfce21f60f3ff34
```

Now, our interface was renamed to `Abstract_Device` and we're just using it to specify our API. We derive the `Device` from this interface type (`Abstract_Device`) as a null record. In a prototype — such as the `Show_Device` procedure — we can use the null record as expected.

102.2.5 Example: Extending Interfaces

Note: This section was originally written by Quentin Ochem and published as Gem #48: Extending Interfaces in Ada 2005[483].

Using new interfaces

Let's assume we have the following interface:

Listing 34: animals.ads

```
package Animals is

   type Animal is interface;

   procedure Eat (Beast : in out Animal)
     is abstract;

end Animals;
```

Code block metadata

[483] https://www.adacore.com/gems/gem-48

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.OO_Prog.Interfaces.
 ↪Extending_Interfaces
MD5: 10d462cd0a0decea9ce7869659e26281
```

All types implementing the `Animal` interface have to override the `Eat` operation:

Listing 35: animals-cats.ads

```
package Animals.Cats is

   type Cat is new Animal with null record;

   procedure Eat (Beast : in out Cat);

end Animals.Cats;
```

Listing 36: animals-cats.adb

```
package body Animals.Cats is

   procedure Eat (Beast : in out Cat) is
   begin
      --  no implementation yet
      null;
   end Eat;

end Animals.Cats;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.OO_Prog.Interfaces.
 ↪Extending_Interfaces
MD5: f777bf850c812186f922e46f3a1f04c7
```

Listing 37: show_cat.adb

```
with Animals.Cats; use Animals.Cats;

procedure Show_Cat is
   C : Cat;
begin
   C.Eat;
end Show_Cat;
```

Now, after a while, the developer of `Animal` might feel the need to let animals eat something specific, and would like to add the following operation to the interface:

```
procedure Eat (Beast : in out Animal;
               Thing : in out A_Thing);
```

Unfortunately, there are hundreds of species of animals implementing this interface, and having to migrate everything will be too painful. Not to mention that most of them don't even need this new way of eating --- they're just happy eating some random amount of anonymous food. Extending this interface is just not the way to go --- so the extension has to be done separately, in a new interface, such as:

Listing 38: animals-extensions.ads

```
package Animals.Extensions is

   type Animal_Extension_1 is interface;
```

(continues on next page)

(continued from previous page)

```
4
5     type A_Thing is null record;
6     --  no implementation yet
7
8     procedure Eat
9       (Beast : in out Animal_Extension_1;
10       Thing : in out A_Thing) is abstract;
11
12  end Animals.Extensions;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.OO_Prog.Interfaces.
 ↪Extending_Interfaces
MD5: 8c3cfd6a19ee2977f58268d50291efd3
```

So now, Animals that need to rely on this new way of eating will need to be declared, such as:

Listing 39: animals-cats.ads

```
1   with Animals.Extensions; use Animals.Extensions;
2
3   package Animals.Cats is
4
5     type Cat is new
6       Animal and Animal_Extension_1
7         with null record;
8
9     procedure Eat
10      (Beast : in out Cat);
11
12    procedure Eat
13      (Beast : in out Cat;
14       Thing : in out A_Thing);
15
16  end Animals.Cats;
```

Listing 40: animals-cats.adb

```
1   package body Animals.Cats is
2
3     procedure Eat (Beast : in out Cat) is
4     begin
5        --  no implementation yet
6        null;
7     end Eat;
8
9     procedure Eat (Beast : in out Cat;
10                   Thing : in out A_Thing) is
11    begin
12       --  no implementation yet
13       null;
14    end Eat;
15
16  end Animals.Cats;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.OO_Prog.Interfaces.
 ↪Extending_Interfaces
```

(continues on next page)

(continued from previous page)

```
MD5: a649b28055c673e8fbe224bfe360bc06
```

Listing 41: show_cat.adb

```
with Animals.Cats;       use Animals.Cats;
with Animals.Extensions; use Animals.Extensions;

procedure Show_Cat is
   C : Cat;
   T : A_Thing;
begin
   C.Eat (T);
end Show_Cat;
```

Note that it's even possible to enforce the fact that an extension of `Animal` has to be an `Animal` in the first place, by writing:

```
type Animal_Extension_1 is interface and Animal;
```

which will lead to a simpler declaration for type `Cat`, as there's no longer a need to extend from two interfaces:

```
type Cat is new
  Animal_Extension_1 with null record;
```

The rest of the code will remain completely untouched thanks to this change. Calls to the new subprogram will require some additional amount of work though, as we'll first have to check that the type of an `Animal` that we're dealing with is indeed a descendant of `Animal_Extension_1`, and perform a conversion to that interface's class, before calling the new version of `Eat`:

Listing 42: show_animal_eat.adb

```
with Animals;            use Animals;
with Animals.Cats;       use Animals.Cats;
with Animals.Extensions; use Animals.Extensions;

procedure Show_Animal_Eat is
   C : Cat;
   T : A_Thing;

   A : Animal'Class := C;
begin
   if A in Animal_Extension_1'Class then
      Animal_Extension_1'Class (A).Eat (T);
   end if;
end Show_Animal_Eat;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.OO_Prog.Interfaces.
 ↪Extending_Interfaces
MD5: d9f48b460709ad9d7a2e51868082410e
```

Using null procedures

Since Ada 2005, we have the notion of null procedures. As *discussed previously* (page 653), a null procedure is a procedure that is declared using **is null** and logically has an empty body. Fortunately, null procedures are allowed in interface definitions — they define the default behavior of such a subprogram as doing nothing. Back to the `Animal` example, the programmer can declare the interface's `Eat` primitive as follows:

```
procedure Eat (Beast : in out Animal;
               Thing : in out A_Thing) is null;
```

This is adapted code:

Listing 43: animals.ads

```
package Animals is

   type Animal is interface;

   type A_Thing is null record;
   --  no implementation yet

   procedure Eat
     (Beast : in out Animal) is abstract;

   procedure Eat
     (Beast : in out Animal;
      Thing : in out A_Thing) is abstract;

end Animals;
```

Listing 44: animals-cats.ads

```
package Animals.Cats is

   type Cat is new Animal with null record;

   procedure Eat (Beast : in out Cat);

   procedure Eat (Beast : in out Cat;
                  Thing : in out A_Thing);

end Animals.Cats;
```

Listing 45: animals-cats.adb

```
package body Animals.Cats is

   procedure Eat (Beast : in out Cat) is
   begin
      --  no implementation yet
      null;
   end Eat;

   procedure Eat (Beast : in out Cat;
                  Thing : in out A_Thing) is
   begin
      --  no implementation yet
      null;
   end Eat;

```

(continues on next page)

(continued from previous page)

```
16 end Animals.Cats;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.OO_Prog.Interfaces.Null_
 ↪Procedures
MD5: 65a55bb7f44ebfbf1696509bb1bf32ef
```

All of our hundreds of kinds of animals will automatically inherit from this procedure, but won't have to implement it. The addition of this declaration does not break source compatibility with the contract of the `Animal` interface. Moreover, as no new types are involved, it's a lot easier to make calls to this subprogram --- no more need to check membership or write a type conversion, and we can just write:

Listing 46: show_animal_eat.adb

```
1  with Animals;            use Animals;
2  with Animals.Cats;       use Animals.Cats;
3
4  procedure Show_Animal_Eat is
5     C : Cat;
6     T : A_Thing;
7
8     A : Animal'Class := C;
9  begin
10    A.Eat (T);
11 end Show_Animal_Eat;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.OO_Prog.Interfaces.Null_
 ↪Procedures
MD5: 89e765b5e5853453898007f0ebb531ac
```

which will execute as a no-op except for animals that have explicitly overridden the primitive.

102.2.6 Calling inherited subprograms

Note: This section was originally written by Emmanuel Briot and published as blog post Calling inherited subprograms in Ada[484].

In object-oriented code, it is often the case that we need to call inherited subprograms. Some programing languages make it very easy by introducing a new keyword *super* (although this approach has its limits for languages that allow multiple inheritance of implementation).

In Ada, things are slightly more complicated. Let's take an example, using the traditional geometric classes that are often found in text books:

Listing 47: geometric_forms.ads

```
1  package Geometric_Forms is
2
3     type Polygon is tagged private;
```

(continues on next page)

[484] https://blog.adacore.com/calling-inherited-subprograms-in-ada

(continued from previous page)

```
   procedure Initialize (Self : in out Polygon);

   type Square is new Polygon with private;

   overriding
   procedure Initialize (Self : in out Square);

private

   type Polygon is tagged null record;
   type Square is new
     Polygon with null record;

end Geometric_Forms;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.OO_Prog.Calling_Inherited_
 ↪Subprograms.Geometric_Forms
MD5: 799b0d4b6153b29675d49d7422c89d61
```

Let's assume now that Square's Initialize needs to call Polygon's Initialize, in addition to doing a number of square specific setups. To do this, we need to use type conversions to change the view of Self, so that the compiler statically knows which Initialize to call. The code thus looks like:

Listing 48: geometric_forms.adb

```
package body Geometric_Forms is

   procedure Initialize (Self : in out Polygon) is
   begin
      null;
   end Initialize;

   overriding
   procedure Initialize (Self : in out Square) is
   begin
      Initialize (Polygon (Self));
      --  ^^^^^^^^^^^^^^^^^^^^^^^^
      --  calling inherited procedure

      --  ... square-specific setups
   end Initialize;

end Geometric_Forms;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.OO_Prog.Calling_Inherited_
 ↪Subprograms.Geometric_Forms
MD5: 8aff1914d6d96312124534b024263a73
```

Listing 49: show_geometric_forms.adb

```
with Geometric_Forms; use Geometric_Forms;

procedure Show_Geometric_Forms is
   S : Square;
begin
```

(continues on next page)

(continued from previous page)

```
   S.Initialize;
end Show_Geometric_Forms;
```

The main issue with this code (apart from its relative lack of readability) is the need to hard-code the name of the ancestor class. If we suddenly realize that a Square is after all a special case of a Rectangle, and thus decide to add the new rectangle class, the code needs to be changed (and not just in the spec), as in:

Listing 50: geometric_forms.ads

```
package Geometric_Forms is

   type Polygon is tagged private;
   procedure Initialize (Self : in out Polygon);

   type Rectangle is new
     Polygon with private;       --  NEW

   overriding
   procedure Initialize
     (Self : in out Rectangle);  --  NEW

   type Square is new
     Rectangle with private;     --  MODIFIED

   overriding
   procedure Initialize
     (Self : in out Square);

private

   type Polygon is tagged null record;
   type Rectangle is new
     Polygon with null record;
   type Square is new
     Rectangle with null record;

end Geometric_Forms;
```

Listing 51: geometric_forms.adb

```
package body Geometric_Forms is

   procedure Initialize (Self : in out Polygon) is
   begin
      null;
   end Initialize;

   overriding
   procedure Initialize
     (Self : in out Rectangle)
   is
   begin
      Initialize (Polygon (Self));
      --  ^^^^^^^^^^^^^^^^^^^^^^^^
      --  calling inherited procedure

      --  ... rectangle-specific setups
   end Initialize;

```

(continues on next page)

(continued from previous page)

```
   procedure Initialize (Self : in out Square) is
   begin
      Initialize (Rectangle (Self));  --  MODIFIED
      --  ... square-specific setups
   end Initialize;

end Geometric_Forms;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.OO_Prog.Calling_Inherited_
↪Subprograms.Geometric_Forms
MD5: da298530f9d8af2079bfb6b9b090f874
```

Listing 52: show_geometric_forms.adb

```
with Geometric_Forms; use Geometric_Forms;

procedure Show_Geometric_Forms is
   S : Square;
begin
   S.Initialize;
end Show_Geometric_Forms;
```

The last change --- in the implementation of the `Initialize` procedure of the `Square` type --- is easy to forget when one modifies the inheritance tree, and its omission would result in not initializing the `Rectangle` specific data.

Let's look into how the code should best be organized to limit the risks here. An interesting idiom is the one that makes use of parent subtypes. The trick is to always define a `Parent` subtype every time one extends a type, and use that subtype when calling the inherited procedure. Here is a full example:

Listing 53: geo_forms.ads

```
package Geo_Forms with Pure is

end Geo_Forms;
```

Listing 54: geo_forms-polygons.ads

```
package Geo_Forms.Polygons is

   type Polygon is tagged private;
   procedure Initialize (Self : in out Polygon);

private

   type Polygon is tagged null record;

end Geo_Forms.Polygons;
```

Listing 55: geo_forms-rectangles.ads

```
with Geo_Forms.Polygons;

package Geo_Forms.Rectangles is

   subtype Parent is
     Geo_Forms.Polygons.Polygon;
```

(continues on next page)

(continued from previous page)

```
   type Rectangle is new
     Parent with private;

   overriding
   procedure Initialize (Self : in out Rectangle);

private

   type Rectangle is new Parent with null record;

end Geo_Forms.Rectangles;
```

Listing 56: geo_forms-squares.ads

```
with Geo_Forms.Rectangles;

package Geo_Forms.Squares is

   subtype Parent is
     Geo_Forms.Rectangles.Rectangle;

   type Square is new Parent with private;

   overriding
   procedure Initialize (Self : in out Square);

private

   type Square is new Parent with null record;

end Geo_Forms.Squares;
```

Listing 57: geo_forms-polygons.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Geo_Forms.Polygons is

   procedure Initialize (Self : in out Polygon) is
   begin
      Put_Line ("Initializing Polygon type...");
   end Initialize;

end Geo_Forms.Polygons;
```

Listing 58: geo_forms-rectangles.adb

```
with Ada.Text_IO;        use Ada.Text_IO;
with Geo_Forms.Polygons; use Geo_Forms.Polygons;

package body Geo_Forms.Rectangles is

   overriding
   procedure Initialize (Self : in out Rectangle)
   is
   begin
      Initialize (Parent (Self));

      --  ... rectangle-specific setups
      Put_Line ("Initializing Rectangle type...");
```

(continues on next page)

(continued from previous page)

```
   end Initialize;

end Geo_Forms.Rectangles;
```

Listing 59: geo_forms-squares.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Geo_Forms.Rectangles;
use  Geo_Forms.Rectangles;

package body Geo_Forms.Squares is

   procedure Initialize (Self : in out Square) is
   begin
      Initialize (Parent (Self));

      --  ... square-specific setups
      Put_Line ("Initializing Square type...");
   end Initialize;

end Geo_Forms.Squares;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.OO_Prog.Calling_Inherited_
 ↪Subprograms.Geometric_Forms_2
MD5: bb71890cf9c083c14d18c2bb617b3462
```

Listing 60: show_geo_forms.adb

```
with Ada.Text_IO;       use Ada.Text_IO;
with Geo_Forms.Squares; use Geo_Forms.Squares;

procedure Show_Geo_Forms is
   S : Square;
begin
   Put_Line ("Initialize Square object:");

   S.Initialize;
end Show_Geo_Forms;
```

Now, if we want to add an extra `Parallelogram` class between `Polygon` and `Rectangle`, we just need to change the definition of the `Parent` subtype in the `Rectangles` package, and no change is needed for the body.

This is not a new syntax nor a new idiom, but is worth considering it when one is developing a complex hierarchy of types, or at least a hierarchy that is likely to change regularly in the future.

102.2.7 Dynamic Polymorphism

102.2.8 Controlled types

102.2.9 Ada.Tags package

102.2.10 User-defined indexing

Relevant topics

- User-Defined Indexing[485]

102.3 Generics

102.3.1 Mapping of Definite and Indefinite Subtypes

Earlier on, we had a discussion about *definite and indefinite subtypes* (page 295). In this section, we look into formal definite and indefinite types and how those types are mapped.

We can distinguish between the definite and indefinite version of many formal types. For example, consider the simple formal type `type T is private`, which is the definite version of a formal nonlimited private type. The indefinite version of this formal type is `type T (<>) is private`. Here, the syntax (<>) is used to distinguish the indefinite form from the definite form.

Let's create a generic package using the definite form of the formal nonlimited private type and map an actual data type to it:

Listing 61: definite_formal_type_example.ads

```
generic
   type T is private;
package Definite_Formal_Type_Example is
   Dummy : T;
end Definite_Formal_Type_Example;
```

Listing 62: show_map_to_definite_formal_type.ads

```
with Definite_Formal_Type_Example;

package Show_Map_To_Definite_Formal_Type is

   type Null_Record is null record;

   package Map_Definite_Type is new
     Definite_Formal_Type_Example
       (T => Null_Record);

end Show_Map_To_Definite_Formal_Type;
```

Code block metadata

[485] http://www.ada-auth.org/standards/22rm/html/RM-4-1-6.html

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Mapping_Definite_
 ↪Indefinite_Subtypes.Definite_Formal_Type
MD5: 431182c92ae0fdbc594ab15a9097829d
```

We can map any nonlimited, definite type to the type T above. However, we cannot map indefinite types to it:

Listing 63: show_map_to_definite_formal_type.ads

```
with Definite_Formal_Type_Example;

package Show_Map_To_Definite_Formal_Type is

   type Simple_Record (Extended : Boolean) is
   record
      V : Integer;
      case Extended is
         when False =>
            null;
         when True  =>
            V_Float : Float;
      end case;
   end record;

   package Map_Indefinite_Type is new
     Definite_Formal_Type_Example
       (T => Simple_Record);
   --  ERROR: trying to map an indefinite type
   --         to a formal definite type!

end Show_Map_To_Definite_Formal_Type;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Mapping_Definite_
 ↪Indefinite_Subtypes.Definite_Formal_Type
MD5: d0056ed8c1e14d5ace18f75db87213e3
```

Build output

```
show_map_to_definite_formal_type.ads:16:04: error: instantiation error at definite_
 ↪formal_type_example.ads:4
show_map_to_definite_formal_type.ads:16:04: error: unconstrained subtype not␣
 ↪allowed (need initialization)
show_map_to_definite_formal_type.ads:16:04: error: provide initial value or␣
 ↪explicit discriminant values
show_map_to_definite_formal_type.ads:16:04: error: or give default discriminant␣
 ↪values for type "T"
show_map_to_definite_formal_type.ads:18:14: error: actual for "T" must be a␣
 ↪definite subtype
gprbuild: *** compilation phase failed
```

When we try to compile this example, we get a compilation error at the declaration of the Map_Indefinite_Type package. We could solve this problem by changing type T to a formal indefinite type, for example:

Listing 64: indefinite_formal_type_example.ads

```
generic
   type T (<>) is private;
package Indefinite_Formal_Type_Example is
   function Dummy (Unused : T)
```

(continues on next page)

(continued from previous page)

```
                    return Boolean is
     (True);
end Indefinite_Formal_Type_Example;
```

Listing 65: show_map_to_indefinite_formal_type.ads

```
with Indefinite_Formal_Type_Example;

package Show_Map_To_Indefinite_Formal_Type is

   type Simple_Record (Extended : Boolean) is
   record
      V : Integer;
      case Extended is
         when False =>
            null;
         when True  =>
            V_Float : Float;
      end case;
   end record;

   package Map_Indefinite_Type is new
     Indefinite_Formal_Type_Example
       (T => Simple_Record);

end Show_Map_To_Indefinite_Formal_Type;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Mapping_Definite_
 ↪Indefinite_Subtypes.Indefinite_Formal_Type
MD5: 75d4a2f453f43df66f43621a12f2b655
```

Now, we don't get a compilation error because type T allows us to map an indefinite type. Note that we could still map a definite type to type T. For example:

Listing 66: show_map_to_indefinite_formal_type.ads

```
with Indefinite_Formal_Type_Example;

package Show_Map_To_Indefinite_Formal_Type is

   type Null_Record is null record;

   package Map_Definite_Type is new
     Indefinite_Formal_Type_Example
       (T => Null_Record);

end Show_Map_To_Indefinite_Formal_Type;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Mapping_Definite_
 ↪Indefinite_Subtypes.Indefinite_Formal_Type
MD5: da162dc365d4cde78563455aba741228
```

In other words, we can map any nonlimited type — indefinite or definite — to a formal indefinite nonlimited private type.

Many instances of formal types have an indefinite and a definite version. Here are a few examples:

- Formal limited private type:
  - Definite version: `type T is limited private`
  - Indefinite version: `type T (<>) is limited private`
- Tagged private type:
  - Definite version: `type T is tagged private`
  - Indefinite version: `type T (<>) is tagged private`
- Abstract tagged limited private type:
  - Definite version: `type T is abstract tagged limited private`
  - Indefinite version: `type T (<>) is abstract tagged limited private`

Appendix A of the *Introduction to Ada course* (page 269) provides a detailed list of formal types and their variations.

Note that, instead of just using a formal indefinite nonlimited private type, we could be more specific about the discriminants that we use for type T. Consider the following example:

Listing 67: formal_type_discriminants_example.ads

```
generic
   type T (B : Boolean) is private;
package Formal_Type_Discriminants_Example is
   function Dummy (Unused : T)
                   return Boolean is
     (True);
end Formal_Type_Discriminants_Example;
```

Listing 68: show_map_to_formal_type_with_discrimants.ads

```
with Formal_Type_Discriminants_Example;

package Show_Map_To_Formal_Type_With_Discrimants
is
   type Simple_Record (Extended : Boolean) is
   record
      V : Integer;
      case Extended is
         when False =>
            null;
         when True  =>
            V_Float : Float;
      end case;
   end record;

   type Integer_Array is
     array (Positive range <>) of Integer;

   type Simple_Record_2 (Last : Integer) is record
      A : Integer_Array (1 .. Last);
   end record;

   type Null_Record is null record;

   package Map_Boolean_Discriminant is new
     Formal_Type_Discriminants_Example
       (T => Simple_Record);

end Show_Map_To_Formal_Type_With_Discrimants;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Mapping_Definite_
 ↪Indefinite_Subtypes.Formal_Type_Discriminants
MD5: ee2adf563c64292178619713a4409d55
```

Here, we replaced (<>) by (B : Boolean) in the declaration of type T. This means that, now, we can only map indefinite types with that specific list of discriminants. For example, we cannot map the following types:

Listing 69: show_map_to_formal_type_with_discrimants.ads

```
with Formal_Type_Discriminants_Example;

package Show_Map_To_Formal_Type_With_Discrimants
is
   type Integer_Array is
     array (Positive range <>) of Integer;

   type Simple_Record_2 (Last : Integer) is record
      A : Integer_Array (1 .. Last);
   end record;

   type Null_Record is null record;

   package Map_Type_With_Integer_Discriminant
   is new
     Formal_Type_Discriminants_Example
       (T => Simple_Record_2);

   package Map_Definite_Type is new
     Formal_Type_Discriminants_Example
       (T => Null_Record);

end Show_Map_To_Formal_Type_With_Discrimants;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Mapping_Definite_
 ↪Indefinite_Subtypes.Formal_Type_Discriminants
MD5: ed288cdb24431da6c9747827baf197a7
```

Build output

```
show_map_to_formal_type_with_discrimants.ads:17:14: error: types of actual␣
 ↪discriminants must match formal
show_map_to_formal_type_with_discrimants.ads:17:14: error: instantiation abandoned
show_map_to_formal_type_with_discrimants.ads:21:14: error: actual for "T" must␣
 ↪have discriminants
show_map_to_formal_type_with_discrimants.ads:21:14: error: instantiation abandoned
gprbuild: *** compilation phase failed
```

The compilation of this example fails as expected because, as soon as we specify a list of discriminants for a formal type, we can only map actual types that have the exact same discriminants. We cannot use a type with a different set of discriminants — as in the declaration of Map_Type_With_Integer_Discriminant — nor a definite type — as in the declaration of Map_Definite_Type.

102.3.2 Formal incomplete types

A formal incomplete type has the following syntax:

Listing 70: using_formal_incomplete.ads

```
generic
  type Formal_Incomplete;
package Using_Formal_Incomplete
  with Pure is
end Using_Formal_Incomplete;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Incomplete_
 ↪Types.Simple_Formal_Incomplete_Type
MD5: 16d238f53482621e27d593d4fea4e40e
```

We can use them to map incomplete types when instantiating generic packages or subprograms. For example:

Listing 71: show_inst_formal_incomplete.ads

```
with Using_Formal_Incomplete;

package Show_Inst_Formal_Incomplete is

   type R;

   package R_Pkg is new
     Using_Formal_Incomplete (R);

   type R is record
      I : Integer;
   end record;

end Show_Inst_Formal_Incomplete;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Incomplete_
 ↪Types.Simple_Formal_Incomplete_Type
MD5: 3cd35b673e9f407736fb6f4ef9f40378
```

As we've seen before, incomplete types are rather restricted in terms of usage. Therefore, formal incomplete types are typically used in conjunction with other generic packages or subprograms. We explain later how to use them to create *signature packages* (page 1938).

A formal incomplete type can also be tagged:

```
generic
  type Incomplete_Tagged is tagged;
package Dummy;
```

Let's see an example:

Listing 72: formal_incomplete_tagged_type_example.ads

```
generic
  type Incomplete_Tagged is tagged;
  with function Test (V : Incomplete_Tagged)
                      return Boolean;
```

(continues on next page)

(continued from previous page)

```
package Formal_Incomplete_Tagged_Type_Example
is

   procedure Perform_Test (I : Incomplete_Tagged);

end Formal_Incomplete_Tagged_Type_Example;
```

Listing 73: formal_incomplete_tagged_type_example.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Formal_Incomplete_Tagged_Type_Example
is

   procedure Perform_Test (I : Incomplete_Tagged)
   is
   begin
      if Test (I) then
         Put_Line ("Test passed!");
      else
         Put_Line ("Test failed!");
      end if;
   end Perform_Test;

end Formal_Incomplete_Tagged_Type_Example;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Incomplete_
↪Types.Formal_Incomplete_Tagged_Types
MD5: c51d6def93918eca66b6c4ea7481f7fe
```

Note that this example only compiles because `Incomplete_Tagged` is tagged. If it was an *untagged* formal incomplete type, we wouldn't be allowed to call the `Test` function in the body of `Perform_Test`. This is possible, however, with tagged formal incomplete types — as well as with other kinds of formal types.

102.3.3 Formal packages

Abstracting definitions into packages

In this section and in the next ones, we will reuse the generic reversing algorithm that we discussed in the *chapter about generics* (page 138) from the introductory course.

Listing 74: test_reverse_colors.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Test_Reverse_Colors is
   generic
      type T is private;
      type Index is range <>;
      type Array_T is array (Index range <>) of T;
   procedure Generic_Reverse_Array
     (X : in out Array_T);

   procedure Generic_Reverse_Array
     (X : in out Array_T) is
```

(continues on next page)

(continued from previous page)

```
   begin
      for I in X'First ..
               (X'Last + X'First) / 2 loop
         declare
            Tmp     : T;
            X_Left  : T renames X (I);
            X_Right : T renames X
                           (X'Last + X'First - I);
         begin
            Tmp     := X_Left;
            X_Left  := X_Right;
            X_Right := Tmp;
         end;
      end loop;
   end Generic_Reverse_Array;

   type Color is (Black, Red, Green, Blue, White);
   type Color_Array is
     array (Integer range <>) of Color;

   procedure Reverse_Color_Array is new
     Generic_Reverse_Array
       (T      => Color,
       Index   => Integer,
       Array_T => Color_Array);

   My_Colors : Color_Array (1 .. 5) :=
                (Black, Red, Green, Blue, White);

begin
   for C of My_Colors loop
      Put_Line ("My_Color: " & Color'Image (C));
   end loop;

   New_Line;
   Put_Line ("Reversing My_Color...");
   New_Line;
   Reverse_Color_Array (My_Colors);

   for C of My_Colors loop
      Put_Line ("My_Color: " & Color'Image (C));
   end loop;

end Test_Reverse_Colors;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Packages.
 ↪Reverse_Color
MD5: 5f33a6a1ec087a6dec9e3eec54b9e835
```

Runtime output

```
My_Color: BLACK
My_Color: RED
My_Color: GREEN
My_Color: BLUE
My_Color: WHITE

Reversing My_Color...
```

(continues on next page)

(continued from previous page)

```
My_Color: WHITE
My_Color: BLUE
My_Color: GREEN
My_Color: RED
My_Color: BLACK
```

In that example, we were declaring three formal types for the **Generic**_Reverse_Array procedure: a type T, a range Index and the array type Array_T. However, we could abstract the array definition into a separate package and reuse it for the generic procedure. This could be potentially useful in case we want to create more generic procedures for the same array.

In order to achieve this, we start by first specifying a generic package that contains the generic array type definition:

Listing 75: simple_generic_array_pkg.ads

```
generic
   type T is private;
   type Index is range <>;
package Simple_Generic_Array_Pkg is
   type Array_T is array (Index range <>) of T;
end Simple_Generic_Array_Pkg;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Packages.
 ↪Simple_Generic_Array_Pkg
MD5: 55bce5b4a6106b2a50334190d5ae9405
```

As you can see, this definition is the same that we've seen in the previous section: we just moved it into a separate package. Now, we have a definition of Array_T that can be reused in multiple places.

The next step is to reuse the Simple_Generic_Array_Pkg package in the **Generic**_Reverse_Array procedure. By doing this, we can eliminate the declaration of the Index and Array_T types that we had before, since the definition will come from the Simple_Generic_Array_Pkg package.

In order to reuse the Simple_Generic_Array_Pkg package in the **Generic**_Reverse_Array procedure, we need to use a formal package parameter in the form:

```
with package P is new Simple_Generic_Array_Pkg(<params>)
```

This will allow us to reuse definitions from the generic package.

This is the updated version of the our test application for the reversing algorithm:

Listing 76: test_reverse_colors_simple_pkg.adb

```
with Ada.Text_IO;
use  Ada.Text_IO;

with Simple_Generic_Array_Pkg;

procedure Test_Reverse_Colors_Simple_Pkg is

   generic
      type T is private;
      with package P is new
        Simple_Generic_Array_Pkg (T      => T,
```

(continues on next page)

(continued from previous page)

```
                                    others => <>);
   procedure Reverse_Array (X : in out P.Array_T);

   procedure Reverse_Array (X : in out P.Array_T)
   is
      use P;
   begin
      for I in X'First ..
               (X'Last + X'First) / 2 loop
         declare
            Tmp     : T;
            X_Left  : T renames X (I);
            X_Right : T renames X
                           (X'Last + X'First - I);
         begin
            Tmp     := X_Left;
            X_Left  := X_Right;
            X_Right := Tmp;
         end;
      end loop;
   end Reverse_Array;

   type Color is (Black, Red, Green, Blue, White);

   package Color_Pkg is new
     Simple_Generic_Array_Pkg (T     => Color,
                               Index => Integer);

   procedure Reverse_Color_Array is new
     Reverse_Array (T => Color, P => Color_Pkg);

   My_Colors : Color_Pkg.Array_T (1 .. 5) :=
                 (Black, Red, Green, Blue, White);
begin
   for C of My_Colors loop
      Put_Line ("My_Color: " & Color'Image (C));
   end loop;

   New_Line;
   Put_Line ("Reversing My_Color...");
   New_Line;
   Reverse_Color_Array (My_Colors);

   for C of My_Colors loop
      Put_Line ("My_Color: " & Color'Image (C));
   end loop;

end Test_Reverse_Colors_Simple_Pkg;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Packages.
 ↪Simple_Generic_Array_Pkg
MD5: e3d2b8ceecf8cc61b03835fde1722800
```

Runtime output

```
My_Color: BLACK
My_Color: RED
My_Color: GREEN
My_Color: BLUE
```

(continues on next page)

(continued from previous page)

```
My_Color: WHITE

Reversing My_Color...

My_Color: WHITE
My_Color: BLUE
My_Color: GREEN
My_Color: RED
My_Color: BLACK
```

In this example, we're first instantiating the `Simple_Generic_Array_Pkg` package, thereby creating the `Color_Pkg` package. We then proceed to use this `Color_Pkg` package in the instantiation of the generic `Reverse_Array` procedure. Also, in the declaration of the `My_Colors` array, we make use of the array type definition from the `Color_Pkg` package.

Formal package parametrization

Note that we're using partial parametrization for the formal package parameter P in the previous example. Partial parametrization makes use of **`others => <>`** to indicate that the generic declaration takes the definitions from the package argument provided in the generic instantiation:

Listing 77: show_partial_parametrization.ads

```
with Simple_Generic_Array_Pkg;

package Show_Partial_Parametrization is

   generic
      type T is private;
      with package P is new
        Simple_Generic_Array_Pkg (T      => T,
                                  others => <>);
   procedure Reverse_Array (X : in out P.Array_T);

end Show_Partial_Parametrization;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Packages.
 ↪Simple_Generic_Array_Pkg
MD5: 604248e82e59e8a194cc188392e18617
```

For the previous example, the definitions come from the declarations of the `Color_Pkg` package:

A complete parametrization, in constrast, contains the definition of all types in the generic declaration. For example:

Listing 78: show_complete_parametrization.ads

```
with Simple_Generic_Array_Pkg;

package Show_Complete_Parametrization is

   generic
      type T is private;
      type Index is range <>;
      with package P is new
```

(continues on next page)

(continued from previous page)

```
9          Simple_Generic_Array_Pkg (T     => T,
10                                   Index => Index);
11    procedure Reverse_Array (X : in out P.Array_T);
12
13 end Show_Complete_Parametrization;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Packages.
 ↪Simple_Generic_Array_Pkg
MD5: 64a268ea779d4b767225b447ac76f33d
```

Another approach is to take all definitions from the formal package parameter:

Listing 79: show_box_parameter.ads

```
1  with Simple_Generic_Array_Pkg;
2
3  package Show_Box_Parameter is
4
5     generic
6        with package P is new
7          Simple_Generic_Array_Pkg (<>);
8     procedure Reverse_Array (X : in out P.Array_T);
9
10 end Show_Box_Parameter;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Packages.
 ↪Simple_Generic_Array_Pkg
MD5: 2c2a92699d829795c3b446c15e0cd304
```

In this case, package P contains all type and subprogram definitions that are used by the generic `Reverse_Array` procedure. By using the box syntax (`<>`), we indicate that we make use of all definitions from the formal package parameter.

Abstracting procedures into packages

In the previous example, we moved the array type definition into a separate package, but left the generic procedure (`Reverse_Array`) in the test application. We could also move the generic procedure into the generic package:

Listing 80: generic_array_pkg.ads

```
1  generic
2     type T is private;
3     type Index is range <>;
4  package Generic_Array_Pkg is
5     type Array_T is array (Index range <>) of T;
6
7     procedure Reverse_Array (X : in out Array_T);
8  end Generic_Array_Pkg;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Packages.
 ↪Generic_Array_Pkg
MD5: 7de92a2887bd931bdbfe309eb5b33d90
```

The advantage of this approach is that we don't need to repeat the formal declaration for the Reverse_Array procedure. Also, this simplifies the instantiation in the test application.

However, the disadvantage of this approach is that it also increases code size: every instantiation of the generic package generates code for each subprogram from the package. Also, compilation time tends to increase significantly. Therefore, developers must be careful when considering this approach.

Because we have a procedure declaration in the generic package, we need a corresponding package body. Here, we can simply reuse the existing code and move the procedure into the package body. In the test application, we just instantiate the **Generic**_Array_Pkg package and make use of the array type (Array_T) and the procedure (Reverse_Array):

```
Color_Pkg.Reverse_Array (My_Colors);
```

This is the generic package body:

Listing 81: generic_array_pkg.adb

```
1  package body Generic_Array_Pkg is
2     procedure Reverse_Array (X : in out Array_T) is
3     begin
4        for I in X'First ..
5                 (X'Last + X'First) / 2 loop
6           declare
7              Tmp     : T;
8              X_Left  : T renames X (I);
9              X_Right : T renames X
10                            (X'Last + X'First - I);
11          begin
12             Tmp     := X_Left;
13             X_Left  := X_Right;
14             X_Right := Tmp;
15          end;
16       end loop;
17    end Reverse_Array;
18 end Generic_Array_Pkg;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Packages.
 ↪Generic_Array_Pkg
MD5: 1c432546df692da33b9fa2305db174c3
```

Abstracting the test application

In the previous examples, we've focused only on abstracting the reversing algorithm. However, we could have decided to also abstract our little test application. This could be useful if we, for example, decide to test other procedures that change elements of an array.

In order to achieve this, we have to abstract quite a few elements. We will therefore declare the following formal parameters:

- the string S containing the array name;
- the formal **Generic**_Array_Pkg package parameter, which is a generic package implemented in the previous section;
- the formal Image function that converts an element of type T to a string;
- the formal Pkg_Test procedure that performs some operation on the array.

Note that Image and Pkg_Test are examples of formal subprograms, which have been discussed in the introductory course. Also, note that S is an example of a formal object, which we discuss in later section.

This is a version of the test application that makes use of the generic Perform_Test procedure:

Listing 82: test_reverse_colors_pkg.adb

```
with Ada.Text_IO;
use  Ada.Text_IO;

with Generic_Array_Pkg;

procedure Test_Reverse_Colors_Pkg is

   generic
      S : String;
      with package Array_Pkg is new
        Generic_Array_Pkg (<>);
      use Array_Pkg;
      with function Image (E : T)
                           return String is <>;
      with procedure Pkg_Test
             (X : in out Array_T);
   procedure Perform_Test (X : in out Array_T);

   procedure Perform_Test (X : in out Array_T) is
   begin
      for C of X loop
         Put_Line (S & ": " & Image (C));
      end loop;

      New_Line;
      Put_Line
        ("Performing operation on " & S & "...");
      New_Line;
      Pkg_Test (X);

      for C of X loop
         Put_Line (S & ": " & Image (C));
      end loop;
   end Perform_Test;

   type Color is (Black, Red, Green, Blue, White);

   package Color_Pkg is new
     Generic_Array_Pkg (T     => Color,
                        Index => Integer);

   My_Colors : Color_Pkg.Array_T (1 .. 5) :=
                 (Black, Red, Green, Blue, White);

   procedure Perform_Test_Reverse_Color_Array
   is new
     Perform_Test
       (S         => "My_Color",
        Image     => Color'Image,
        Array_Pkg => Color_Pkg,
        Pkg_Test  => Color_Pkg.Reverse_Array);
begin
   Perform_Test_Reverse_Color_Array (My_Colors);
end Test_Reverse_Colors_Pkg;
```

Code block metadata

```

 ↪Generic_Array_Pkg
MD5: a7101cddddfe709d9bf3269af101f759
```

Runtime output

```
My_Color: BLACK
My_Color: RED
My_Color: GREEN
My_Color: BLUE
My_Color: WHITE

Performing operation on My_Color...

My_Color: WHITE
My_Color: BLUE
My_Color: GREEN
My_Color: RED
My_Color: BLACK
```

In this example, we create the procedure `Perform_Test_Reverse_Color_Array` as an instance of the generic procedure (`Perform_Test`). Note that:

- For the formal `Image` function, we make use of the `Image` attribute of the `Color` type
- For the formal `Pkg_Test` procedure, we reference the `Reverse_Array` procedure from the package.

Note that this example includes a formal package declaration:

```
with package Array_Pkg is new
  Generic_Array_Pkg (<>);
```

Previously, we've seen package instantiations that define the elements. For example:

```
package Color_Pkg is new
  Generic_Array_Pkg (T     => Color,
                     Index => Integer);
```

In this case, however, we're simply using `(<>)`, as discussed in the section on *formal package parametrization* (page 1931). This means that `Perform_Test` makes use of the default definition used for the instance of `Generic_Array_Pkg`.

Cascading generic packages

In the code example from the previous section, we declared four formal parameters for the `Perform_Test` procedure. Two of them are directly related to the array that we're using for the test:

- S: the string containing the array name
- the function `Image` that converts an elements of the array to a string

We could abstract our implementation even further by moving these elements into a separate package named `Generic_Array_Bundle` and reference the `Generic_Array_Pkg` there. This would create a chain of generic packages:

```
Generic_Array_Bundle <= Generic_Array_Pkg
```

This strategy demonstrates that, in Ada, it is really straightforward to make use of generics in order to abstracts algorithms.

First, let us define the new Generic_Array_Bundle package, which references the Generic_Array_Pkg package and the two formal elements (S and Image) mentioned previously:

Listing 83: generic_array_bundle.ads

```
with Generic_Array_Pkg;

generic
   S : String;
   with package Array_Pkg is new
     Generic_Array_Pkg (<>);
   with function Image (E : Array_Pkg.T)
                        return String is <>;
package Generic_Array_Bundle is
end Generic_Array_Bundle;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Packages.
 ↪Generic_Array_Pkg
MD5: a76cae02d6396c023398830dc294f7c4
```

Then, we update the definition of Perform_Test:

Listing 84: test_reverse_colors_pkg.adb

```
with Ada.Text_IO;
use  Ada.Text_IO;

with Generic_Array_Pkg;
with Generic_Array_Bundle;

procedure Test_Reverse_Colors_Pkg is

   generic
      with package Array_Bundle is new
        Generic_Array_Bundle (<>);
      use Array_Bundle;
      use Array_Pkg;
      with procedure Pkg_Test
             (X : in out Array_T);
   procedure Perform_Test (X : in out Array_T);

   procedure Perform_Test (X : in out Array_T) is
   begin
      for C of X loop
         Put_Line (S & ": " & Image (C));
      end loop;

      New_Line;
      Put_Line ("Reversing " & S & "...");
      New_Line;
      Pkg_Test (X);

      for C of X loop
         Put_Line (S & ": " & Image (C));
      end loop;
   end Perform_Test;

   type Color is (Black, Red, Green, Blue, White);

```

(continues on next page)

(continued from previous page)

```
36    package Color_Pkg is new
37      Generic_Array_Pkg (T     => Color,
38                         Index => Integer);
39
40    My_Colors : Color_Pkg.Array_T (1 .. 5) :=
41                  (Black, Red, Green, Blue, White);
42
43    package Color_Array_Bundle is new
44      Generic_Array_Bundle
45        (S         => "My_Color",
46         Image     => Color'Image,
47         Array_Pkg => Color_Pkg);
48
49    procedure Perform_Test_Reverse_Color_Array
50    is new
51      Perform_Test
52        (Array_Bundle => Color_Array_Bundle,
53         Pkg_Test     => Color_Pkg.Reverse_Array);
54  begin
55    Perform_Test_Reverse_Color_Array (My_Colors);
56  end Test_Reverse_Colors_Pkg;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Packages.
 ↪Generic_Array_Pkg
MD5: 80d9beb1c60c1b7d0882b271353a5c01
```

Runtime output

```
My_Color: BLACK
My_Color: RED
My_Color: GREEN
My_Color: BLUE
My_Color: WHITE

Reversing My_Color...

My_Color: WHITE
My_Color: BLUE
My_Color: GREEN
My_Color: RED
My_Color: BLACK
```

Note that, in this case, we reduce the number of formal parameters to only two:

- `Array_Bundle`: an instance of the new `Generic_Array_Bundle` package
- the procedure `Pkg_Test` that we already had before

We could go even further and move `Perform_Test` into a separate package. However, this will be left as an exercise for the reader.

Signature Packages

Signature packages are used to group a set of types and subprograms that serve as a formal package parameter in another generic package. In the source-code examples of the previous section, we've seen the package `Generic_Array_Bundle`, which was used as a formal package for the generic procedure `Perform_Test`. `Generic_Array_Bundle` is an example of a signature package.

In this simple example, we define the signature package `Sig_Pkg`:

Listing 85: sig_pkg.ads

```
generic
   type T is private;
   with function Image (E : T)
                        return String is <>;
package Sig_Pkg is
end Sig_Pkg;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Packages.
 ↪Sig_Pkg
MD5: 0565dca6fecaf6c14c7bc743cf5614d7
```

As a standalone package, `Sig_Pkg` is not really useful. However, it becomes useful when used as a formal package in other generic declarations. For example, let's use this signature package for the generic procedure Show of a package P:

Listing 86: p.ads

```
with Sig_Pkg;

package P is
   generic
      with package SP is new Sig_Pkg (<>);
   procedure Show (V : SP.T);
end P;
```

Listing 87: p.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body P is
   procedure Show (V : SP.T) is
   begin
      Put_Line ("Value: " & SP.Image (V));
   end Show;
end P;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Packages.
 ↪Sig_Pkg
MD5: 31464b6554bbea03dae6755d2cfa1755
```

Finally, we can use this package in an application:

Listing 88: main.adb

```
with Sig_Pkg;
with P;
```

(continues on next page)

(continued from previous page)

```
3
4  procedure Main is
5     package Int_P is new Sig_Pkg (Integer,
6                                   Integer'Image);
7     procedure Show_Int is new P.Show (Int_P);
8
9     V : Integer;
10 begin
11    V := 42;
12    Show_Int (V);
13 end Main;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Packages.
 ↪Sig_Pkg
MD5: 9750b47b5961dad4f40f5288b9e16889
```

Runtime output

```
Value:  42
```

We can also use formal incomplete types for signature packages. For example:

Listing 89: formal_incomplete_type_example.ads

```
1  generic
2    type Incomplete;
3    with function "+" (V1, V2 : Incomplete)
4                       return Incomplete;
5    with function "-" (V1, V2 : Incomplete)
6                       return Incomplete;
7  package Formal_Incomplete_Type_Example
8    with Pure is
9  end Formal_Incomplete_Type_Example;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Packages.
 ↪Signature_Package_Formal_Incomplete_Type
MD5: a305f6c19a4210eff546d9ea943dbc0d
```

This allows us to map other formal incomplete types, for example:

Listing 90: map_incomplete_type_example.ads

```
1  with Formal_Incomplete_Type_Example;
2
3  generic
4     type T;
5     with package P is new
6       Formal_Incomplete_Type_Example
7         (T,
8          others => <>);
9  package Map_Incomplete_Type_Example
10   with Pure is
11 end Map_Incomplete_Type_Example;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Packages.
 ↪Signature_Package_Formal_Incomplete_Type
MD5: 733ba8b1deadbb345fccf372eafe2ca9
```

In general, signature packages aren't used in isolation, but in combination with other generic packages. Also, they don't define anything themselves. In this sense, signature packages don't have an associated package body.

Using signature packages is an useful approach to clean-up the declaration of generic packages or subprograms that contain many formal parameters. You may move these formal parameters into multiple signature packages, each one containing a group of formal parameters that belong together. Also, multiple signature packages can be cascaded to create more complex generic implementations.

102.3.4 Formal objects

Formal objects are used to bind objects to a generic specification. They are similar to parameters in subprograms and can have **in** or **in out** modes.

One of the simplest applications of formal objects is to use them to configure a generic subprogram or package during instantiation. For example, we can implement a generic function that processes an array of floating-point values and calculates an output value. This calculation is implemented in two versions:

- a standard version;
- a faster version that is less accurate than the standard version.

While the generic implementation offers both variants, developers can select the version that is more appropriate for their system during instantiation.

Listing 91: show_formal_object.adb

```
with Ada.Text_IO;
use  Ada.Text_IO;

procedure Show_Formal_Object is

   type Array_Float is
     array (Positive range <>) of Float;

   generic
      Use_Fast_Version : Boolean;
   function Gen_Calc (A : Array_Float)
                      return Float;

   function Gen_Calc (A : Array_Float)
                      return Float is
   begin
      if Use_Fast_Version then
         Put_Line ("Using fast version");
      else
         Put_Line ("Using standard version");
      end if;

      --  Implementation missing here...
      return 0.0;
   end Gen_Calc;

   function Calc is new
     Gen_Calc (Use_Fast_Version => True);
```

(continues on next page)

(continued from previous page)

```
29
30    Vals : Array_Float (1 .. 2) := (0.5, 0.3);
31    X    : Float;
32
33 begin
34    X := Calc (Vals);
35 end Show_Formal_Object;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Objects.
 ↪Formal_Object
MD5: c0673bbbda51207d472a2e01c810649a
```

Runtime output

```
Using fast version
```

In this example, we instantiate the *fast* version of `Gen_Calc`.

Input-output formal objects

Formal objects with **`in out`** mode are used to bind objects in an instance of a generic specification. For example, we may bind a global object from a package to the instantiation of a generic procedure, so that all calls to this instance make use of that object internally.

In the application below, we create a database using a container and bind it to procedures that display information from the database in a specific format.

The `Data_Elements` package describes the data fields of the data container. It also includes an `Image` function that returns a string based on the specified field.

Listing 92: data_elements.ads

```
1  with Ada.Calendar; use Ada.Calendar;
2
3  with Ada.Strings.Unbounded;
4  use  Ada.Strings.Unbounded;
5
6  package Data_Elements is
7
8     type Data_Element is record
9        First_Name : Unbounded_String;
10       Last_Name  : Unbounded_String;
11       Birthday   : Time;
12    end record;
13
14    type Data_Fields is
15      (First_Name_F, Last_Name_F,
16       Birthday_F, Age_F);
17
18    function Image (D : Data_Element;
19                    F : Data_Fields) return String;
20
21 end Data_Elements;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Objects.In_
 ↪Out_Formal_Object
MD5: a939466f9ea6809e15d1bf3e96154ef4
```

This is the corresponding package body:

Listing 93: data_elements.adb

```
with Ada.Calendar.Formatting;
use  Ada.Calendar.Formatting;

with Ada.Calendar.Time_Zones;
use  Ada.Calendar.Time_Zones;

package body Data_Elements is
   TZ   : Time_Offset := UTC_Time_Offset;

   function To_Year (D : Duration)
                     return Natural is
     (Natural (D) / 86_400 / 365);

   function Image (D : Data_Element;
                   F : Data_Fields)
                   return String is
      Now : Time := Clock;
      Age : Natural := To_Year (Now - D.Birthday);
   begin
      case F is
         when First_Name_F =>
           return To_String (D.First_Name);

         when Last_Name_F  =>
           return To_String (D.Last_Name);

         when Birthday_F   =>
           return Image (D.Birthday, True, TZ);

         when Age_F        =>
           return Natural'Image (Age);
      end case;
   end Image;

end Data_Elements;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Objects.In_
 ↪Out_Formal_Object
MD5: 134c8a87b7abba1a8cb0982933567ed9
```

Note that the age field in the Image function (represented by Age_F) isn't a field from the data container, but a calculated value instead.

The Data package below implements the data container using a vector. It includes the generic procedure Display that exhibits the information from the data container based on the fields specified by the developer at the procedure instantiation.

Listing 94: data.ads

```
with Ada.Containers;
with Ada.Containers.Vectors;

```

(continues on next page)

(continued from previous page)

```
with Data_Elements; use Data_Elements;

package Data is

   type Data_Container is private;

   procedure Insert (C : in out Data_Container;
                     V : Data_Element);

   type Data_Fields_Array is
     array (Positive range <>) of Data_Fields;

   generic
      Container : in out Data_Container;
      Fields    : Data_Fields_Array;
      Header    : String := "";
   procedure Display;

private

   package Vectors is new Ada.Containers.Vectors
     (Index_Type   => Natural,
      Element_Type => Data_Element);

   type Data_Container is record
      V : Vectors.Vector;
   end record;

end Data;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Objects.In_
 ↪Out_Formal_Object
MD5: 2b43548c05314b3d81f335eb7d655ea4
```

Note that, in addition to `Container`, which is a formal input-output object, we make use of the `Fields` and `Header` objects, which are formal input objects. Also, note that we could have declared `Container` as a parameter of `Display` instead of declaring it as a formal object:

```
generic
   Fields    : Data_Fields_Array;
   Header    : String := "";
procedure Display (Container : in out Data_Container);
```

In this case, we wouldn't be able to bind a local `Container` object to the instantiation of the `Display` procedure. Instead, we would always have to pass the container as an argument. Potentially, we could pass the wrong container to the procedure. By using a formal input-output object, we make sure that a specific object is bound to the procedure. This design decision ensures that we always have the same object being used in all calls to an instance of the `Display` procedure.

This is the corresponding body of the `Data` package:

Listing 95: data.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Data is

```

(continues on next page)

(continued from previous page)

```
   procedure Insert (C : in out Data_Container;
                     V : Data_Element) is
   begin
      C.V.Append (V);
   end Insert;

   procedure Display is
   begin
      if Header /= "" then
         Put_Line (Header);
         New_Line;
      end if;

      for E of Container.V loop
         for F of Fields loop
            Put (Image (E, F) & " ");
         end loop;
         New_Line;
      end loop;

      New_Line;
   end Display;

end Data;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Objects.In_
 ↪Out_Formal_Object
MD5: 4aee672c541c4d611c6d42daeb97bc91
```

Finally, we implement the `Test_Data_Container` procedure, which makes use of the data container:

Listing 96: test_data_container.adb

```
with Ada.Strings.Unbounded;
use  Ada.Strings.Unbounded;

with Ada.Calendar.Formatting;

with Data;          use Data;
with Data_Elements; use Data_Elements;

procedure Test_Data_Container is

   package App_Data_Container is

      --
      --  Data container for all operations.
      --
      C : Data_Container;

      --
      --  Display procedures are specific for
      --  the data container.
      --

      procedure Display_First_Name_Age is new
        Display (Container => C,
                 Fields    => (1 => First_Name_F,
```

(continues on next page)

(continued from previous page)

```
                                2 => Age_F),
                Header    => "FIRST_NAME AGE");

      procedure Display_Name_Birthday is new
        Display (Container => C,
                 Fields    => (1 => First_Name_F,
                               2 => Last_Name_F,
                               3 => Birthday_F),
                 Header    => "NAME BIRTHDAY");
   end App_Data_Container;

   use App_Data_Container;

   --
   --  Data container initialization
   --

   procedure Init_Container is
      function To_US (S : String)
                      return Unbounded_String
        renames
          To_Unbounded_String;
   begin
      Insert
        (C, (First_Name => To_US ("John"),
             Last_Name  => To_US ("Smith"),
             Birthday   =>
               Ada.Calendar.Formatting.Time_Of
                 (Year        => 1951,
                  Month       => 5,
                  Day         => 1)));

      Insert
        (C, (First_Name => To_US ("Alice"),
             Last_Name  => To_US ("Williams"),
             Birthday   =>
               Ada.Calendar.Formatting.Time_Of
                 (Year        => 1968,
                  Month       => 10,
                  Day         => 12)));
   end Init_Container;

begin
   Init_Container;

   Display_First_Name_Age;
   Display_Name_Birthday;

end Test_Data_Container;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Objects.In_
 ↪Out_Formal_Object
MD5: 6aa7d4bc7346ad4c94e262d0ae147eea
```

In this example, we declare the data container `C` and bind it to two instantiations of the `Display` procedure:

- `Display_First_Name_Age`, which displays the first name and age of each person from the database;

- `Display_Name_Birthday`, which displays the full name and birthday of each person.

102.3.5 Formal definite and indefinite types

Relevant topics

- **discriminants**
  - `A'Constrained`

102.3.6 Formal incomplete type

Relevant topics

- Formal incomplete type mentioned in Formal Types[486]

102.3.7 Default subtype mark

Relevant topics

- Default subtype mark (**`or use`**) mentioned in Formal Types[487]

102.3.8 Formal private and derived types

Relevant topics

- Formal Private and Derived Types[488]

102.3.9 Formal interfaces

Generating subprogram specifications

Formal interfaces can be used to generate a collection of pre-defined subprograms for new types. For example, let's suppose that, for a given type T, we need at least a pair of subprograms that set and get elements of type T based on another type. We might want to convert back and forth between the types T and **`Integer`**. In addition, we might want to convert from and to other types (e.g., **`Float`**). To implement this, we can define the following generic interface:

[486] http://www.ada-auth.org/standards/22rm/html/RM-12-5.html
[487] http://www.ada-auth.org/standards/22rm/html/RM-12-5.html
[488] http://www.ada-auth.org/standards/22rm/html/RM-12-5-1.html

Listing 97: gen_interface.ads

```
package Gen_Interface is

   generic
      type TD is private;
      type TI is interface;
   package Set_Get is
      type T is interface and TI;

      procedure Set (E : in out T;
                     D :        TD) is abstract;
      function Get (E : T)
                    return TD is abstract;
   end Set_Get;

end Gen_Interface;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Interfaces.
↪Gen_Interface
MD5: 38b5f63212d4b2cd3b8cae5f25aa5dd5
```

In this example, the package Set_Get defines subprograms that allow converting from any definite type (TD) and the interface type (TI).

We then proceed to declare packages for converting between **Integer** and **Float** types and the interface type. Also, we declare an actual tagged type that combines these conversion subprograms into a single type:

Listing 98: my_type_pkg.ads

```
with Gen_Interface;

↪Gen_Interface
MD5: 037d367000b95cf97bf73cffe68c5f70
```

First, we declare the packages `Set_Get_Integer` and `Set_Get_Float` based on the generic `Set_Get` package. Next, we declare `My_Type` based on the interface type from these two packages. By doing this, `My_Type` now needs to implement the actual conversion from and to **`Integer`** and **`Float`** types.

Note that, in the private part of `My_Type`, we're storing the floating-point and integer representations that we receive in the calls to the `Set` procedures. However, we could have complex data as well and just use conversion subprograms to provide a simplified representation of the complex data.

This is just an example on how we could implement these `Set` and `Get` subprograms:

Listing 99: my_type_pkg.adb

```
package body My_Type_Pkg is

   procedure Set (E : in out My_Type;
                  D :        Integer) is
   begin
      E.I := D;
      E.F := Float (D);
   end Set;

   function Get (E : My_Type)
                 return Integer is
   begin
      return E.I;
   end Get;

   procedure Set (E : in out My_Type;
                  D :        Float) is
   begin
      E.F := D;
      E.I := Integer (D);
   end Set;

   function Get (E : My_Type)
                 return Float is
   begin
      return E.F;
```

(continues on next page)

(continued from previous page)

```
27    end Get;
28
29 end My_Type_Pkg;
```

```

Facilitating arrays of interfaces

Formal interfaces can facilitate the handling of arrays of interface types. Let's consider an interface type TI and the derived tagged types T and T2. We may declare arrays containing elements that access the TI class. These arrays can be initialized with elements that access types T or T2. Also, we may process these arrays with an operation Op using the API of the TI interface.

Listing 101: ti_pkg.ads

```
1  package TI_Pkg is
2
3     type TI is interface;
4
5     procedure Op (E : in out TI) is abstract;
6
7     type TI_Class_Access is
8       access all TI'Class;
9
10    type TI_Array is
11      array (Positive range <>) of TI_Class_Access;
12
13    procedure Op (A : in out TI_Array);
14
15 end TI_Pkg;
```

Listing 102: ti_pkg.adb

```
package body TI_Pkg is

   procedure Op (A : in out TI_Array) is
   begin
      for E of A loop
         E.Op;
      end loop;
   end Op;

end TI_Pkg;
```

Listing 103: t_pkg.ads

```
with TI_Pkg; use TI_Pkg;

package T_Pkg is

   type T is new
     TI with null record;

   type T_Class_Access is
     access all T'Class;

   type T_Array is
     array (Positive range <>) of T_Class_Access;

   --  Missing implementation
   procedure Op (E : in out T) is null;

   type T2 is new T with null record;

   --  Missing implementation
   procedure Op (E : in out T2) is null;

end T_Pkg;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Interfaces.
↪Interface_Array
MD5: c208f22e16177feb22263caaaeefbde9
```

This is a test application that declares an array A of the interface type TI and calls Op for A:

Listing 104: test_t.adb

```
with TI_Pkg; use TI_Pkg;
with T_Pkg;  use T_Pkg;

procedure Test_T is

   A : TI_Array (1 .. 3) :=
         (1 => new T,
          2 => new T2,
          3 => new T);

begin

   Op (TI_Array (A));

```

(continues on next page)

(continued from previous page)

```
15 end Test_T;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Interfaces.
 ↪Interface_Array
MD5: 033474d9262d6a410dc39371960b7163
```

This example doesn't work if we use an array of the derived type T:

```
with TI_Pkg; use TI_Pkg;
with T_Pkg;  use T_Pkg;

procedure Test_T is

   A : T_Array (1 .. 3) :=
         (1 => new T,
          2 => new T2,
          3 => new T);

begin

   Op (A);

end Test_T;
```

This is incorrect because Op expects an array of type TI, not T. Even if the type T is derived from TI, the corresponding array type is not. Formal interfaces can be used to create a generic version of Op that operates directly on an array of type T. Let's look at an example.

The example below calculates the average of interface types that are *convertible* to floating-point values. We consider that a type is convertible to floating-point if it provides a To_Float function. This is implemented with the Float_Cnvt_Type interface. We also declare a generic package containing the Average function, which calculates the average of an array containing elements of a *convertible type* (i.e. any type derived from the Float_Cnvt_Type interface).

Listing 105: float_interface_pkg.ads

```
1  package Float_Interface_Pkg is
2
3     type Float_Cnvt_Type is interface;
4     function To_Float (E : Float_Cnvt_Type)
5                        return Float is abstract;
6
7  end Float_Interface_Pkg;
```

Listing 106: float_interface_pkg-ops.ads

```
1  generic
2     type Float_Cnvt_T is new
3       Float_Cnvt_Type with private;
4     type Float_Cnvt_Class_Access is
5       access all Float_Cnvt_T'Class;
6     type Float_Cnvt_Array is
7       array (Positive range <>) of
8         Float_Cnvt_Class_Access;
9  package Float_Interface_Pkg.Ops is
10
11    function Average (A : Float_Cnvt_Array)
```

(continues on next page)

(continued from previous page)

```

procedure Show_Average is
```

(continues on next page)

(continued from previous page)

```
7
8     package Ops is new Float_Interface_Pkg.Ops
9       (Float_Cnvt_T            => T,
10       Float_Cnvt_Class_Access => T_Class_Access,
11       Float_Cnvt_Array        => T_Array);
12
13    A : T_Array (1 .. 3) :=
14          (1 => new T,
15           2 => new T2,
16           3 => new T);
17
18    Avg : Float;
19 begin
20    for I in A'Range loop
21       A (I).Set (1.0);
22
23       if A (I).all in T2'Class then
24          declare
25             A_I : T2_Class_Access :=
26                      T2_Class_Access (A (I));
27          begin
28             A_I.Set_Ext (3.0);
29          end;
30       end if;
31    end loop;
32
33    Avg := Ops.Average (A);
34
35    Put_Line ("Avg: " & Float'Image (Avg));
36
37 end Show_Average;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Interfaces.
 ↪Float_Interface_Pkg
MD5: 07eccebea13b79c5e8376da3e43b6eba
```

Runtime output

```
Avg:  2.00000E+00
```

In this example, we declare the array A with elements of both T and T2 types. After initializing the elements of A, we call the Average function from Ops, an instance of the generic package `Float_Interface_Pkg.Ops`.

Discussion: formal interfaces vs. other approaches

In Ada, we basically have three approaches to describe interfaces for generic types. In addition to the approach using formal interfaces that we've just seen above, we also have these approaches:

- Formal subprograms, which we've presented in the introductory course (in the *chapter about generics* (page 128) of the Introduction to Ada course).
- Signature packages, which we've discussed in a *previous section* (page 1938).

Let's briefly recapitulate these approaches:

Listing 111: interface_approaches.ads

```
package Interface_Approaches is

   -------------------------------
   --  Using Formal Subprograms --
   -------------------------------
   package Using_Formal_Subprograms is

      generic
         type T is private;
         with procedure P (E : T) is <>;
      package Pkg is
      end Pkg;

   end Using_Formal_Subprograms;

   -------------------------------
   --  Using Signature Packages --
   -------------------------------
   package Using_Signature_Packages is

      generic
         type T2;
         with procedure P (E : T2) is <>;
      package Sig_Pkg is
      end Sig_Pkg;

      generic
         type T is private;
         with package SP is new Sig_Pkg (T, <>);
      package Pkg is
      end Pkg;

   end Using_Signature_Packages;

   -------------------------
   --  Using Tagged Types --
   -------------------------
   package Using_Tagged_Types is

      type I is interface;
      procedure P (E : I) is abstract;

      generic
         type T is new I with private;
      package Pkg is
      end Pkg;

   end Using_Tagged_Types;

end Interface_Approaches;
```

Code block metadata

```

 ↪Interface_Approaches
MD5: 2a41eb250e30d6a60deb4406ed273697
```

The following subsections discuss the pros and cons of each approach. For the source-code examples, we'll implement a generic hash table.

Interfaces using formal subprograms

Formal subprograms, combined with a formal type, can be used to define an implicit interface. Let's look at the implementation of a generic hash table:

Listing 112: interface_using_formal_function.ads

```
with Ada.Containers; use Ada.Containers;

package Interface_Using_Formal_Function is

   generic
      type T is private;
      with function Hash (Self : T)
                          return Hash_Type is <>;
   package Hash_Tables is
      --  Missing implementation
   end Hash_Tables;

end Interface_Using_Formal_Function;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Interfaces.
↪Interface_Using_Formal_Function
MD5: a879c3e6f938fe35336667e390981633
```

In contrast to formal interfaces, the interface described with formal subprograms is implicit: we don't have an explicit **interface** type defined here. However, the combination of type T and the function Hash represent an interface.

The fact that we don't declare an explicit interface has the disadvantage of not being as obvious as when the **interface** keyword is used in the code. Developers are forced to recognize the design pattern: they have to deduce that the intention of declaring T and Hash is to define an interface. However, this approach has the advantage of not requiring the use of tagged types in the package instantiation.

This is an example of a package instantiating the generic hash table:

Listing 113: instantiation_using_formal_function.ads

```
with Ada.Containers; use Ada.Containers;
with Ada.Strings.Hash;

with Interface_Using_Formal_Function;
use  Interface_Using_Formal_Function;

package Instantiation_Using_Formal_Function is

   type My_Type is record
      Key   : String (1 .. 100);
      Key_2 : String (1 .. 100);
   end record;

   function Hash (Self : My_Type)
                  return Hash_Type is
     (Ada.Strings.Hash (Self.Key));

   function Alt_Hash (Self : My_Type)
                      return Hash_Type is
     (Ada.Strings.Hash (Self.Key_2));

```

(continues on next page)

(continued from previous page)

```
   package My_Type_Hash_Tables is new
     Hash_Tables (My_Type);

   package My_Type_Alt_Hash_Tables is new
     Hash_Tables (T    => My_Type,
                  Hash => Alt_Hash);

end Instantiation_Using_Formal_Function;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Interfaces.
 ↪Interface_Using_Formal_Function
MD5: dab3415d33c1ea08e11a2fa3311f31b7
```

Note that, in the declaration of the `My_Type_Hash_Tables`, we're not specifying the `Hash` function for the instantiation of the generic `Hash_Tables` package. This is possible for two reasons:

- In the declaration of the formal function parameter, we're using **`is <>`**, which automatically selects a function with the same name and a compatible signature in the package instantiation if available.
- For `My_Type`, we've declared a function that has the same name as the formal function and the expected signature.

If the above-mentioned conditions are not met, we have to provide an argument for the formal function parameter in the package instantiation.

We may also instantiate the formal package using alternative versions of the function associated with the formal package. This is what we're doing in the declaration of the `My_Type_Alt_Hash_Tables` package. In this case, we're using `Alt_Hash` instead of `Hash` for the formal function parameter. Note that, because the name of the actual function doesn't match the name of the formal function, we need to indicate it explicitly.

Interfaces using signature packages

The basic form of signature packages is similar to the approach we've just seen using formal subprograms: a signature package defines an interface using a formal type and formal subprograms.

Signature packages make it more explicit that the types and subprograms defined in the package represent an interface. This is an advantage over the approach using formal subprograms directly. However, using signature package isn't as explicit as using the **`interface`** keyword.

As mentioned before, signature packages aren't used in isolation, but in combination with other generic packages. Also, they don't define anything themselves. These features might provide a hint that a package is used to represent an interface.

Let's look at the implementation of a generic hash table using a signature package:

Listing 114: interface_using_signature_package.ads

```
with Ada.Containers; use Ada.Containers;

package Interface_Using_Signature_Package is

   generic
      type Element;
```

(continues on next page)

(continued from previous page)

```
      with function Hash (Self : Element)
                           return Hash_Type is <>;
   package Hashable_Signature is
   end Hashable_Signature;

   generic
      type T is private;
      with package T_Hashable is new
        Hashable_Signature (T, <>);
   package Hash_Tables is
      --  Missing implementation
   end Hash_Tables;

end Interface_Using_Signature_Package;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Interfaces.
 ↪Interface_Using_Signature_Package
MD5: 7605b79b134de4dacb46f209a0667e0a
```

Note that this approach is more verbose than the previous one using formal subprograms directly. In this case, we have to declare two generic packages instead of one.

This is an example of a package instantiating a signature package and the generic hash table:

Listing 115: instantiation_using_signature_package.ads

```
with Ada.Containers; use Ada.Containers;
with Ada.Strings.Hash;

with Interface_Using_Signature_Package;
use  Interface_Using_Signature_Package;

package Instantiation_Using_Signature_Package is

   type My_Type is record
      Key   : String (1 .. 100);
      Key_2 : String (1 .. 100);
   end record;

   function Hash (Self : My_Type)
                  return Hash_Type is
     (Ada.Strings.Hash (Self.Key));

   function Alt_Hash (Self : My_Type)
                      return Hash_Type is
     (Ada.Strings.Hash (Self.Key_2));

   package My_Type_Hashable is new
     Hashable_Signature (My_Type, Hash);

   package My_Type_Hash_Tables is new
     Hash_Tables (My_Type, My_Type_Hashable);

   package My_Type_Alt_Hashable is new
     Hashable_Signature (My_Type, Alt_Hash);

   package My_Type_Alt_Hash_Tables is new
     Hash_Tables (My_Type, My_Type_Alt_Hashable);
```

(continues on next page)

(continued from previous page)

```
33
34 end Instantiation_Using_Signature_Package;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Interfaces.
 ↪Interface_Using_Signature_Package
MD5: 6ddc6ef10095b7c328cdf71a79bef468
```

This approach shares the same advantage listed for the previous approach: we may use any type, not only tagged types for instantiating the generic package. However, when using signature packages, the generic package instantiation also becomes more verbose: we have to instantiate two packages instead of one to achieve the same result. For the example above, we first declare the `My_Type_Hashable` package and use it in the declaration of the `My_Type_Hash_Tables` package.

The advantage of this approach is that the instantiation of the actual package (the hash table in our example) is simplified: instead of passing all formal subprograms as parameters to `My_Type_Hash_Tables`, we only need to specify the signature package which contains the complete interface. When implementing complex interfaces, this approach might lead to a cleaner design than the previous approach using formal subprograms directly.

Similar to the previous approach, we may also instantiate the formal package using alternative versions of the function associated with the formal package. This is what we're doing in the declaration of the `My_Type_Alt_Hash_Tables` package.

Interfaces using tagged types

Finally, let's discuss the design of generic packages using formal interfaces and tagged types. In contrast to the two approaches mentioned above, formal interfaces explicitly indicate what's the interface in the implementation through the **`interface`** keyword. No interpretation of design patterns is needed in this case.

For the approaches we've discussed earlier (using formal subprograms and signature packages), we were free to use any type in the instantiation of the generic package. However, for generic packages using formal interfaces, we can only use tagged types in the instantiation. This may be a serious restriction, especially if we have to deal with existing code containing types that are *not* tagged. Fortunately, in this case, we can use the previous approaches to implement interfaces.

Let's look at the implementation of a generic hash table using a formal interface:

Listing 116: interface_using_tagged_types.ads

```
1  with Ada.Containers; use Ada.Containers;
2
3  package Interface_Using_Tagged_Types is
4
5     type Hashable is interface;
6     function Hash (Self : Hashable)
7                    return Hash_Type is abstract;
8
9     generic
10       type T is new Hashable with private;
11    package Hash_Tables is
12       --  Missing implementation
13    end Hash_Tables;
14
15 end Interface_Using_Tagged_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Interfaces.
 ↪Interface_Using_Tagged_Types
MD5: 9c95e8b832067b99949d2bbf91ee1dde
```

This is an example of a package instantiating the generic hash table using a tagged type:

Listing 117: instantiation_using_tagged_types.ads

```
with Ada.Containers; use Ada.Containers;
with Ada.Strings.Hash;

with Interface_Using_Tagged_Types;
use  Interface_Using_Tagged_Types;

package Instantiation_Using_Tagged_Types is

   type My_Type is new Hashable with record
      Key   : String (1 .. 100);
      Key_2 : String (1 .. 100);
   end record;

   function Hash (Self : My_Type)
                  return Hash_Type is
     (Ada.Strings.Hash (Self.Key));

   package My_Type_Hash_Tables is new
     Hash_Tables (My_Type);

end Instantiation_Using_Tagged_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Interfaces.
 ↪Interface_Using_Tagged_Types
MD5: 76939a8a60a27c4e9aa18c3dba8aa97b
```

The instantiation of generic packages is much simpler in this case: we don't have to pass operations as parameters in the package instantiation. In this example, the declaration of My_Type_Hash_Tables is very straightforward: we just have to specify the tagged type (My_Type). All operations are *implicitly defined* in the tagged type, so we don't have to specify them. Conversely, we're bound to use the implementation associated with the type. We cannot easily replace Hash by Alt_Hash as in the previous approaches. In order to do that, we have to declare a derived type and override the Hash function. This is how we may create the My_Type_Alt_Hash_Tables package using the alternative hashing function, as we did in the previous approaches:

Listing 118: instantiation_using_alt_tagged_types.ads

```
with Ada.Containers;   use  Ada.Containers;
with Ada.Strings.Hash;

with Interface_Using_Tagged_Types;
use  Interface_Using_Tagged_Types;

with Instantiation_Using_Tagged_Types;
use  Instantiation_Using_Tagged_Types;

package Instantiation_Using_Alt_Tagged_Types is

   type My_Alt_Type is new
```

(continues on next page)

(continued from previous page)

```
13       My_Type with null record;
14
15    overriding function Hash (Self : My_Alt_Type)
16                              return Hash_Type is
17       (Ada.Strings.Hash (Self.Key_2));
18
19    package My_Type_Alt_Hash_Tables is new
20       Hash_Tables (My_Alt_Type);
21
22 end Instantiation_Using_Alt_Tagged_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Interfaces.
 ↪Interface_Using_Tagged_Types
MD5: 88014f5c7009149787c7e0df6dad58a7
```

In this example, the Hash function of the `My_Alt_Type` type corresponds to the `Alt_Hash` function that we implemented in the previous approaches.

Formal synchronized interfaces

Formal synchronized interfaces are a specialized case of formal interfaces that can be used for task types and protected types. Since formal synchronized interfaces are similar to formal interfaces, we can reuse the previous source-code example with minimal adaptations.

When adapting the `Gen_Interface` package, we just need to make use of the **`synchronized`** keyword:

Listing 119: gen_sync_interface.ads

```
1  package Gen_Sync_Interface is
2
3     generic
4        type TD is private;
5        type TI is synchronized interface;
6     package Set_Get is
7        type T is synchronized interface and TI;
8
9        procedure Set (E : in out T;
10                      D :        TD) is abstract;
11       function Get (E : T)
12                    return TD is abstract;
13    end Set_Get;
14
15 end Gen_Sync_Interface;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Interfaces.
 ↪Formal_Synchronized_Interfaces
MD5: 3bd70e5996554365758f533161cb0ab1
```

Note that we're also renaming some packages (e.g., renaming `Gen_Interface` to `Gen_Sync_Interface`) to better differentiate between them. This approach is used in the adaptations below as well.

When adapting the `My_Type_Pkg`, we again need to make use of the **`synchronized`** keyword. Also, we need to declare `My_Type` as a protected type and adapt the subprogram

and component declarations. Note that we could have used a task type instead. This is the adapted package:

Listing 120: my_sync_type_pkg.ads

```
with Gen_Sync_Interface;

package My_Sync_Type_Pkg is

   type My_Type_Interface is
     synchronized interface;

   package Set_Get_Integer is new
     Gen_Sync_Interface.Set_Get
       (TD => Integer,
        TI => My_Type_Interface);
   use Set_Get_Integer;

   package Set_Get_Float is new
     Gen_Sync_Interface.Set_Get
       (TD => Float,
        TI => My_Type_Interface);
   use Set_Get_Float;

   protected type My_Type is new
     Set_Get_Integer.T and Set_Get_Float.T with

      overriding procedure Set (D : Integer);
      function Get return Integer;

      overriding procedure Set (D : Float);
      function Get return Float;
   private
      I : Integer;
      F : Float;
   end My_Type;

end My_Sync_Type_Pkg;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Interfaces.
 ↪Formal_Synchronized_Interfaces
MD5: 4e42c16d1a0cc13e4e7549fe42a1628e
```

In the package body, we just need to adapt the access to components in the subprograms:

Listing 121: my_sync_type_pkg.adb

```
package body My_Sync_Type_Pkg is

   protected body My_Type is
      procedure Set (D : Integer) is
      begin
         I := D;
         F := Float (D);
      end Set;

      function Get return Integer is
      begin
         return I;
      end Get;
```

(continues on next page)

(continued from previous page)

```
14
15       procedure Set (D : Float) is
16       begin
17          F := D;
18          I := Integer (D);
19       end Set;
20
21       function Get return Float is
22       begin
23          return F;
24       end Get;
25    end My_Type;
26
27 end My_Sync_Type_Pkg;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Interfaces.
↪Formal_Synchronized_Interfaces
MD5: da3c5646a386dba9e7a2fc5d33efec3d
```

Finally, the main application doesn't require adaptations:

Listing 122: show_gen_sync_interface.adb

```
1 with My_Sync_Type_Pkg; use My_Sync_Type_Pkg;
2
3 procedure Show_Gen_Sync_Interface is
4    C : My_Type;
5 begin
6    C.Set (2);
7    C.Set (2.1);
8 end Show_Gen_Sync_Interface;
```

102.3.10 Formal numeric types

Ada supports the use of numeric types for generics. This can be used to describe a numeric algorithm independently of the actual data type. We'll see examples below.

This is the corresponding syntax:

- For floating-point types: `type T is digits <>;`
- For binary fixed-point type: `type T is delta <>;`
- For decimal fixed-point types: `type T is delta <> digits <>;`

In this section, we discuss generic floating-point and binary fixed-point types.

Formal floating-point types

Simple generic package

Let's look at an example of a generic package containing a procedure that *saturates* floating-point numbers. In this code, we work with a normalized range between -1.0 and 1.0. Due to the fact that some calculations might lead to results outside this range, we use the `Saturate` procedure to put values back into the normalized range.

This is the package specification:

Listing 123: gen_float_ops.ads

```
generic
   type F is digits <>;
package Gen_Float_Ops is
   procedure Saturate (V : in out F);
end Gen_Float_Ops;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
 ↪Types.Generic_Float
MD5: 3c921d920672f13af6968be8a13ac87e
```

This is the package body:

Listing 124: gen_float_ops.adb

```
package body Gen_Float_Ops is

   procedure Saturate (V : in out F) is
   begin
      if V > 1.0 then
         V := 1.0;
      elsif V < -1.0 then
         V := -1.0;
      end if;
   end Saturate;

end Gen_Float_Ops;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
 ↪Types.Generic_Float
MD5: 509e13c06a7a32ff64b2ee9a979fbf16
```

Finally, we create a test application:

Listing 125: show_float_ops.adb

```
with Ada.Text_IO;    use Ada.Text_IO;
with Gen_Float_Ops;

procedure Show_Float_Ops is

   package Float_Ops is new
     Gen_Float_Ops (F => Float);
   use Float_Ops;

   package Long_Float_Ops is new
```

(continues on next page)

(continued from previous page)

```
     Gen_Float_Ops (F => Long_Float);
   use Long_Float_Ops;

   F  : Float := 0.5;
   LF : Long_Float := -0.5;

begin
   F  := F + 0.7;
   LF := LF - 0.7;

   Put_Line ("F:  " & Float'Image (F));
   Put_Line ("LF: " & Long_Float'Image (LF));

   Saturate (F);
   Saturate (LF);

   Put_Line ("F:  " & Float'Image (F));
   Put_Line ("LF: " & Long_Float'Image (LF));

end Show_Float_Ops;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
 ↪Types.Generic_Float
MD5: 3a6da3dc103b19dce58f2147daad87e9
```

Runtime output

```
F:   1.20000E+00
LF: -1.20000000000000E+00
F:   1.00000E+00
LF: -1.00000000000000E+00
```

In this application, we create two instances of the `Gen_Float_Ops` package: one for the **`Float`** type and one for the **`Long_Float`** type. We then make use of computations whose results are outside the normalized range. By calling the `Saturate` procedure, we ensure that the values are inside the range again.

Operations in generic packages

In this section, we discuss how to declare operations associated with floating-point types in generic packages.

Let's first define a package that implements a new type `My_Float` based on the standard **`Float`** type. For this type, we override the addition operator with an implementation that saturates the value after the actual addition.

This is the package specification:

Listing 126: float_types.ads

```
package Float_Types is

   type My_Float is new Float;
   function "+" (A, B : My_Float) return My_Float;

end Float_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
 ↪Types.Float_Types
MD5: 66f207e01db4a4deaaae738986a93b96
```

This is the corresponding package body:

Listing 127: float_types.adb

```
package body Float_Types is

   procedure Saturate (V : in out My_Float) is
   begin
      if V > 1.0 then
         V := 1.0;
      elsif V < -1.0 then
         V := -1.0;
      end if;
   end Saturate;

   overriding function "+" (A, B : My_Float)
                            return My_Float is
   begin
      return R : My_Float do
         R := My_Float (Float (A) + Float (B));
         Saturate (R);
      end return;
   end "+";

end Float_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
 ↪Types.Float_Types
MD5: 5cde49311153ce0723fe46433e875450
```

Next, we create a package containing a procedure that accumulates floating-point values. This is the package specification:

Listing 128: gen_float_acc.ads

```
generic
   type F is digits <>;
   with function "+" (A, B : F) return F is <>;
package Gen_Float_Acc is
   procedure Acc (V : in out F; S : F);
end Gen_Float_Acc;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
 ↪Types.Float_Types
MD5: 3c7b794df56e0f520eec62cb72c57d0b
```

In this specification, we declare a formal function for the addition operator using `with function`. This operator is used by the Acc procedure in the package body. Also, because we use <> in the specification, the corresponding addition operator for type F is selected.

This is the package body:

Listing 129: gen_float_acc.adb

```
package body Gen_Float_Acc is

   procedure Acc (V : in out F; S : F) is
   begin
      V := V + S;
   end Acc;

end Gen_Float_Acc;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
 ↪Types.Float_Types
MD5: 99b22670c5f6cf233d43d9b0844be6ce
```

This is a test application that makes use of the Float_Types and Gen_Float_Acc packages.

Listing 130: show_float_overriding.adb

```
with Ada.Text_IO;    use Ada.Text_IO;

with Float_Types; use Float_Types;
with Gen_Float_Acc;

procedure Show_Float_Overriding is

   package Float_Ops is new
     Gen_Float_Acc (F => My_Float);
   use Float_Ops;

   F1, F2 : My_Float := 0.5;

begin
   Put_Line ("F1:  " & My_Float'Image (F1));
   Put_Line ("F2:  " & My_Float'Image (F2));

   Acc (F1, 3.0);
   F2 := F2 + 3.0;

   Put_Line ("F1:  " & My_Float'Image (F1));
   Put_Line ("F2:  " & My_Float'Image (F2));

end Show_Float_Overriding;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
 ↪Types.Float_Types
MD5: 9ede9e75a2ef3f35ef7c5a7b15aba415
```

Runtime output

```
F1:   5.00000E-01
F2:   5.00000E-01
F1:   1.00000E+00
F2:   1.00000E+00
```

We create an instance of the Gen_Float_Acc by using the My_Float type declared in the Float_Types package. Because we used <> in the specification of **function** "+" (in the Gen_Float_Acc package), the compiler will automatically select the addition operator that

we've overriden in the Float_Types package, so that we don't need to specify it in the package instantiation.

The main reason for the formal subprogram in the specification of the Gen_Float_Acc package is that it prevents the compiler from selecting the standard operator. We could have removed the **function** "+" from the specification, as illustrated in the example below, where we modified the Gen_Float_Acc package:

```
generic
   type F is digits <>;
   --  no "with function" here!
package Gen_Float_Acc is
   procedure Acc (V : in out F; S : F);
end Gen_Float_Acc;

package body Gen_Float_Acc is

   procedure Acc (V : in out F; S : F) is
   begin
      --  Using standard addition for universal
      --  floating-point type (digits <>) here:
      V := V + S;
   end Acc;

end Gen_Float_Acc;
```

In this case, however, even though we declared a custom addition operator for the My_Float type in the Float_Types package, an instantiation of the modified Gen_Float_Acc package would always make use of the standard addition:

```
--  This makes use of the type definition of
--  My_Float, but not its overridden operators.
package Float_Ops is new
  Gen_Float_Acc (F => My_Float);
```

Because the type F is declared as **digits** <>, which corresponds to the universal floating-point data type, the compiler selects operators associated with the universal floating-point data type in the package body. By specifying the formal subprogram, we make sure that the operator associated with the actual type is used.

Alternatively, we could make use of the Float_Types package directly in the generic package. For example:

Listing 131: gen_float_acc.ads

```
1 with Float_Types; use Float_Types;
2
3 generic
4    type F is new My_Float;
5 package Gen_Float_Acc is
6    procedure Acc (V : in out F; S : F);
7 end Gen_Float_Acc;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
 ↪Types.Float_Types
MD5: 466368b61162f357805371de4732a4e6
```

In this case, because the formal type is now based on My_Float, the corresponding operator for My_Float is used in the Acc procedure.

Formal fixed-point types

Simple generic package

In the previous section, we looked into an example of saturation for generic floating-point types. Let's adapt this example for fixed-point types. This is the package specification:

Listing 132: gen_fixed_ops.ads

```
generic
   type F is delta <>;
package Gen_Fixed_Ops is
   function Sat_Add (V1, V2 : F) return F;
end Gen_Fixed_Ops;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
 ↪Types.Generic_Fixed
MD5: 461295f9c581128c2d83d6b1aa591108
```

For the fixed-point version, we specify the normalized range in the definition of the data type. Therefore, any computation that leads to values out of the normalized range will raise a `Constraint_Error` exception. In order to circumvent this, we can declare a fixed-point data type with a wider range and use it in combination with the actual operation that we want to perform -- an addition, in this case. This approach can be seen in the implementation of `Sat_Add`, which computes the addition using the local `Ovhd_Fixed` type with wider range, calls the `Saturate` procedure and converts the data type back into the original range.

Listing 133: gen_fixed_ops.adb

```
with Ada.Text_IO;    use Ada.Text_IO;

package body Gen_Fixed_Ops is

   Ovhd_Depth : constant Positive := 64;
   Ovhd_Bits  : constant := 32;
   Ovhd_Delta : constant :=
                  2.0 ** Ovhd_Bits /
                  2.0 ** (Ovhd_Depth - 1);

   type Ovhd_Fixed is delta Ovhd_Delta range
     -2.0 ** Ovhd_Bits ..
      2.0 ** Ovhd_Bits - Ovhd_Delta
        with Size => Ovhd_Depth;

   --  Ensure that Ovhd_Fixed has enough headroom
   pragma Assert (Ovhd_Fixed'First <=
                  2.0 * Ovhd_Fixed (F'First));
   pragma Assert (Ovhd_Fixed'Last  >=
                  2.0 * Ovhd_Fixed (F'Last));

   --  Ensure that the precision is at least
   --  the same
   pragma Assert (Ovhd_Fixed'Small <= F'Small);

   procedure Saturate (V : in out Ovhd_Fixed)
      with Inline;

   procedure Saturate (V : in out Ovhd_Fixed) is
```

(continues on next page)

(continued from previous page)

```
      First : constant Ovhd_Fixed :=
                Ovhd_Fixed (F'First);
      Last  : constant Ovhd_Fixed :=
                Ovhd_Fixed (F'Last);
   begin
      if V > Last then
         V := Last;
      elsif V < First then
         V := First;
      end if;
   end Saturate;

   function Sat_Add (V1, V2 : F) return F is
      VC1 : Ovhd_Fixed := Ovhd_Fixed (V1);
      VC2 : Ovhd_Fixed := Ovhd_Fixed (V2);
      VC  : Ovhd_Fixed;
   begin
      VC := VC1 + VC2;
      Saturate (VC);
      return F (VC);
   end Sat_Add;

end Gen_Fixed_Ops;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
↪Types.Generic_Fixed
MD5: 25a1919929c8e9f7f6af0a9e727c2972
```

Ovhd_Fixed is a 64-bit fixed-point data type. By using Asserts in the package body that compare this data type to the formal F type from the package specification, we ensure that the local fixed-point data type has enough overhead to cope with any fixed-point operation that we want to implement. Also, we ensure that we don't lose precision when converting back-and-forth between the local type and the original type.

We then use the Gen_Fixed_Ops package in a test application:

Listing 134: show_fixed_ops.adb

```
with Ada.Text_IO;    use Ada.Text_IO;
with Gen_Fixed_Ops;

procedure Show_Fixed_Ops is

   F_Depth  : constant Positive := 16;
   LF_Depth : constant Positive := 32;

   F_Delta  : constant :=
                1.0 / 2.0 ** (F_Depth - 1);
   LF_Delta : constant :=
                1.0 / 2.0 ** (LF_Depth - 1);

   type Fixed is
     delta F_Delta
     range -1.0 .. 1.0 - F_Delta
       with Size => F_Depth;

   type Long_Fixed is
     delta LF_Delta
     range -1.0 .. 1.0 - LF_Delta
```

(continues on next page)

(continued from previous page)

```
      with Size => LF_Depth;

   package Fixed_Ops is new
     Gen_Fixed_Ops (F => Fixed);
   use Fixed_Ops;

   package Long_Fixed_Ops is new
     Gen_Fixed_Ops (F => Long_Fixed);
   use Long_Fixed_Ops;

   F  : Fixed      :=  0.5;
   LF : Long_Fixed := -0.5;

begin
   Put_Line ("F:  " & Fixed'Image (F));
   Put_Line ("LF: " & Long_Fixed'Image (LF));

   F  := Sat_Add (F,   0.75);
   LF := Sat_Add (LF, -0.75);

   Put_Line ("F:  " & Fixed'Image (F));
   Put_Line ("LF: " & Long_Fixed'Image (LF));

end Show_Fixed_Ops;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
↪Types.Generic_Fixed

```

Runtime output

```
F:   0.50000
LF: -0.5000000000
F:   0.99997
LF: -1.0000000000
```

In this test application, we declare two fixed-point data types: the 16-bit type `Fixed` and the 32-bit type `Long_Fixed`. These types are used to create instances of the `Gen_Fixed_Ops`. By calling `Sat_Add`, we ensure that the result of adding fixed-point values will always be in the allowed range and the computation will never raise an exception.

Operations in generic packages

In this section, we discuss how to declare operations associated with fixed-point types in generic packages. We start by adapting the examples used for floating-point in the previous section, so that fixed-point types are used instead.

First, we define a package that implements a new fixed-point type called `Fixed`. For this type, we override the addition operator with an implementation that saturates the value after the actual addition. This is the package specification:

Listing 135: fixed_types.ads

```
package Fixed_Types is

   F_Depth : constant Positive := 16;
   F_Delta     : constant :=
```

(continues on next page)

(continued from previous page)

```
                    1.0 / 2.0 ** (F_Depth - 1);

   type Fixed is
     delta F_Delta
     range -1.0 .. 1.0 - F_Delta
       with Size => F_Depth;

   function "+" (A, B : Fixed) return Fixed;

end Fixed_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
 ↪Types.Generic_Fixed
MD5: 560960880d6d216a7b93b582cd5137e6
```

In the package body, we make use of the Gen_Fixed_Ops package that we discussed earlier in the previous section. By instantiating the Gen_Fixed_Ops package, we can use the Sat_Add function in the implementation of the saturating addition operator.

Listing 136: fixed_types.adb

```
with Gen_Fixed_Ops;

package body Fixed_Types is

   package Fixed_Ops is new
     Gen_Fixed_Ops (F => Fixed);
   use Fixed_Ops;

   function "+" (A, B : Fixed) return Fixed is
   begin
      return R : Fixed do
         R := Sat_Add (A, B);
      end return;
   end "+";

end Fixed_Types;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
 ↪Types.Generic_Fixed
MD5: a6045d3d30ccae5596081797a46a24c9
```

Build output

```
fixed_types.adb:6:26: warning: instance uses predefined operation, not primitive␣
 ↪operation "+" at fixed_types.ads:12
```

Next, we create a package containing a procedure that accumulates fixed-point values. This is the package specification:

Listing 137: gen_fixed_acc.ads

```
generic
   type F is delta <>;
   with function "+" (A : F; B : F)
                      return F is <>;
package Gen_Fixed_Acc is
```

(continues on next page)

(continued from previous page)

```
   procedure Acc (V : in out F; S : F);
end Gen_Fixed_Acc;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
 ↪Types.Generic_Fixed
MD5: 14e898a51afd4ff89fda616f56c1bfe4
```

In this specification, we declare a formal function for the addition operator using `with function`. This operator is used by the Acc procedure in the package body, which we show next.

Listing 138: gen_fixed_acc.adb

```
package body Gen_Fixed_Acc is

   procedure Acc (V : in out F; S : F) is
   begin
      V := V + S;
   end Acc;

end Gen_Fixed_Acc;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
 ↪Types.Generic_Fixed
MD5: afe6490b1196a9efbaf3b9341298e861
```

Build output

```
fixed_types.adb:6:26: warning: instance uses predefined operation, not primitive␣
 ↪operation "+" at fixed_types.ads:12
```

This is a test application that makes use of the Fixed_Types and Gen_Fixed_Acc packages.

Listing 139: show_fixed_overriding.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Fixed_Types; use Fixed_Types;
with Gen_Fixed_Acc;

procedure Show_Fixed_Overriding is

   package Fixed_Ops is new
     Gen_Fixed_Acc (F => Fixed);
   use Fixed_Ops;

   F1 : Fixed := -0.5;

begin
   Put_Line ("F1:  " & Fixed'Image (F1));

   Acc (F1, -0.9);

   Put_Line ("F1:  " & Fixed'Image (F1));
end Show_Fixed_Overriding;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Abstraction-Oriented_Prog.Generics.Formal_Numeric_
 ↪Types.Generic_Fixed
MD5: 8bed27d2f3c3e2313c28947c0974f2da
```

Build output

```
fixed_types.adb:6:26: warning: instance uses predefined operation, not primitive␣
 ↪operation "+" at fixed_types.ads:12
```

Runtime output

```
F1:  -0.50000
F1:  -1.00000
```

We create an instance of the Gen_Fixed_Acc by using the Fixed type declared in the Fixed_Types package. We then call Acc to accumulate and saturate a fixed-point variable.

As mentioned earlier in the section on generic floating-point types, the main reason for the formal subprogram in the specification of the Gen_Fixed_Acc package is that it prevents the compiler from selecting the standard operator. Alternatively, we could make use of the Fixed_Types package directly in the generic package:

```
with Fixed_Types; use Fixed_Types;

generic
   type F is new Fixed;
package Gen_Fixed_Acc is
   procedure Acc (V : in out F; S : F);
end Gen_Fixed_Acc;
```

CHAPTER

SIX

INTERFACING WITH THE EXTERNAL WORLD

106.1 File I/O

106.1.1 Efficient Stream I/O for Array Types

Note: This section was originally written by Patrick Rogers and published as Gem #39: Efficient Stream I/O for Array Types by Pat Rogers[508]

106.1.2 Container streaming

106.2 Interfacing with C and C++

106.2.1 Interfacing with C

Using unconstrained types

In the previous examples, we're being careful about the data types: all of them are coming from the `Interfaces.C` package. Using Ada built-in types when interfacing with C can be problematic, especially in case of unconstrained types. For example:

```
/*% filename: test.h */

char * my_func (void);
```

This is the function implementation:

```
#include <stdio.h>
#include "test.h"

char * my_func (void)
{
  return "hello";
}
```

In the Ada application, we try to import this as a `String` type:

[508] https://www.adacore.com/gems/gem-39

```
with Interfaces.C;
use  Interfaces.C;

with Ada.Text_IO;
use  Ada.Text_IO;

procedure Show_C_Func is

   function my_func return String
     with
       Import        => True,
       Convention    => C;

   S : String := my_func;

begin
   Put_Line (S);
end Show_C_Func;
```

When running this application, we'll get a `Storage_Error` exception. Therefore, the recommendation is to be very careful about the data types and use the `Interfaces.C` package whenever possible for interfacing with C.

106.2.2 Interfacing with C++

All the previous examples focused on interfacing with C code. For C++, the same methods apply. However, there are a few differences that we need to take into account:

- When importing or exporting variables and subprograms, we replace 'C' by 'Cpp' in the `Convention` aspect of their declaration.
- In the project file for **`gprbuild`**, we replace 'C' by 'C++' in the Languages entry.

There are other aspects specific to C++ that we also have to take into account. This section will discuss them.

C++ symbol mangling

Let's start by adapting a previous example and *converting* it to C++ (actually, mainly just replacing the C compiler by a C++ compiler). The header file is still basically the same:

```
extern int func_cnt;
int my_func (int a);
```

And this is the corresponding implementation:

```
#include "test.hh"

int func_cnt = 0;

int my_func (int a)
{
  func_cnt++;

  return a * 2;
}
```

In the Ada application, as mentioned before, we need to replace 'C' by 'Cpp' in the `Convention` of the declarations:

```
with Interfaces.C; use Interfaces.C;
with Ada.Text_IO;  use Ada.Text_IO;

procedure Show_Cpp_Func is

   function my_func (a : int) return int
     with
       Import        => True,
       Convention    => Cpp,
       External_Name => "_Z7my_funci";

   V : int;

   func_cnt : int
     with
       Import        => True,
       Convention    => Cpp;

begin
   V := my_func (1);
   V := my_func (2);
   V := my_func (3);
   Put_Line ("Result is "
             & int'Image (V));

   Put_Line ("Function was called "
             & int'Image (func_cnt)
             & " times");

end Show_Cpp_Func;
```

Also, in the declaration of `my_func`, we need to include a reference to the original name using `External_Name`. If we leave this out, the linker won't be able to find the original implementation of `my_func`, so it won't build the application. Note that the function name is not `my_func` anymore (as it was the case for the C version). Instead, it is now called `_Z7my_funci`. This situation is caused by symbol mangling.

In C, the symbol names in object files match the symbol name in the source-code. In C++, due to symbol mangling, the symbol names of subprograms in the object files are different from the corresponding source-code implementation. Also, because symbol mangling is not standardized, different compilers might use different methods. The most prominent example is the difference between the gcc and MSVC compilers. However, since GNAT is based on gcc, we can build applications using Ada and C++ code without issues — as long as we use the same compiler.

In order to retrieved the mangled symbol names, we can simply generate bindings automatically by using **g++** with the `-fdump-ada-spec` option:

```
g++ -c -fdump-ada-spec -C ./test.hh
```

Alternatively, we could use binary examination tools to retrieve the symbol names from a library. Examples of such tools are **nm** for Mac and Linux, and **dumpbin.exe** for Windows.

C++ classes

We'll now focus on binding object-oriented features of C++ into Ada. Let's adapt the previous example to make use of classes. This is adapted header file:

```
class Test {
public:
  Test();
  int my_func (int a);
  int get_cnt();
private:
  int func_cnt;
};
```

And this is the corresponding implementation:

```
#include "test.hh"

Test::Test() :
  func_cnt(0)
{
};

int
Test::my_func (int a)
{
  func_cnt++;

  return a * 2;
}

int
Test::get_cnt()
{
  return func_cnt;
}
```

Because of the more complex structure, the recommendation is to generate bindings using **g++** and, if needed, adapt the file. Let's first run **g++**:

```
g++ -c -fdump-ada-spec -C ./test.hh
```

The generated bindings look like this:

```
pragma Ada_2005;
pragma Style_Checks (Off);

with Interfaces.C; use Interfaces.C;

package test_hh is

   package Class_Test is
      type Test is limited record
         func_cnt : aliased int;  -- ./test.hh:7
      end record;
      pragma Import (CPP, Test);

      function New_Test return Test;  -- ./test.hh:3
      pragma CPP_Constructor (New_Test, "_ZN4TestC1Ev");

      function my_func (this : access Test; a : int) return int;  -- ./test.hh:4
      pragma Import (CPP, my_func, "_ZN4Test7my_funcEi");
```

(continues on next page)

(continued from previous page)

```
      function get_cnt (this : access Test) return int;  -- ./test.hh:5
      pragma Import (CPP, get_cnt, "_ZN4Test7get_cntEv");
   end;
   use Class_Test;
end test_hh;
```

As we can see, the original C++ class (`Test`) is represented as a nested package (`test_hh.Class_Test`) in the Ada bindings.

The Ada application can then use the bindings:

```
with Interfaces.C; use Interfaces.C;
with Ada.Text_IO;  use Ada.Text_IO;
with test_hh;      use test_hh;

procedure Show_Cpp_Class is
   use Class_Test;

   V : int;

   T  : aliased Test := New_Test;
   TA : access Test := T'Access;

begin
   V := my_func (TA, 1);
   V := my_func (TA, 2);
   V := my_func (TA, 3);
   Put_Line ("Result is " & int'Image (V));

   Put_Line ("Function was called "
             & int'Image (get_cnt (TA))
             & " times");

end Show_Cpp_Class;
```

Note that, in the Ada application, we cannot use the prefixed notation. This notation would be more similar to the corresponding syntax in C++. This restriction is caused by the fact that the automatic generated bindings don't use tagged types. However, if we adapt the declaration of `Test` and replace it by `type Test is tagged limited record ...`, we'll be able to write `TA.my_func(1)` and `TA.get_cnt` in our application.

Another correction we might want to make is in the visibility of the `Test` record. In the original C++ class, the `func_cnt` element was declared in the private part of the `Test` class. However, in the generated bindings, this element has been exposed, so it could be accessed directly in our application. In order to correct that, we can simply move the type declaration to the private part of the `Class_Test` package and indicate that in the public part of the package (by using `type Test is limited private;`).

After these adaptations, we get the following bindings:

```
pragma Ada_2005;
pragma Style_Checks (Off);

with Interfaces.C; use Interfaces.C;

package test_hh is

   package Class_Test is
      type Test is tagged limited private;
      pragma Import (CPP, Test);
```

(continues on next page)

(continued from previous page)

```
      function New_Test return Test;  -- ./test.hh:3
      pragma CPP_Constructor (New_Test, "_ZN4TestC1Ev");

      function my_func (this : access Test; a : int) return int;  -- ./test.hh:4
      pragma Import (CPP, my_func, "_ZN4Test7my_funcEi");

      function get_cnt (this : access Test) return int;  -- ./test.hh:5
      pragma Import (CPP, get_cnt, "_ZN4Test7get_cntEv");
   private
      type Test is tagged limited record
         func_cnt : aliased int;  -- ./test.hh:7
      end record;
   end;
   use Class_Test;
end test_hh;
```

And this is the adapted Ada application:

```
with Interfaces.C; use Interfaces.C;
with Ada.Text_IO;  use Ada.Text_IO;
with test_hh;      use test_hh;

procedure Show_Cpp_Class is
   use Class_Test;

   V : int;

   T : aliased Test := New_Test;
   TA : access Test := T'Access;

begin
   V := TA.my_func (1);
   V := TA.my_func (2);
   V := TA.my_func (3);
   Put_Line ("Result is "
             & int'Image (V));

   Put_Line ("Function was called "
             & int'Image (TA.get_cnt)
             & " times");

end Show_Cpp_Class;
```

C++ constructors

Note: This section was originally written by Javier Miranda and Arnaud Charlet, and published as Gem #61: Interfacing with C++ constructors[509] and Gem #62: C++ constructors and Ada 2005[510]

CHAPTER

SEVEN

APPENDICES

107.1 Legacy features

107.1.1 Nested packages

Nested packages, as the name suggests, are declared within a parent package. This contrasts with child packages, which are declared independently. For example, this would be a nested package for the Week package:

Listing 1: week.ads

```
package Week is

   Mon : constant String := "Monday";
   Tue : constant String := "Tuesday";
   Wed : constant String := "Wednesday";
   Thu : constant String := "Thursday";
   Fri : constant String := "Friday";
   Sat : constant String := "Saturday";
   Sun : constant String := "Sunday";

   package Nested is

      function Get_First_Of_Week return String;

   end Nested;

end Week;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Appendices.Packages.Nested_Packages.Simple_Example
MD5: 427390dab94e2a4b11f19fd74497c436
```

In contrast to child packages, we don't write `package body Week.Nested is ...` to implement the package body of Nested. Instead, the package body of Nested is *nested* in the package body of the parent package Week:

Listing 2: week.adb

```
package body Week is

   package body Nested is

      function Get_First_Of_Week return String is
      begin
         return Mon;
```

(continues on next page)

(continued from previous page)

```
      end Get_First_Of_Week;

   end Nested;

end Week;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Appendices.Packages.Nested_Packages.Simple_Example
MD5: 3fdc3229225cb3a139a55288dc84d30e
```

We can now use elements from `Week.Nested` in a test application:

Listing 3: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Week;

procedure Main is
   use Week.Nested;
begin
   Put_Line ("First day of the week is "
             & Get_First_Of_Week);
end Main;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Appendices.Packages.Nested_Packages.Simple_Example
MD5: 2f396dad4e5d612754ee5ef1d16b0406
```

Runtime output

```
First day of the week is Monday
```

Note that we cannot access the `Week.Nested` package directly using `with Week.Nested` because `Nested` is actually part of `Week`, not a child package. We can, however, still write `use Week.Nested` — as we did in the example above.

Visibility

Let's now discuss visibility of nested packages. Because the body of nested packages is part of the body of their parent, nested packages have the same visibility as their parent package. Let's rewrite the previous example using nested packages to illustrate this:

Listing 4: book.ads

```
package Book is

   Title : constant String :=
             "Visible for my children";

   function Get_Title return String;

   function Get_Author return String;

   package Additional_Operations is

      function Get_Extended_Title return String;

```

(continues on next page)

(continued from previous page)

```
      function Get_Extended_Author return String;

   end Additional_Operations;

end Book;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Appendices.Packages.Nested_Packages.Visibility
MD5: f721943bf8bf91d35efd80b96575ca36
```

Now, because Author is declared before the body of the nested package Additional_Operations, we can use it in the implementation of the Get_Extended_Author function:

Listing 5: book.adb

```
package body Book is

   Author : constant String :=
             "Author not visible for my children";

   function Get_Title return String is
   begin
      return Title;
   end Get_Title;

   function Get_Author return String is
   begin
      return Author;
   end Get_Author;

   package body Additional_Operations is

      function Get_Extended_Title return String
      is
      begin
         return "Book Title: " & Title;
      end Get_Extended_Title;

      function Get_Extended_Author return String
      is
      begin
         return "Book Author: " & Author;
      end Get_Extended_Author;

   end Additional_Operations;

end Book;
```

Code block metadata

```
Project: Courses.Advanced_Ada.Appendices.Packages.Nested_Packages.Visibility
MD5: 99304ef4ed8e3a10fac58be0d704b036
```

This is the test application in this case:

Listing 6: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Book;
```

(continues on next page)

(continued from previous page)

```
3
4  procedure Main is
5     use Book.Additional_Operations;
6  begin
7     Put_Line (Get_Extended_Title);
8     Put_Line (Get_Extended_Author);
9  end Main;
```

107.1.2 separate compilation

Relevant topics

- Subunits of Compilation Units[511]

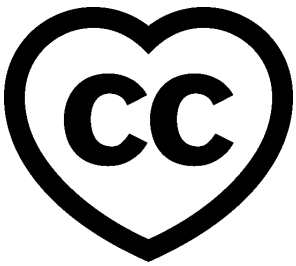
If you remix, transform, or build upon the material, you must distribute your contributions under the same license as the original. You can find license details on this page[512]



This course will teach you the basics of the Ada programming language and is intended for those who already have a basic understanding of programming techniques. You will learn how to apply those techniques to programming in Ada.

This document was written by Patrick Rogers.

Note: The code examples in this course use an 80-column limit, which is a typical limit for Ada code. Note that, on devices with a small screen size, some code examples might be difficult to read.

Note: Each code example from this book has an associated "code block metadata", which contains the name of the "project" and an MD5 hash value. This information is used to identify a single code example.

You can find all code examples in a zip file, which you can download from the learn website[513]. The directory structure in the zip file is based on the code block metadata. For example, if you're searching for a code example with this metadata:

- Project: Courses.Intro_To_Ada.Imperative_Language.Greet
- MD5: cba89a34b87c9dfa71533d982d05e6ab

you will find it in this directory:

```
projects/Courses/Intro_To_Ada/Imperative_Language/Greet/
cba89a34b87c9dfa71533d982d05e6ab/
```

In order to use this code example, just follow these steps:

1. Unpack the zip file;
2. Go to target directory;
3. Start GNAT Studio on this directory;
4. Build (or compile) the project;
5. Run the application (if a main procedure is available in the project).

INTRODUCTION

CHAPTER

NINE

ESSENTIAL DESIGN IDIOMS FOR PACKAGES

109.1 Motivation

Packages, especially library packages, are modules, and as such they are the fundamental building blocks of Ada programs. There is no language-prescribed way to use packages when designing an application, the language just specifies what is legal. However, some legal approaches are more advisable than others.

In particular, packages should exhibit high cohesion and loose coupling[1]. Cohesion is the degree to which the declarations within a module are related to one another, in terms of the problem being solved. In short, unrelated entities should not be declared in the same module so that the reader can focus on one primary concept. Coupling is the degree to which a module depends upon other modules. Loose coupling enhances comprehension and maintenance because it allows the developer/reader to examine and modify the module in relative isolation. Coupling and cohesion are interrelated, in that higher cohesion tends to result in less coupling.

109.2 Solution

Three idioms for packages were envisioned when the language was first designed. They were introduced and described in detail by the Rationale document for the initial language design[2]. They were then further developed in Grady Booch's book *Software Engineering with Ada*[3], a foundational work on design with the (sequential part of the) language. Booch added a fourth idiom, the Abstract Data Machine, to the three described by the Rationale.

These four idioms have proven themselves capable of producing packages that exhibit high cohesion and loose coupling, resulting in more comprehensible and more maintainable source code.

These idioms pre-date later package facilities, such as private packages and hierarchical packages. Idioms for those packages will be described separately.

Although generic packages are not actually packages, their instantiations are packages so these design idioms apply to generic packages as well.

Because these are idioms for modules, they are differentiated by what the package declarations can contain. But as you will see, what they can contain is a reflection of the degree of information hiding applied.

[1] Yourdon, E. and L. L. Constantine (1979). Structured Design: Fundamentals of a Discipline of Computer Program and System Design, Prentice-Hall.

[2] Ichbiah, J., J. Barnes, et al. (1986). Rationale for the Design of the Ada Programming Language.

[3] Booch, G. (1983). Software Engineering with Ada, Benjamin/Cummings Publishing Company.

109.3 Essential Idiom 1: Named Collection of Declarations

In the first idiom the package declaration can contain other declarations only for the following:

- Objects (constants and variables)
- Types
- Exceptions

The idea is to factor out the common content required by multiple clients. Declaring common content in one place and letting clients reference the one unit makes the most sense.

For example, the following package declares several physical constants used in a high-fidelity aircraft simulator. These constants are utilized throughout the simulator code, so they are declared in one place and then referenced as needed:

```
package Physical_Constants is
   Polar_Radius    : constant  := 20_856_010.51; --  feet
   Equatorial_Radius : constant  := 20_926_469.20; --  feet
   Earth_Diameter : constant  :=
     2.0 * ((Polar_Radius + Equatorial_Radius)/2.0);
   Gravity  : constant  := 32.1740_4855_6430_4; --  feet/second**2
   Sea_Level_Air_Density    : constant  := 0.002378; --  slugs/foot**3
   Altitude_Of_Tropopause  : constant  := 36089.0; --  feet
   Tropopause_Temperature  : constant  := -56.5; --  degrees-C
end Physical_Constants;
```

No information hiding is applied with this idiom.

109.3.1 Pros

Packages designed with this idiom will have high cohesion and low coupling.

The idiom also enhances maintainability because changes to the values, if necessary, need only be made in one place.

109.3.2 Cons

When a library package contains variable declarations, these variables comprise global data. In this sense *global* means potential visibility to multiple clients. Global data should be avoided by default, because the effects of changes are potentially pervasive, throughout the entire set of clients that have visibility to it. In effect the developer must understand everything before changing anything. The introduction of new bugs is a common result. But if, for some compelling reason, the design really called for global data, this idiom provides the way to declare it.

109.4 Essential Idiom 2: Groups of Related Program Units

In this idiom, the package can contain all of the declarations allowed by the first idiom, but will also contain declarations for operations, usually subprograms but other units are also allowed, e.g., protected types/objects. Hence:

- Objects (constants and variables)
- Types
- Exceptions
- Operations

The intent is that the types declared in the package are used by the operations, e.g., in the formal parameters and/or function return types. In particular, though, the types are not private types.

For example:

```
package Linear_Algebra is
   type Vector is array (Positive range <>) of Real;
   type Matrix is array (Positive range <>, Positive range <>) of Real;
   function "+" (Left, Right : Vector) return Vector;
   function "*" (Left, Right : Vector) return Matrix;
   -- ...
end Linear_Algebra;
```

In this code, `Vector` and `Matrix` are the types under consideration. The type `Real` might be declared here too, but it might be better declared in a *Named Collection of Declarations* (page 1998) package referenced in a with-clause. In any case this package declares types and subprograms that manipulate values of the types via parameters.

Variables might also be declared in the package, but not as the central purpose of the package. Perhaps we want to have a variable whose value is used as the default for some formal parameters. Clients can change the default for subsequent calls by first assigning a different value to the variable, unlike a hardcoded literal chosen by the developer. For example:

```
Default_Debounce_Time : Time_Span := Milliseconds (75);
--  The default amount of time used to debounce an input pin.
--  This value is tunable.

procedure Await_Active
  (This : Discrete_Input;
   Debounce_Time : Time_Span := Default_Debounce_Time);
```

With this idiom, information hiding applies to the implementations of the visible subprograms in the package body, as well as any internal entities declared in the body for the sake of implementing the visible subprograms.

As mentioned, these idioms apply to generic packages as well. For example, the more realistic approach would be to make type Real be a generic formal type:

```
generic
   type Real is digits <>;
package Linear_Algebra is
   type Vector is array (Positive range <>) of Real;
   type Matrix is array (Positive range <>, Positive range <>) of Real;
   function "+" (Left, Right : Vector) return Vector;
   function "*" (Left, Right : Vector) return Matrix;
```

(continues on next page)

(continued from previous page)

```
   --  ...
end Linear_Algebra;
```

109.4.1 Pros

The types and the associated operations are grouped together, hence highly cohesive. Such packages usually can be loosely coupled as well.

Clients have all the language-defined operations available that the type representations provide. In the case of `Vector` and `Matrix`, clients have compile-time visibility to the fact they are array types. Therefore, clients can manipulate `Vector` and `Matrix` values as arrays: they can create values via aggregates, for example, and can use array indexing to get to specific components.

109.4.2 Cons

Clients can write code that depends on the type's representation, and can be relied upon to do so. Consequently, a change in the representation will potentially require redeveloping the client code, which could be extensive and expensive.

However, compile-time visibility to the type representations may be necessary to meet client expectations. For example, engineers expect to use indexing with vectors and matrices. Ada — by design — does not allow developers to redefine extremely low-level operations such as array indexing. Consequently, those types must be compile-time visible to clients as array types. We could define functions as alternatives to indexing and aggregates, but would clients accept that relatively heavy approach?

109.5 Notes

1. The rules for what these idiomatic packages contain are not meant to be iron-clad; hybrids are possible but should be considered initially suspect and reviewed accordingly.

109.6 Bibliography

ABSTRACT DATA TYPES

110.1 Motivation

In the previous idiom (the *Groups of Related Program Units* (page 1999)), client compile-time visibility to the type's representation is both an advantage and a disadvantage. Visibility to the representation makes available the expressiveness of low-level syntax, such as array indexing and aggregates, but in so doing allows client source code to be dependent on the representation. In the vast majority of cases, the resulting economic and engineering disadvantages far outweigh the advantages.

For the sake of illustration, let's make up a *stack* type that can contain values of type **Integer**. (We use type **Integer** purely for the sake of convenience.) Let's also say that any given Stack object will contain at most a fixed number of values, and arbitrarily pick 100 for that upper bound. The likely representation for the Stack type will require both an array for the contained values and a *stack pointer* indicating the *top* of the stack. Hence this will be a composite type, probably a record type. If we use the *Groups of Related Program Units* (page 1999) idiom the code might look like this:

```
package Integer_Stacks is
   Capacity : constant := 100;
   type Content is array  (1 .. Capacity) of Integer;
   type Stack is record
      Values : Content;
      Top    : Integer range 0 .. Capacity := 0;
   end record;
   procedure Push  (This : in out Stack; Item : in Integer);
   procedure Pop  (This : in out Stack;  Item : out Integer);
   function Empty (This : Stack) return Boolean;
end Integer_Stacks;
```

With this design the compiler will allow client code to directly read and update the two components within any Stack object. For example, given some Stack variable named X, the client can read the value of X.Top, say to determine if X is empty. But by the same token, the client code could change X.Top to some arbitrary value unrelated to the logical top of the stack, completely violating stack semantics.

As a result, where would one look in the source code to find a bug in the handling of some Stack object? It could be literally anywhere in all the client code that uses package Integer_Stacks.

Similarly, changes to the internal representation of a type may become necessary as new requirements are identified. At best, the client code will now fail to compile, making identification of the problem areas simple. At worst, the client code will remain legal but no longer functional. Perhaps an additional component was added that the original components now rely upon, or the original components are used in new ways. Conceivably every client use of Integer_Stacks might need to be changed. Once we find them all we'll have to rewrite them to address the changes in the representation. That's potentially very expensive, perhaps prohibitively so. Worse, our *fixes* will likely introduce new bugs.

These disadvantages argue for an alternative. That is the purpose of this next idiom, known as the Abstract Data Type (ADT)[1],[2].

110.2 Solution

Abstraction is one of the central principles of software engineering because it is one of the primary ways that humans manage complexity. The idea is to focus on the essentials, in effect the *what*, while ignoring all the inessential implementation details, i.e., the *how*. For example, when we drive a car and want to stop, we press the brake pedal. We don't also think about how the pedal makes the car stop, just that it does so. That's an example of abstraction. In the same way, we know that pressing the accelerator pedal increases the speed of the car, that rotating the steering wheel changes the direction of travel, and so on. If to control the car we had to think about how each part actually works — the brake cylinder and brake pads, the fuel injectors, the spark plugs, the steering shaft, the tie rods, and everything else — we'd certainly crash.

We use abstraction in programming for the same reason. In higher-level languages an array is an abstraction for the combination of a base address and offset. A file system is composed of a number of layered abstractions, including at the top files, then tracks, then sectors, then blocks, ultimately down to individual bytes. A data structure, such as a stack, a queue, or a linked list is an example of an abstraction, as is a valve, an air-lock, and an engine when represented in software. Even procedures and functions are abstractions for lower-level operations. Decomposing via abstractions allows us to manage complexity because at any given layer we can focus on what is being done, rather than how.

Therefore, an abstract data type is a type that is abstract in the sense that[2]:

- It is a higher level of abstraction than the built-in programming language types.
- It is functionally characterized entirely by the operations defined by the ADT itself, along with the common basic operations such as assignment, object declarations, parameter passing, and so on. In particular, clients are not allowed to perform operations that are determined by the type's internal representation. Ideally, this protection is enforced by tools.

The ADT may also be abstract in the sense of object-oriented programming but that is an unrelated issue.

In Ada we use *private types* to define abstract data types because private types make the type's name visible to clients, but not the representation. These types are composed using syntactical building blocks: a package declaration, separated into two parts, containing a type declared in two parts, and containing declarations for subprograms to manipulate objects of the type via parameters. The compiler uses the building-blocks' compile-time visibility rules to enforce the protections against representation-based operations. (We assume the reader is familiar with private types, but this is such an important, central facility in Ada that we will explain them in some detail anyway.)

Therefore, an ADT package declaration may contain any of the following:

- Constants (but probably not variables)
- A private type
- Ancillary Types
- Exceptions
- Operations

[1] Booch, G. (1983). Software Engineering with Ada, Benjamin/Cummings Publishing Company.
[2] Liskov, B. and S. Zilles (1974). Programming with Abstract Data Types. ACM SIGPLAN symposium on Very high level languages.

In general, at most one private type should be declared per ADT package, for the sake of simplicity. Note that the *limited-with* construct directly facilitates declaring mutually-dependent private types declared in their own dedicated packages. However, it is not unreasonable to declare more than one private type in the same package, especially if one of the types is clearly the primary type and the other private type is related to the first. For example, in defining an ADT for a maze, we could declare a private type named `Maze` to be the primary abstraction. But mazes have positions within them, and as clients have no business knowing how positions are represented, both `Maze` and `Position` could reasonably be declared as private types in the same package.

Any form of private type is allowed with this idiom: basic private types, tagged/abstract/limited private types, private type extensions, and so forth. What's important is that the representation occurs in the private part so that is it not compile-time visible to clients.

The abstraction's operations will consist of subprograms that each have a formal parameter of the type. Clients will declare objects of the type and pass these objects to the formal parameters in order to manipulate those objects.

The operations are known as *primitive operations* because they have the compile-time visibility to the private type's representation necessary to implement the required behavior.

Clients can create their own operations by calling the type's primitive operations, but client's cannot compile any operation that manipulates the internal representation directly.

Consider the following revision to the package `Integer_Stacks`, now as an ADT:

```
package Integer_Stacks is
   type Stack is private;
   procedure Push (This : in out Stack; Item : in Integer);
   procedure Pop (This : in out Stack;  Item : out Integer);
   function Empty (This : Stack) return Boolean;
   Capacity : constant := 100;
private
   type Content is array  (1 .. Capacity) of Integer;
   type Stack is record
      Values : Content;
      Top    : Integer range 0 .. Capacity := 0;
   end record;
end Integer_Stacks;
```

The package declaration now includes the **`private`** reserved word, about half-way down by itself in the example above, thus dividing the package declaration into the *public part* and the *private part*. The compiler only allows clients compile-time visibility to the package public part. No client code that references anything in the private part will compile successfully.

The declaration for the type `Stack` now has two pieces, one in the package visible part and one in the package private part. The visible piece introduces the type name, ending with the word **`private`** to indicate that the representation is not provided to clients.

Client code can use the type name to declare objects because the name is visible. Likewise, clients can declare their own subprograms with parameters of type `Stack`, or use type `Stack` as the component type in a composite type declaration. Clients can use a private type in any way consistent with the rest of the visible type declaration, except for anything representation-dependent.

The full type definition occurs in the package private part. Therefore, for any given object of the type, the representation details — the two record components in this example — cannot be referenced in client code. Clients must instead use the operations defined by the package, passing the client objects to the formal parameters. Only the bodies of these operations have compile-time visibility to the representation of the `Stack` parameters, so only they can implement the functionality for those parameters.

Because the package-defined subprograms are the only code that can access the internals of objects of the type, the designer's intended abstract operations are strictly enforced as the only direct manipulation possible. As we mentioned, basic operations such as assignment are allowed, unless the ADT is limited as well as private, but these basic operations do not violate the abstraction.

Other ancillary type declarations may of course also be required in the package, either for the implementation or as additional parameters for the visible operations. The array type Content is an example of such an ancillary type. In this case it is hidden from clients because it is strictly an implementation artifact.

The ADT idiom extends the information hiding applied by the *Groups of Related Program Units* (page 1999) idiom to include the type's representation.

The compile-time lack of visibility to the representation means that clients no longer have a way to construct ADT values from the constituent parts. For example, record aggregates are no longer possible for clients using the `Stack` ADT. Likewise, clients no longer have a way to read the individual constituent components. (Whether doing so is appropriate will be addressed below.) Therefore, an ADT package may include *constructor* and *selector/accessor* subprograms. (The term *constructor* is only conceptually related to the same term in some other languages, such as C++.)

For an example of an abstraction that includes constructors and selectors, imagine there is no language-defined `Complex` number type. We could use the following ADT approach:

```
package Complex_Numbers is
   type Complex_Number is private;
   --  function operating on Complex_Number, eg "+" ...
   --  constructors and selectors/accessors
   function Make (Real_Part, Imaginary_Part : Float) return Complex_Number;
   function Real_Part (This : Complex_Number) return Float;
   function Imaginary_Part (This : Complex_Number) return Float;
private
   type Complex_Number is record
      Real_Part : Float;
      Imaginary_Part : Float;
   end record;
end Complex_Numbers;
```

In the above, the function `Make` is a constructor that replaces the use of aggregates for constructing `Complex_Number` values. Callers pass two floating-point values to be assigned to the components of the resulting record type. In the `Stack` ADT a constructor for `Stack` objects wasn't required because any stack has a known initial state, i.e., empty, and the component default initialization is sufficient to achieve that state. Complex numbers don't have any predeterminable state, it's up to clients, so the constructor is required.

Likewise, functions `Real_Part` and `Imaginary_Part` are selector/accessor functions that return the corresponding individual component values, given an argument of type `Complex_Number`. They are provided because complex numbers have those two parts by definition in mathematics. Clients can reasonably expect to be able to get such values from a given object. (The function names need not be distinct from the component names but can be if desired.)

However, by default, selector/accessor functions are not included in the ADT idiom, and especially not for every component of the representation. There are no *getter* operations if you are familiar with that term.

There may be cases when what looks like an accessor function is provided, when in fact the function computes the return value. Similarly, there may be functions that simply return the value of a component but are part of the abstraction and happen to be implementable by returning the value of a component. For example, a real stacks ADT package would include a function indicating the extent of the object — that is, the number of values currently contained. In our example implementation the Top component happens to indicate that

value, beyond indicating the current top of the stack. The body of the `Extent` function can then be as follows:

```
function Extent (This : Stack) return Natural is (This.Top);
```

But a different representation might not have a `Top` component so the function would be implemented in some other way. (We would have declared a subtype of **`Natural`**, using `Capacity` as the upper bound, for the function result type.)

True *getter* functions that do not meet an abstraction-defined requirement and exist purely to provide client access to the otherwise hidden representation components should not be included. Their usage makes the client code dependent on the representation, just as if the client had direct access. For the same reason, by default there are no *setter* procedures for the representation components. Both kinds of operations should be considered highly suspect. There's no point in hiding the representation if these operations will make it available to clients, albeit indirectly.

110.3 Pros

The advantages of an ADT result from the strong interface presented, with guaranteed enforcement by the compiler rather than by reliance on client good behavior. The ADT designer can rely on client adherence to the intended abstraction because client code that violates the designer's abstraction — directly manipulating the internals of the type — will not compile. Clients must call the designer's operations to manipulate the objects.

A package defining a strong interface will exhibit high cohesion, thereby aiding comprehension and, consequently, both development and maintenance.

An ADT enhances maintainability because a bug in the ADT implementation must be in the package that defines the ADT itself. The rest of the application need not be explored because nothing elsewhere that accessed the representation would compile. (We ignore child packages for the time-being.) The maintenance phase is the most expensive of the project phases for correcting errors, so this is a significant benefit.

Although changes to the internal representation of an ADT may become necessary, the scope of those changes is limited to the ADT package declaration and body because legal client code cannot depend on the representation of a private type. Consequently, changes to the type's representation can only require recompilation (and hence relinking) of client code, but not rewriting.

A change in representation may have non-functional considerations that prompt a change in client usage, such as performance changes, but it will not be a matter of the legality of the client code. Illegal client usage of an ADT wouldn't have compiled successfully in the first place.

The private type is the fundamental approach to creating abstractions in Ada, just as the use of the *public*, *private*, and *protected* parts of classes is fundamental to creating abstractions in class-oriented languages. Not every type can be private, as illustrated by the client expectation for array indexing in Ada. Not every type should be private, for example those that are explicitly numeric. But the ADT should be the default design idiom when decomposing a problem into a solution.

110.4 Cons

There is more source code text required in an ADT package compared to the idiom in which the representation is not hidden (the *Groups of Related Program Units* (page 1999)). The bulk of the additional text is due to the functions and procedures required to provide the capabilities that the low-level representation-based syntax might have provided, i.e., the *constructor* and *selector/accessor* functions. We say *might have provided* because these additional operations are by no means necessarily included. In general, the additional text required for private types is worth the protections afforded.

110.5 Relationship With Other Idioms

The package-oriented idioms described here and *previously* (page 1997) are the foundational program composition idioms because packages are the primary structuring unit in Ada. That is especially true of the *Abstract Data Type* (page 2001) idiom, which is the primary type specification facility in Ada. Additional package-oriented idioms will be described, especially regarding hierarchical packages, but those kinds of packages are optional. The basic package is not optional in Ada for a program of any significant size or complexity. (One could have a program consisting entirely of the main program, but either that program is relatively simple and small, or it is badly structured.) As a consequence, other idioms will exist within packages designed using one of these idioms, or some other package idiom.

110.6 Notes

1. With the package idioms that declare one or more types, especially the ADT idiom, the principle of Separation of Concerns dictates that objects of the type used by clients be declared by clients in client units, not in the same package that declares the type or types.
2. The Ada Rationale document did not introduce the concept of Abstract Data Types. The ADT concept had already been introduced and recognized as effective when the first version of Ada was being designed[2]. The Ada language requirements document, *Steelman*[3], uses the term "Encapsulated Definitions" and describes the information hiding to be provided. Steelman does not specify the implementation syntax because requirements documents do not include such directives. The language designers implemented those requirements via package private parts and private types.
3. The ADT is the conceptual foundation for the *class* construct's visibility control in some class-oriented languages.

CHAPTER

ONE

ABSTRACT DATA MACHINES

111.1 Motivation

111.2 Solution

The Abstract Data Machine (ADM) is similar to the *Abstract Data Type* (page 2001) in that it presents an abstraction, something that doesn't already exist in the programming language. Furthermore, like the ADT, operations are provided to manipulate the abstraction data, state that is not otherwise compile-time visible to client code. These operations are thus enforced as the only manipulation possible, as per the designer's intent. (The Abstract Data Machine was introduced by Booch as the Abstract State Machine, but that name can be confused with another concept that, though somewhat related, is not the same thing.)

Unlike the ADT, however, the ADM does not define the abstraction as a type. To understand this point, recall that type declarations are descriptions for objects that will contain data. For example, our earlier `Stack` type was defined as a record containing two components: an array to hold the values logically contained by the `Stack`, and an integer indicating the logical top of that array. No data actually exist, i.e., are allocated storage, until objects are declared. Clients can declare as many objects of type `Stack` as they require, and each object has a distinct, separate copy of those two components.

Clients can, of course, choose to declare only one object of a given type, in which case only one instance of the data described by the type will exist. But in that case, other than convenience there is no functional difference from declaring objects of the component types directly, rather than indirectly via some enclosing type. Instead of using the `Stack` type to declare a single composite object, for example, the developer could have instead declared two objects, one for the array and one for the stack pointer:

```
Capacity : constant := 100;
type Content is array  (1 .. Capacity) of Integer;
Values : Content;
Top    : Integer range 0 .. Capacity := 0;
```

or even this, using an anonymously-typed array:

```
Capacity : constant := 100;
Values : array  (1 .. Capacity) of Integer;
Top    : Integer range 0 .. Capacity := 0;
```

If there is only one *stack* these two objects will suffice.

That's what the ADM does. The necessary state for a single abstraction instance is declared in a package, usually a library package. But as an abstraction, those data declarations must not be compile-time visible to clients. Therefore, the state is declared in either the package private part or the package body. Doing so requires that visible operations be

made available to clients, as any abstraction would require. Hence the package is the abstraction instance, as opposed to one or more objects of a type.

Therefore, the package declaration's visible section will contain only the following:

- Constants (but almost certainly not variables)
- Ancillary Types
- Exceptions
- Operations

The package declaration's private part and the package body may contain all the above, but especially one or the other (or both) will contain object declarations representing the abstraction's state.

Consider the following ADM version of the package `Integer_Stacks`, now renamed to `Integer_Stack` for reasons we will discuss shortly. In this version we declare the state in the package body.

```
package Integer_Stack is
   procedure Push (Item : in Integer);
   procedure Pop (Item : out Integer);
   function Empty return Boolean;
   Capacity : constant := 100;
end Integer_Stack;

package body Integer_Stack is
   Values : array  (1 .. Capacity) of Integer;
   Top    : Integer range 0 .. Capacity := 0;
   procedure Push  (Item : in Integer) is
   begin
      --  ...
      Top := Top + 1;
      Values (Top) := Item;
   end Push;
   procedure Pop (Item : out Integer) is ... end Pop;
   function Empty return Boolean is (Top = 0);
end Integer_Stack;
```

Now there is no type presenting a `Stack` abstraction, and the operations do not take a stack parameter because the package and its data is the abstraction instance. There is only one stack of integers with this idiom. That is why the name of the package is changed from `Integer_Stacks`, i.e., from the plural form.

As with the ADT idiom, clients of an ADM can only manipulate the encapsulated state indirectly, via the visible operations. The difference is that the state to be manipulated is no longer a formal parameter. For example:

```
Integer_Stack.Push (42);
```

That call places the value 42 in the array `Integer_Stack.Values` located within the package body. Compare that to the ADT approach, in which objects of type `Stack` are manipulated:

```
Answers : Stack;
--  ...
Push (Answers, 42);
```

That call places the value 42 in the array `Answers.Values`, i.e., within the `Answers` variable. Clients can declare as many `Stack` objects as they require, and each will contain a distinct copy of the state defined by the type. In the ADM version there is only one stack and therefore one instance of the state.

Rather than declare the abstraction state in the package body, we could just as easily declare it in the package's private section:

```
package Integer_Stack is
   procedure Push (Item : in Integer);
   procedure Pop (Item : out Integer);
   function Empty return Boolean;
   Capacity : constant := 100;
private
   Values : array  (1 .. Capacity) of Integer;
   Top    : Integer range 0 .. Capacity := 0;
end Integer_Stack;
```

Doing so doesn't change anything from the client code point of view. Just as clients have no compile-time visibility to declarations in the package body, they have no compile-time visibility to the items in the package private part. This placement also doesn't change the fact that there is only one instance of the data. We've only changed where the data are declared. (We will discuss the effect of child packages separately.)

The private section wasn't required when the data were declared in the package body. That's typical when using this idiom but is not a necessary characteristic.

The ADM idiom applies information hiding to the internal state, similar to the ADT idiom, except that the state is not in objects. As well, like the *Groups of Related Program Units* (page 1999), the implementations of the visible subprograms are hidden by the package body, along with any non-visible entities required for their implementation.

There will be no constructor functions returning a value of the abstraction type because there is no such type with the ADM. However, there could be one or more initialization procedures, operating directly on the hidden state in the package private part or package body. In the `Stack` ADM there is no need because of the reasonable initial state, as is true with the ADT version.

The considerations regarding selectors/accessors are the same for the ADM as for the ADT idiom, so they are not provided by default. Also like the ADT, so-called *getters* and *setters* are highly suspect and not provided by the idiom by default.

111.3 Pros

In terms of abstraction and information hiding, the ADM provides the same advantages as the ADT idiom: clients have no representation details visible and must use the operations declared in the package to manipulate the state. The compiler enforces this abstract view. The ADM also has the ADT benefit of knowing where any bugs could possibly be located. If there is a bug in the manipulation, it must be in the one package defining the abstraction itself. No other code would have the compile-time visibility necessary.

This idiom can be applied to any situation requiring abstraction, including hardware. For example, a particular microprocessor had an on-board rotary switch for arbitrary use by system designers. The switch value was available to the software via an 8-bit integer located at a dedicated memory address, mapped like so:

```
Switch : Unsigned_8 with
   Volatile,
   Address => System.Storage_Elements.To_Address (16#FFC0_0801#);
```

Reading the value of the memory-mapped `Switch` variable provided the current switch value.

However, the memory at that address was read-only, and rightly so because the only way to change the value was to physically rotate the switch. Writing to that address had no

effect whatsoever. Although doing so was a logical error no indication was provided by the hardware. That silence was potentially confusing to developers. It certainly looked like a variable, after all. Declaring it as a constant wouldn't suffice because the user could rotate the switch during execution.

Furthermore, although mapped as a byte, the physical switch has only 16 total positions, read as the values zero through fifteen. An unsigned byte has no such constraints.

A good general rule is that if something shouldn't be done by clients, we should use the compiler to make it impossible. That's better than debugging, any day. Therefore, we will use the ADM idiom to represent the rotary switch. The compiler will enforce the read-only view and the operation can handle the range constraint. The ADM is a reasonable choice because there is only one such physical switch; a type doesn't bring any advantages in this case. The following illustrates the approach:

```
with Interfaces; use Interfaces;
package Rotary_Switch is
   subtype Values is Unsigned_8 range 0 .. 15;
   function State return Values;
end Rotary_Switch;
```

Clients can then call the function `Rotary_Switch.State` to get the switch's current value, as a constrained subtype. The body will handle all the details.

```
with System.Storage_Elements;  use System.Storage_Elements;
package body Rotary_Switch is
   Switch : Unsigned_8 with Volatile, Address => To_Address (16#FFC0_0801#);
   function State return Values is
   begin
      if Switch in Values then
         return Switch;
      else
         raise Program_Error;
      end if;
   end State;
end Rotary_Switch;
```

The range check in the function body might be considered over-engineering because the switch is a physical device that cannot have more than 16 values, but physical devices have a habit of springing surprises. Note that *attribute Valid* (page 382) would not be useful here because there are no invalid bit patterns for an unsigned integer. If, on the other hand, we were working with an enumeration type, for example, then `'Valid` would be useful.

111.4 Cons

An ADM defines only one abstraction instance. If more than one is required, the developer must copy-and-paste the entire package and then change the package unit name.

Furthermore, the ADM cannot be used to compose other types, e.g., as the component type in an array or record type. The ADM cannot be used to define the formal parameter of a client-defined subprogram, cannot be dynamically allocated, and so on.

But if one can know with certainty that only one thing is ever going to be represented, as in the hardware switch example, the ADM limitations are irrelevant. That said, certainty is usually not available — even the hardware changes.

CHAPTER

TWO

PROGRAMMING BY EXTENSION

112.1 Motivation

When declaring entities in a package, developers should ensure that the client view — the package visible part — contains no implementation artifacts. Doing so is important conceptually, but also practically, because any declarations visible to clients inevitably will be used by clients and, as a result, will become permanent fixtures because removal would cause expensive changes in the client code.

The intended client API declarations must be in the package visible part, of course. The question, then, is whether to declare implementation artifacts in the package private part or in the package body. Those are the two parts of a package that do not make declarations compile-time visible to client code.

Some of these entities must be declared in the package private part because they are required in the declaration of some other entity appearing in that part. For example, when using the *ADT idiom* (page 2001), an ancillary type might be required for the completion of the private type. That was the case with the *ADT version* (page 2003) of the `Integer_Stacks` package, repeated here for convenience:

```
package Integer_Stacks is
   type Stack is private;
   --  ...
   Capacity : constant := 100;
private
   type Content is array  (1 .. Capacity) of Integer;
   type Stack is record
      Values : Content;
      Top    : Integer range 0 .. Capacity := 0;
   end record;
end Integer_Stacks;
```

The array type `Content` is required for the `Stack` record component because anonymously-typed array components are illegal. Clients have no business using the type `Content` directly so although it would be legal to declare it in the public part, declaration in the private part is proper.

Likewise, a function called to provide the default initial value for a private type's component must be declared prior to the reference. If the function is truly only part of the implementation, we should declare it in the package private part rather than the public part.

In contrast, there may be implementation-oriented entities that are referenced only in the package body. They could be declared in the package body but could alternatively be declared in the package declaration's private part. Those are the entities (declarations) in question for this idiom.

For a concrete example, here is an elided *ADM version of the stack abstraction* (page 2010), with the stack state declared in the package body:

```
package Integer_Stack is
   procedure Push (Item : in Integer);
   procedure Pop (Item : out Integer);
   function Empty return Boolean;
   Capacity : constant := 100;
end Integer_Stack;

package body Integer_Stack is
   Values : array  (1 .. Capacity) of Integer;
   Top    : Integer range 0 .. Capacity := 0;
   procedure Push  (Item : in Integer) is
   begin
      --  ...
      Top := Top + 1;
      Values (Top) := Item;
   end Push;
   procedure Pop (Item : out Integer) is ...
   function Empty return Boolean is ...
end Integer_Stack;
```

We could add the package private part to the package declaration and move the state of the *ADM* (page 2009) — the two variables in this case — up there without any other changes. The subprogram bodies have the same visibility to the two variables either way. (There is no requirement for the `Content` type because `Values` is not a record component. Anonymously-typed array objects are legal.) From the viewpoint of the language and the abstraction the location is purely up to the developer.

112.2 Solution

When you have a choice, placement in either the package private part or the package body is reasonable, but only one of the two locations is amenable to future requirements.

Specifically, placement in the private part of the package will allow *programming by extension*[1] via hierarchical *child* packages. Child packages can be written immediately after the *parent* package but can also be written years later, thus accommodating changes due to new requirements.

Programming by extension allows us to extend an existing package's facilities without having to change the existing package at all. Avoiding source code changes to the existing package is important because doing so might be very expensive. In certified systems the changed package would require re-certification, for example. Changes to the parent package are avoidable because child packages have compile-time visibility to the private part of the ancestor package (actually the entire ancestor package hierarchy, any of which could be useful). Thus, the extension in the child package can depend on declarations in the existing parent package's private part.

Therefore, if the developer can know, with certainty, that no visibility beyond the one package will ever be appropriate, the declaration should go in the package body. Otherwise, it should go in the package private part, just in case an extension becomes necessary later.

Using our ADM stack example, we could move the state from the package body to the private part:

```
package Integer_Stack is
   procedure Push (Item : in Integer);
   procedure Pop (Item : out Integer);
   function Empty return Boolean;
```

(continues on next page)

[1] Barnes, J. (1998). Programming In Ada 95, Addison-Wesley.

(continued from previous page)

```
   Capacity : constant := 100;
private
   Values : array  (1 .. Capacity) of Integer;
   Top    : Integer range 0 .. Capacity := 0;
end Integer_Stack;
```

Note that the private part was not otherwise required by the language in this example.

With that change, a new child package could be created with extended functionality:

```
package Integer_Stack.Utils is
   procedure Reset;
end Integer_Stack. Utils;

package body Integer_Stack.Utils is
   procedure Reset is
   begin
      Top := 0;
   end Reset;
end Integer_Stack.Utils;
```

These child packages are not client code, they contain extensions to the existing abstraction. Hence they are part of what may be considered a subsystem consisting of the original package and the new child package. The child package contains an extension of the abstraction defined by the parent package, so the child is directly related. Given that characterization of child packages we can say that the parent package private part is not visible to client code and, therefore, does not represent a *leak* of implementation details to clients.

112.3 Pros

We can extend an abstraction without changing the source code defining that abstraction, thereby meeting new requirements without incurring potentially expensive redevelopment.

112.4 Cons

Clients could abuse the hierarchical package visibility rules by creating a child package that doesn't really extend the existing package abstraction.

Abuse of the visibility rules allows child packages that can break the abstraction. For example, if we only change the name of procedure `Reset` in package `Integer_Stack.Utils` to `Lose_All_Contained_Data` then the routine has a rather different complexion.

Similarly, abuse of the visibility rules allows child packages that can indirectly leak state from the parent package. For example:

```
package Integer_Stack.Leaker is
   function Current_Top return Integer;
end Integer_Stack.Leaker;

package body Integer_Stack.Leaker is
   function Current_Top return Integer is (Top);
end Integer_Stack.Leaker;
```

We could do that without even requiring a package body, using an expression function for the completion:

```
package Integer_Stack.Leaker is
   function Current_Top return Integer;
private
   function Current_Top return Integer is (Top);
end Integer_Stack.Leaker;
```

The function must be completed in the private part because that is where compile-time visibility to the parent begins within a child package.

Code reviews are the only way to detect these abuses, although detection of potential cases could be automated with an analysis tool such as Libadalang[514].

112.5 Relationship With Other Idioms

We assume the use of the *Abstract Data Type* (page 2001) or *Abstract Data Machine* (page 2009) idioms for the existing package abstraction, as well as for the child package.

112.6 Notes

This guideline will already be used when developing a subsystem (a set of related packages in a common hierarchy) as a structuring approach during initial development. The idiom discussed here is yet another reason to use the private part, but in this case for the sake of the future, rather than initial, development.

The very first version of Ada (Ada 83) did not have hierarchical packages so, typically, anything not required in the private part was declared in the package body. Declaring them in the private part would only clutter the code that had to be there, without any benefit. The author's personal experience and anecdotal information confirms that after Ada 95 introduced hierarchical library units, some declarations in existing package bodies tended to "percolate up" to the package declarations' private parts.

CHAPTER

THREE

CONSTRUCTOR FUNCTIONS FOR ABSTRACT DATA TYPES

113.1 Motivation

In languages supporting object-oriented programming (OOP), including Ada, *constructors* are not inherited when one type is derived from another. That's appropriate because, in general, they would be unable to fully construct values for the new type.

Ada uses tagged types to fully support dynamic OOP. Therefore, in the following, a *derived type* refers to a tagged type that is declared as a so-called *type extension* — a form of inheritance — based on some existing *parent* tagged type. The extension consists of additional components and/or additional or changed operations beyond those inherited from the existing parent type.

This discussion assumes these tagged types are declared in packages designed using the *Abstract Data Type* (page 2001) (ADT) idiom. In particular, the parent type is a private type, and the derived type is declared as a *private extension*. A private extension is a type extension declaration that does not reveal the components added, if any. The parent type could itself be an extended type, but the point is that these types will all be private types one way or another. Declarations as private types and private extensions are not required by the language for inheritance, but as argued in the ADT idiom discussion, doing so is recommended in the strongest terms. OOP doesn't change that, and in fact the encapsulation and information hiding that are characteristic of the ADT idiom are foundational principles for OOP types.

For an example of a private extension, given a tagged type named `Graphics.Shape` one can declare a new type named `Circle` via type extension:

```
type Circle is new Graphics.Shape with private;
```

Although this declaration will occur in the public part of a package, as a private type extension the additional components will not be compile-time visible to client code, conforming to ADT requirements. That's what the word **`private`** indicates in the type declaration.

Functions and procedures that manipulate objects of the private type are *primitive operations* for the type if they are declared in the same package as the type declaration itself. (That location provides the compile-time visibility to the type's representation that is required to implement the subprograms.) Only the primitive operations are inherited during type derivation.

Instead of a distinct constructor syntax, Ada uses regular functions to construct objects of types but the issues are the same. By definition, these so-called *constructor functions* return an object of the type in question. Other primitive functions are not constructors and can be inherited without difficulty.

Therefore, Ada language rules prevent constructor functions from being legally inherited, even though they are primitive operations for the type.

The explanation and illustration for these rules first requires explanation of the word *abstract*. We mentioned above that the package enclosing the type will be designed with

the *Abstract Data Type* (page 2001) idiom. In that idiom *abstract* means that the type represents an abstraction. (See that section for the details.)

The term *abstract* also has a meaning in OOP, one that is unrelated to an ADT. In OOP, an *abstract* type is one that defines an interface but at most a partial implementation. As such, the type can serve as the ancestor type for derived types but cannot be used to declare objects. An abstract type in Ada includes the reserved word **abstract** in the declaration. For example:

```
type Foo is abstract tagged private;
```

Similarly, subprograms can be abstract. These again define an interface, via the subprogram formal parameters and result type, but are not callable units. In Ada these too include the word **abstract** in their declarations, for example:

```
procedure Do_Something (This : in out Foo) is abstract;
```

In contrast, *concrete* types have an actual representation and can be used to declare objects. Likewise, concrete subprograms are fully implemented, callable units. In the following discussion, *abstract* has this OOP sense unless stated otherwise.

With that definition in place, we can explain how Ada prevents constructor inheritance: whenever a tagged type is extended, all inherited constructor functions automatically become abstract functions for the extended type. Assuming the extended child type is not abstract, the type extension will be illegal because only abstract types can have abstract subprograms. Thus, the compiler prevents this inappropriate constructor inheritance.

For an example, both for the code and the Ada rules, consider this simple package declaration that presents the tagged private type `Graphics.Shape`:

```
package Graphics is
   type Shape is tagged private;
   function Make (X, Y : Float) return Shape;
   ...
private
   type Shape is tagged record
      X : Float := 0.0;
      Y : Float := 0.0;
   end record;
end Graphics;
```

Note in particular the primitive function named `Make` that constructs a value of type Shape. The two formal parameters are assigned to the corresponding two components of the object returned by `Make`.

Because type Shape is tagged, other types can extend it:

```
with Graphics;
package Geometry is
   type Circle is new Graphics.Shape with private;  -- a private extension
   --  ...
private
   type Circle is new Graphics.Shape with record
      Radius : Float;
   end record;
end Geometry;
```

Type `Circle` automatically inherits the components and primitive operations defined by type Shape, including the constructor function `Make`. No additional declarations are required in order to inherit these operations or components. The inherited operations are now primitive operations for the new type.

Inherited primitive operations have an unchanged formal parameter and result-type profile,

except for the controlling parameter type name, so although Make now returns a Circle object, the function still only has parameters for the X and Y components. Hence this version of Make could not set the Radius component in the returned Circle value to anything other than some default.

Therefore, to prevent this inherited function from being available, two Ada rules come into play. The first rule specifies that the implicit function is inherited as if declared explicitly abstract:

```
function Make (X, Y : Float) return Circle is abstract;
-- as actually inherited, implicitly
```

Note the reserved word **abstract** in the implicit function declaration. This declaration doesn't actually appear in the source code because all the inherited primitive operations are implicitly declared.

Another rule specifies that only abstract types can have abstract primitive subprograms. Type Circle is not abstract in this sense, therefore the combination of those two rules makes the Circle type extension illegal. Package Geometry will not compile successfully.

Failing to compile is safe — it prevents clients from having a callable function that in general cannot suffice — but requires an alternative so that sufficient constructor functions are possible.

Therefore, a general design idiom is required for defining constructor functions for concrete tagged Abstract Data Types.

113.2 Solution

The general solution uses functions for constructing objects but prevents these functions from being inherited. The problem is thus circumvented entirely.

To prevent their being inherited, the solution prevents the constructor functions from being primitive operations. However, these functions require compile-time visibility to the parent type's representation in order to construct values of the type, as this typically involves assigning values to components in the return object. The alternative approach must supply the compile-time visibility that primitive operations have.

Therefore, the specific solution is to declare constructor functions in a separate package that is a *child* of the package declaring the tagged type. The actual term is a *hierarchical library package* but *child* conveys the concept and is less of a mouthful.

Operations declared in a child package are not primitive operations for the type in the parent package, so they are not inherited when that type is extended. Consequently they do not become abstract.

In addition, the required visibility to the parent type's representation in the private part will be available to the functions' implementations because the private part and body of a child package have compile-time visibility to the parent package's private part.

In this idiom, any package declaring a tagged type, either directly or by type extension, will have a *constructors* child package if constructors are required. For example:

```
package Graphics.Constructors is
   function Make (X, Y : Float) return Shape;
end Graphics.Constructors;
```

and similarly, for Circle:

```
package Geometry.Constructors is
   function Make (X, Y, R : Float) return Circle;
end Geometry.Constructors;
```

Each of these two package declarations will have a package body containing the body of the corresponding function. In fact such packages can declare as many constructor functions as required, overloaded or not.

Clients that want to use a constructor function will specify the constructor package in the context clauses for their units, as usual. The constructor package body for an extended type might very well do so itself, as shown below:

```
with Graphics.Constructors; use Graphics.Constructors;
package body Geometry.Constructors is
   function Make (X, Y, R : Float) return Circle is
     (Circle'(Make (X, Y) with Radius => R));
end Geometry.Constructors;
```

Of course, the name "Constructors" is not required for the child packages. It could be "Ctors", for example (a name common in C++), or something else. But whatever the choice, regularity enhances comprehension so the same child package name should be used throughout.

113.3 Pros

The issue is sidestepped entirely, and as an additional benefit, the parent packages are that much simpler because the constructor function declarations and bodies are no longer present there. The *constructors* child packages themselves will be relatively simple since they contain only the constructor functions and any ancillary code required to implement them. Simpler code enhances comprehension and correctness.

Having the constructors declared in separate packages applies the principle of Separation of Concerns, between the code defining the type's semantics and the code for constructing objects of the type. This principle also enhances comprehension.

113.4 Cons

There will be a child package for each tagged type that requires constructors, hence more packages and files (assuming one unit per file, which is desirable in itself, even if not required by the language).

Some developers might argue for having fewer files, presumably containing larger units. In the author's experience larger units make comprehension, and therefore correctness, unjustifiably difficult if smaller units are possible. Some units are unavoidably large and complicated but often we can achieve relative simplicity.

For those developers, however, the constructor package could be declared instead as a nested package located within the package defining the tagged type. Doing so would achieve the same effect as using a child package because the contained functions would not be primitive. Therefore, they would not inherited.

This alternative would reduce the number of files back to the minimum. However, the defining package would be relatively more complicated because of this nested package. Note that the nested package declaration would require a nested package body too.

In short, the alternative reduces the number of files at the cost of additional unit complexity. (If the issue with the larger number of files is difficulty in locating individual entities of interest, any decent IDE will make doing so trivial.)

The alternative also loses the distinction between clients that use objects of the type and clients that create those objects, because the latter will have context clauses for the constructor packages.

113.5 Relationship With Other Idioms

N/A

113.6 Notes

For those interested, in this section we provide a discussion of alternatives to the solution given, and why they are inadequate.

Changing the behavior of an inherited operation requires an explicit conforming subprogram declaration and therefore a new subprogram body for that operation. This change is known as *overriding* the inherited operation.

Package `Geometry` could declare a function with the additional parameters required to fully construct a value of the new type. In this case the new constructor would include the `Radius` parameter:

```
function Make (X, Y, Radius : Float) return Circle;
```

But such a function would not be overriding for the inherited version because the parameter and result type profile would be different. This function `Make` would overload the inherited function, not override it. The inherited function remains visible, as-is.

In fact, we could even have the compiler confirm that this is not an overriding function by declaring it so:

```
not overriding function Make (X, Y, Radius : Float) return Circle;
```

In general, specifying that a subprogram is not overriding is less convenient than specifying that it is overriding. We only do so in these examples to make everything explicit.

Because that new function is not overriding, the inherited version remains implicitly abstract and the type extension remains illegal. Developers could also override the inherited function, which would make the code legal, but as we have said such a function cannot properly construct values in general, and might be called accidentally. For example:

```
with Graphics;
package Geometry is
   type Circle is new Graphics.Shape with private;

   overriding function Make (X, Y : Float) return Circle;

   not overriding function Make (X, Y, Radius : Float) return Circle;
   -- overloading

   ...
private
   --  ...
end Geometry;
```

Although the overridden Make does not have a Radius parameter and could only assign some default to that component, if that default is reasonable then the overridden function could be called on purpose, i.e., not accidentally. That's not a general solution, however.

Alternatively, developers could use procedures as their constructors, with a mode-out parameter for the result. The procedure would not become implicitly abstract in type extensions, unlike a function.

```
package Graphics is
   type Shape is tagged private;
   procedure Make (Value : out Shape;  X, Y : in Float);
private
   --  ...
end Graphics;
```

And then the client extension would inherit the procedure:

```
with Graphics;
package Geometry is
   type Circle is new Graphics.Shape with private;
   --  procedure Make (Value : out Circle;  X, Y : in Float);  -- inherited
private
   --  ...
end Geometry;
```

However, although now legal, the inherited procedure would not suffice, lacking the required parameter for the Radius component.

Developers might then add an overloaded version with the additional parameter:

```
with Graphics;
package Geometry is
   type Circle is new Graphics.Shape with private;

   --  procedure Make (Value : out Circle;  X, Y : in Float);
   -- inherited

   not overriding procedure Make (Value : out Circle;  X, Y, R : in Float);
   -- not inherited
private
   --  ...
end Geometry;
```

But the same issues arise as with functions. Clients might accidentally call the wrong procedure, i.e., the inherited routine that doesn't have a parameter for the Radius. That routine would not even mention the Radius component, much less assign a default value, so it would have to be overridden in order to do so. This too is not a general solution.

CHAPTER

FOUR

REDUCING OBJECT CODE FROM GENERIC PACKAGE INSTANTIATIONS

114.1 Motivation

Generic unit instantiations are often, but not always, implemented by an Ada compiler as a form of *macro expansion*. In this approach, the compiler produces separate, dedicated object code for every instantiation. The macro expansion approach can produce better run-time performance but can result in large total object code size for the executable when there are many instances, especially when the generic packages instantiated contain a lot of unit declarations. For example, the generic I/O packages contained within package `Ada.Text_IO` are themselves relatively large.

The alternative compiler implementation approach is *code-sharing*, in which distinct instantiations of a given generic unit are implemented with shared object code in a single module.

Clearly, sharing the object code can reduce the total size, but code-sharing can be very complicated to implement, depending on the generic unit itself. For a trivial example, consider the following package:

```
generic
package P is
   Error : exception;
end P;
```

The semantics of the language require that every instantiation of generic package P be a distinct package, as if each instance was instead written explicitly as a non-generic package (at the point of instantiation) with the instance name. As a result, each package instance declares an exception, and these exceptions must be treated as distinct from each other. A code-sharing implementation must maintain that distinction with one object code module.

In the example above, there are no generic formal parameters, nor other declarations within the package declarative part besides the exception, because they are not necessary for that example. However, generic formal parameters can be a problem for code-sharing too. For example, consider this generic package:

```
generic
   Formal_Object : in out Integer;
package P is
   --  ...
end P;
```

This generic package has a generic formal object parameter with mode **`in out`**. (We chose type **`Integer`** purely for convenience.) That specific mode can cause a similar problem as seen in the exception example, because the mode allows the generic package to update the generic actual object passed to it. The shared object code must keep track of which object is updated during execution.

Therefore, when writing the application source code that instantiates generic packages, developers should do so in a manner that minimizes the amount of object code that might result.

114.2 Solution

The application source code should be written in a manner that shares the instantiations themselves, when possible, thereby reducing the number of instantiations that exist.

For example, let's say that several units in the application code require the ability to do I/O on some floating-point type. For simplicity, let's say that this is a type named `Real`, declared in a package named `Common`. Here is a declaration for an example package body that requires the I/O capability:

```
with Ada.Text_IO, Common;
package body User1 is
    package Real_IO is new Ada.Text_IO.Float_IO (Common.Real);
    -- ...
end User1;
```

That's certainly legal, and works, but we've said that several units require I/O for type `Real`. Let's say there are in fact twenty such units. They all do something similar:

```
with Ada.Text_IO, Common;
package body User20 is
    package Real_IO is new Ada.Text_IO.Float_IO (Common.Real);
    --  ...
end User20;
```

As a result, the application has twenty instantiations (at least) of `Ada.Text_IO.Float_IO`. There will be instances named `User1.Real_IO`, `User2.Real_IO`, and so on, up to `User20.Real_IO`. The fact that the local names are all `Real_IO` is irrelevant.

If the compiler happens to use the macro-expansion implementation, that means the application executable will have twenty copies of the object code defined by the generic `Float_IO`. For example, GNAT performs some internal restructuring to avoid this problem for these specific language-defined generic units, but not for application-defined generics.

Instead, we can simply instantiate the generic at the library level:

```
with Ada.Text_IO, Common;
package Real_IO is new Ada.Text_IO.Float_IO (Common.Real);
```

Because the instantiation occurred at the library level, the resulting instance is declared at the library level, and can therefore be named in a "with-clause" like any other library package.

```
with Real_IO;
package body User1 is
    --  ...
end User1;
```

Each client package can use the same instance via the with-clause, and there's only one instance so there's only one copy of the object code.

114.3 Pros

The total object code size is reduced, compared to the alternative of many local instantiations.

114.4 Cons

What would otherwise be an implementation detail hidden from clients can now become visible to them because a (public) library unit can be named in with-clause by any other unit. As a result, this approach should not be used in all cases, not even as a default design approach. Restricting the visibility of the instance may be more important than the amount of object code it contributes. Hiding implementation artifacts allows more freedom to change the implementation without requiring changes to client code.

114.5 Relationship With Other Idioms

None.

114.6 Notes

1. The reader should understand that this issue is not about the number of subprograms within any given package, whether or not the package is a generic package. In the past, some linkers included the entire object code for a given package (instance or not), regardless of the number of subprograms actually used from that package in the application code. That was an issue with reusable library code, for example packages providing mathematical functions. Modern linkers can be told not to include those subprograms not called by the application. For example, with gcc, the compiler can be told to put each subprogram in a separate section, and then the linker can be told to only include in the executable those sections actually referenced. (Data declarations can be reduced that way as well.)

CHAPTER

FIVE

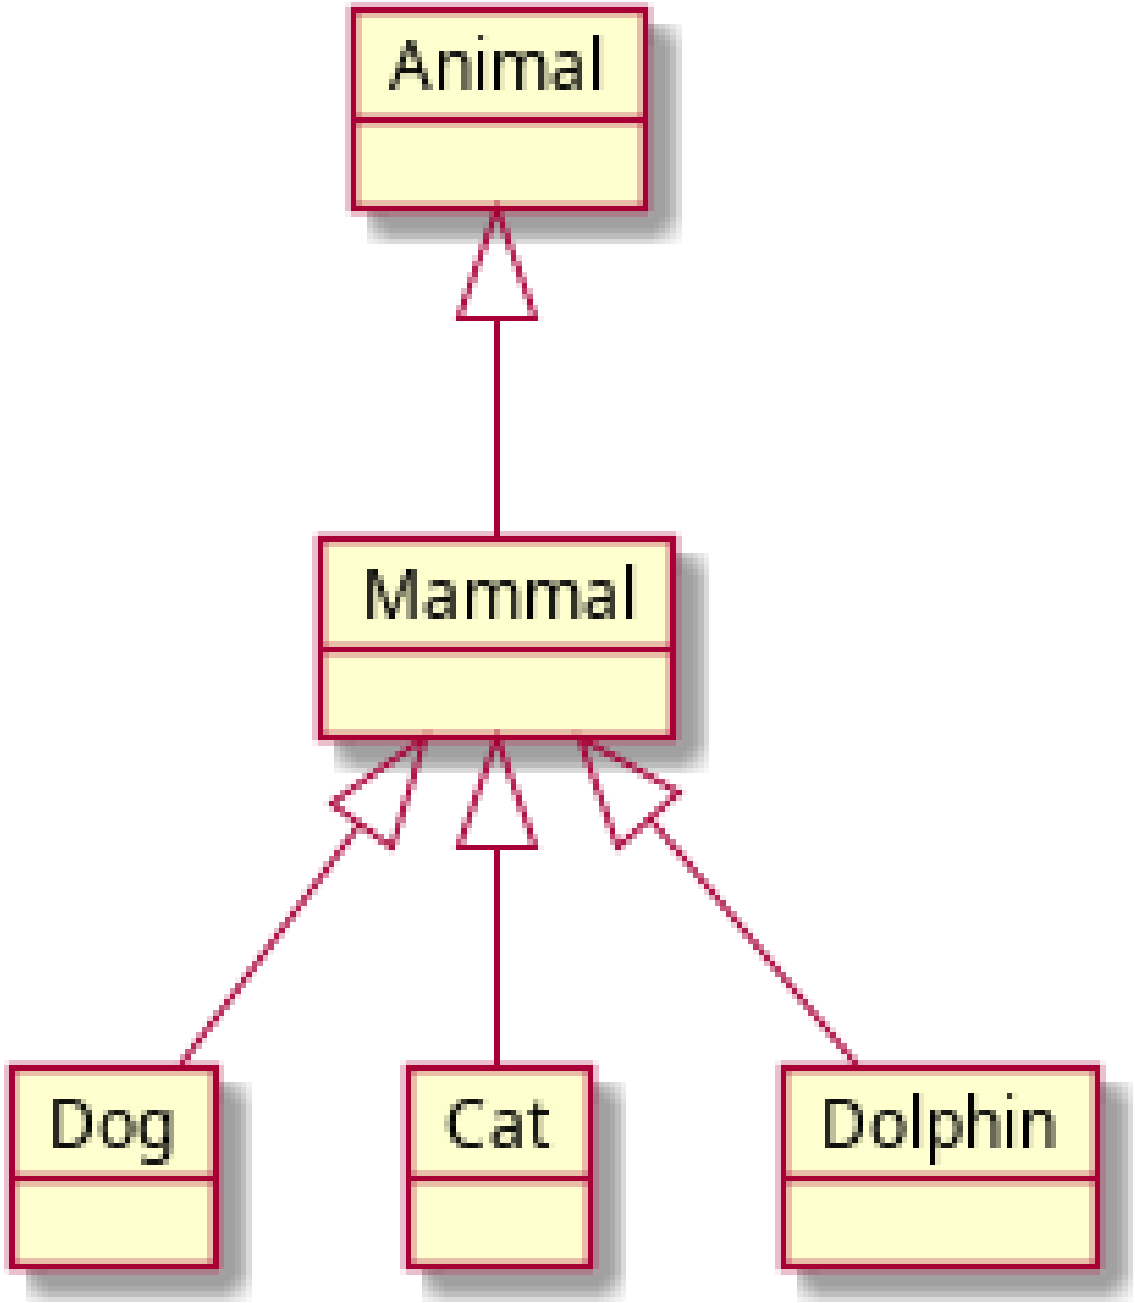
USING BUILDING BLOCKS TO EXPRESS INHERITANCE IDIOMS

115.1 Motivation

Betrand Meyer's magisterial book on OOP[1] includes a taxonomy of inheritance idioms. Two especially well-known entries in that taxonomy are Subtype Inheritance[515] and Implementation Inheritance[516]. The name of the first idiom is perhaps confusing from an Ada point of view because Ada subtypes have a different meaning. In Ada terms we are talking about *derived types*. A derived type is a new, distinct type based on (i.e., derived from) some existing type. We will informally refer to the existing ancestor type as the *parent* type, and the new type as the *child* type. The term *Subtype* in the idiom name refers to the child type.

Subtype Inheritance is the most well-known idiom for inheritance because it is based on the notion of a taxonomy, in which categories and disjoint subcategories are identified. For example, we can say that dogs, cats, and dolphins are mammals, and that all mammals are animals:

[1] Meyer, B. (1997). Object-Oriented Software Construction, Prentice-Hall.
[515] https://en.wikipedia.org/wiki/Subtyping
[516] https://en.wikipedia.org/wiki/Inheritance_(object-oriented_programming)



By saying that the subcategories are disjoint we mean that, for example, dogs are neither cats nor dolphins and cannot be treated as if they are the same.

In software, we use various constructs to represent the categories and subcategories, and use inheritance to organize them. As mentioned above, in Ada we express that inheritance via derived types representing the categories and subcategories. Ada's strong typing ensures they are treated as disjoint entities.

Although the derived child type is distinct from the parent type, the child is the same kind as the parent type. Some authors use *kind of* as the name for the relationship between the child and parent. Meyer uses the term *is-a*[Page 2027, 1], a popular term that we will use too. For example, a cat *is a* mammal, and also is an animal.

The fundamental difference between *Subtype Inheritance* (page 2031) and *Implementation Inheritance* (page 2034) is whether clients have compile-time visibility to the *is-a* relationship between the parent and child types. The relationship exists in both idioms but is not

visible to clients in both. In Subtype Inheritance clients do have compile-time visibility to the relationship, whereas in Implementation Inheritance clients do not have that visibility.

Consequently, with Subtype Inheritance, all of the inherited operations become part of the child type's visible interface. In contrast, with Implementation Inheritance none of those parent capabilities are part of the visible interface. The inherited parent capabilities are only available internally, to implement the child type's representation and its primitive operations.

115.1.1 Building Blocks

Ada uses distinct *building block* constructs to compose types that have specific characteristics and capabilities. In particular, Ada packages, with their control over compile-time visibility, are modules. Private types are combined with packages to define *abstract data types* (page 2001) having hidden representations. Sets of related types are presented explicitly by class-wide types.

In addition, simple reserved words may be attached to a type declaration to refine or expand the capabilities of the type. These type declarations include declarations for derived types, providing considerable flexibility and expressive power for controlling the client's view of the child and parent types.

For example, in Ada, full dynamic OOP capabilities require type declarations to be decorated with the reserved word **tagged**. However, from the beginning Ada has also supported a static form of inheritance, using types that are not tagged. The solution we describe below works with both forms of inheritance.

The developer also has a choice of whether the parent type and/or the child type is a private type. Using private types is the default design choice, for the sake of designing in terms of abstract data types, but is nevertheless optional.

In addition, a type can be both private and tagged. This possibility raises the question of whether the type is *visibly tagged*, i.e., whether the client view of the type includes the tagged characteristic, and hence the corresponding capabilities. Recall that a private type is declared in two steps: the first part occurs in the visible part of the package and introduces the type name to clients. The second part — the type completion — appears in the package private part and specifies the type's actual representation. The question arises because the first step, i.e., the declaration in the package's visible part, need not be tagged, yet can be tagged in the completion in the package private part. For example:

```
package P is
   type Foo is private;  --  not visibly tagged for clients
   -- operations on type Foo
private
   type Foo is tagged record  -- tagged completion
      ...
   end record;
end P;
```

In the above, Foo is not visibly tagged except in the package private part and the package body. As a consequence, the capabilities of tagged types are not available to clients using type Foo. Clients cannot refer to Foo'Class, for example. (The opposite arrangement — tagged in the visible client view but not actually tagged in the private view — is not legal, because clients would be promised capabilities that are not actually available.)

When the parent type is tagged, the type derivation syntax for the child is a *type extension* declaration that introduces the child type's name, specifies the parent type, and then extends the parent representation with child-specific record components, if any. For example:

```
type Child is new Parent with record ... end record;
```

Even though the child type declaration does not include the reserved word **tagged** the child will be a tagged type because the parent type is tagged. The compiler would not allow the extension construct for a non-tagged parent type.

Just as a private type can be visibly tagged or not, a private type can be *visibly derived* or not. When it is visibly derived, clients have a view of the private type that includes the fact of the derivation from the parent type. Otherwise, clients have no view of the parent type. Whether or not the child is visibly derived, the representation is not compile-time visible to clients, as for any private type. For example, type Foo is not visibly derived in the following:

```
package P is
   type Foo is tagged private;  --  visibly tagged but not visibly derived
   -- ...
end P;
```

To be visibly derived, we declare the child type as a private type using a *private extension*. A private extension is like a type extension, in that it introduces the child type name and the parent type. But like any private type declaration, it does not specify the type's representation. This is the first of the two steps for declaring a private type; hence it appears in the package visible part. For example:

```
with ...
package P is
   type Child is new Parent with private;  -- visibly derived from Parent
private
   type Child is new Parent with record ... end record;
end P;
```

The representation additions are not expressed until the private type's completion in the package private part, using a type extension. The steps are the same two for any private type: a declaration in the package visible part, with a completion in the package private part. The difference is the client visibility to the parent type.

115.2 Solution

There are two *solutions* in this entry, one for each of the two inheritance idioms under discussion. First, we will specify our building block choices, then we will show the two idiom expressions in separate subsections.

- We will use tagged types for the sake of the full OOP capabilities. That is the most common choice when inheritance is involved. The static form of inheritance has cases in which it is useful, however those cases are very narrow in applicability.
- We will assume that the parent type and the child type are both private types, i.e., abstract data types, because that is the best practice. See the *Abstract Data Type idiom* (page 2001) for justification and details.
- For the most general capabilities, we will assume that the parent type is visibly tagged.
- We are going to declare the child type in a distinct, dedicated package, following the *ADT idiom* (page 2001). This package may or may not be a hierarchical child of the parent package. The solution approach does not require a child package's special compile-time visibility, although a child package is often necessary for the sake of that visibility.
- Whether the child type is visibly derived will vary with the *inheritance idiom* (page 2034) solution.

To avoid unnecessary code duplication, examples for the two idiom solutions use the same parent type, declared as a simple tagged private type. The parent type could itself be

derived from some other tagged type, but that changes nothing conceptually significant. The parent type is declared in package P, as follows:

```
package P is
   type Parent is tagged private;  -- visibly tagged
   --  primitive operations with type Parent as the
   --  controlling formal parameter
private
   type Parent is tagged record ... end record;
end P;
```

115.2.1 Subtype Inheritance

Recall that Subtype Inheritance requires clients to have compile-time visibility to the *is-a* relationship between the child and parent types. We can satisfy that requirement if we make the child visibly derived from the parent. Hence we declare the private type as a private extension in the visible part of the package:

```
with P; use P;
package Q is
  type Child is new Parent with private;
  --  implicit, inherited primitive Parent operations declared here,
  --  now for type Child
  --  additional primitives for Child explicitly declared, if any
private
  type Child is new Parent with record ... end record;
end Q;
```

The primitive operations from the parent type are implicitly, automatically declared immediately after the private extension declaration. That means those operations are in the visible part of the package, hence clients can invoke them. Any additional operations for the client interface will be explicitly declared in the visible part as well, as will be any overriding declarations for those inherited operations that are to be changed.

For example, here is a basic bank account *ADT* (page 2001) that we will use as the parent type in a derivation:

Listing 1: bank.ads

```
1  with Ada.Strings.Unbounded;  use Ada.Strings.Unbounded;
2  with Ada.Containers.Doubly_Linked_Lists;
3
4  package Bank is
5
6     type Basic_Account is tagged private
7       with Type_Invariant'Class => Consistent_Balance (Basic_Account);
8
9     function Consistent_Balance (This : Basic_Account) return Boolean;
10
11    type Currency is delta 0.01 digits 12;
12
13    procedure Deposit (This   : in out Basic_Account;
14                       Amount : Currency) with
15      Pre'Class  => Open (This) and Amount > 0.0,
16      Post'Class => Balance (This) = Balance (This)'Old + Amount;
17
18    procedure Withdraw (This   : in out Basic_Account;
19                        Amount : Currency) with
20      Pre'Class  => Open (This) and Funds_Available (This, Amount),
21      Post'Class => Balance (This) = Balance (This)'Old - Amount;
```

(continues on next page)

(continued from previous page)

```
22
23    function Balance (This : Basic_Account) return Currency
24      with Pre'Class => Open (This);
25
26    procedure Report_Transactions (This : Basic_Account)
27      with Pre'Class => Open (This);
28
29    procedure Report (This : Basic_Account)
30      with Pre'Class => Open (This);
31
32    function Open (This : Basic_Account) return Boolean;
33
34    procedure Open
35      (This            : in out Basic_Account;
36       Name            : in String;
37       Initial_Deposit : in Currency)
38    with Pre'Class => not Open (This),
39         Post'Class => Open (This);
40
41    function Funds_Available (This : Basic_Account;
42                              Amount : Currency) return Boolean is
43      (Amount > 0.0 and then Balance (This) >= Amount)
44    with Pre'Class => Open (This);
45
46 private
47
48    package Transactions is new
49      Ada.Containers.Doubly_Linked_Lists (Element_Type => Currency);
50
51    type Basic_Account is tagged record
52       Owner           : Unbounded_String;
53       Current_Balance : Currency := 0.0;
54       Withdrawals     : Transactions.List;
55       Deposits        : Transactions.List;
56    end record;
57
58    function Total (This : Transactions.List) return Currency is
59      (This'Reduce ("+", 0.0));
60
61 end Bank;
```

We could then declare an interest-bearing bank account using Subtype Inheritance:

Listing 2: bank-interest_bearing.ads

```
1  package Bank.Interest_Bearing is
2
3     type Account is new Basic_Account with private;
4
5     overriding
6     function Consistent_Balance (This : Account) return Boolean;
7
8     function Minimum_Balance (This : Account) return Currency;
9
10    overriding
11    procedure Open
12      (This            : in out Account;
13       Name            : in String;
14       Initial_Deposit : in Currency)
15    with Pre => Initial_Deposit >= Minimum_Balance (This);
16
```

(continues on next page)

(continued from previous page)

```
   overriding
   procedure Withdraw (This : in out Account;  Amount : Currency);

   function Penalties_Accrued (This : Account) return Currency;
   function Interest_Accrued (This : Account) return Currency;

private

   type Account is new Basic_Account with record
      Penalties          : Transactions.List;
      Interest_Earned    : Transactions.List;
      Days_Under_Minimum : Natural := 0;
   end record;

end Bank.Interest_Bearing;
```

The new type `Bank.Interest_Bearing.Account` inherits all the `Basic_Account` operations in the package visible part. They are, therefore, available to clients. Some of those inherited operations are overridden so that their behavior can be changed. Additional operations specific to the new type are also declared in the visible part so they are added to the client API.

The package private part and the body of package `Bank.Interest_Bearing` have visibility to the private part of package Bank because the new package is a hierarchical child of package Bank. That makes the private function `Bank.Total` visible in the child package, along with the components of the record type `Basic_Account`.

Note that there is no language requirement that the actual parent type in the private type's completion be the one named in the private extension declaration presented to clients. The parent type in the completion must only be in the same derivation class — be the same kind of type — so that it satisfies the *is-a* relationship stated to clients.

For example, we could start with a basic graphics shape:

```
package Graphics is
   type Shape is tagged private;
   --  operations for type Shape ...
   ...
end Graphics;
```

We could then declare a subcategory of Shape that allows translation in some 2-D space:

```
package Graphics.Translatable is
   type Translatable_Shape is new Graphics.Shape with private;
   procedure Translate (This : in out Translatable_Shape;  X, Y : in Float);
...
end Graphics.Translatable;
```

Given that, we could now declare another type visibly derived from Shape, but using `Translatable_Shape` as the actual parent type:

```
with Graphics;
private with Graphics.Translatable;
package Geometry is
   type Circle is new Graphics.Shape with private;
   --  operations for type Circle, inherited from Shape,
   --   and any new ops added ...
private
   use Graphics.Translatable;
   type Circle is new Translatable_Shape with record ... end record;
end Geometry;
```

In the type extension that completes type Circle in the package private part above, the extended parent type is not the one presented to clients, i.e., Graphics.Shape. Instead, the parent type is another type that is derived from type Shape. That substitution is legal and reasonable because Translatable_Shape necessarily can do anything that Shape can do. To understand why that is legal, it is helpful to imagine that there is a *contract* between the package public part and the private part regarding type Circle. As long as Circle can do everything promised to clients — i.e., inherited Shape operations — the contract is fulfilled. Circle inherits Shape operations because Translatable_Shape inherits those operations. The fact that Circle can do more than is contractually required by the client view is perfectly fine.

115.2.2 Implementation Inheritance

Recall that with Implementation Inheritance clients do not have compile-time visibility to the *is-a* relationship between the parent and child types. We meet that requirement by not making the child visibly derived from the parent. Therefore, we declare the child type as a simple tagged private type and only mention the parent in the child type's completion in the package private part:

```
with P; use P;
package Q is
  type Child is tagged private;
   --  explicitly declared primitives for Child
private
  type Child is new Parent with record ...
   --  implicit, inherited primitive operations with type Child
   --  as the controlling formal parameter
end Q;
```

The primitive operations from the parent type are implicitly, automatically declared immediately after the type extension, but these declarations are now located in the package private part. Therefore, the inherited primitive operations are not compile-time visible to clients. Hence clients cannot invoke them. These operations are only visible (after the type completion) in the package private part and the package body, for use with the implementation of the explicitly declared primitive operations.

For example, we might use a *controlled type* in the implementation of a tagged private type. Clients generally don't have any business directly calling the operations defined by the two language-defined controlled types so we usually use implementation inheritance. But if clients did have the need, we would use Subtype Inheritance instead.

For example, the following is a generic package providing an abstract data type for unbounded queues. As such, the Queue type uses dynamic allocation internally. This specific version automatically reclaims the allocated storage when objects of the Queue type cease to exist:

Listing 3: unbounded_sequential_queues.ads

```
1  with Ada.Finalization;
2  generic
3     type Element is private;
4  package Unbounded_Sequential_Queues is
5
6     type Queue is tagged limited private;
7
8     procedure Insert (Into : in out Queue;  Item : in Element) with
9       Post => not Empty (Into) and
10                Extent (Into) = Extent (Into)'Old + 1;
11      --  may propagate Storage_Error
```

(continues on next page)

(continued from previous page)

```
12
13    procedure Remove (From : in out Queue;  Item : out Element) with
14      Pre  => not Empty (From),
15      Post => Extent (From) = Natural'Max (0, Extent (From)'Old - 1);
16
17    procedure Reset (This : in out Queue) with
18       Post => Empty (This) and Extent (This) = 0;
19
20    function Extent (This : Queue) return Natural;
21
22    function Empty (This : Queue) return Boolean;
23
24 private
25
26    type Node;
27
28    type Link is access Node;
29
30    type Node is record
31       Data : Element;
32       Next : Link;
33    end record;
34
35    type Queue is new Ada.Finalization.Limited_Controlled with
36       record
37          Count : Natural := 0;
38          Rear  : Link;
39          Front : Link;
40       end record;
41
42    overriding procedure Finalize (This : in out Queue) renames Reset;
43
44 end Unbounded_Sequential_Queues;
```

The basic operation of assignment usually does not make sense for an abstraction represented as a linked list, so we declare the private type as limited, in addition to tagged and private, and then use the language-defined limited controlled type for the type extension completion in the private part.

Procedures `Initialize` and `Finalize` are inherited immediately after the type extension. Both are null procedures that do nothing. We can leave `Initialize` as-is because initialization is already accomplished via the default values for the `Queue` components. On the other hand, we want finalization to reclaim all allocated storage so we cannot leave `Finalize` as a null procedure. By overriding the procedure we can change the implementation. That change is usually accomplished by writing the corresponding procedure body in the package body. However, in this case we have an existing procedure named `Reset` that is part of the visible (client) API. `Reset` does exactly what we want `Finalize` to do, so we implement the overridden `Finalize` by saying that it is just another name for `Reset`. No completion body for `Finalize` is then required or allowed. This approach has the same semantics as if we did explicitly write a body for `Finalize` that simply called `Reset`, but it avoids the code and the extra layer of subprogram call. Clients can call `Reset` whenever they want, but the procedure will also be called automatically, via `Finalize`, when any `Queue` object ceases to exist.

115.3 Pros

The two idioms are easily composed simply by controlling where in the enclosing package the parent type is mentioned: either in the declaration of the private child type in the package visible part, or in the child type's completion in the package private type.

115.4 Cons

Although the inheritance expressions are simple in themselves, the many ancillary design choices can make the design effort seem more complicated than it really is.

115.5 Relationship With Other Idioms

We assume the *Abstract Data Type idiom* (page 2001), so we are using private types throughout. That includes the child type, and, as we saw, allows us to control the compile-time visibility to the parent type.

CHAPTER

SIX

PROVIDING COMPONENT ACCESS TO ENCLOSING RECORD OBJECTS

116.1 Motivation

In some design situations we want to have a record component that is of a task or protected type. That in itself is trivially accomplished because task types and protected types can be used to declare record components. But there's more to this idiom.

We would want a task type or protected type record component when:

a) a task or protected object (PO) is required to implement part — but not all — of the record type's functionality, and

b) each such task or PO is intended to implement its functionality only for the object logically containing that specific task object or protected object. The record object and contained task/PO object pair is a functional unit, independent of all other such units.

This idiom applies to both enclosed task types and protected types, but for the sake of concision let's assume the record component will be of a protected type.

As part of a functional unit, the PO component will almost certainly be required to reference the other record components in the enclosing record object. That reference will allow the PO to read and/or update those other components. Note that these record components include discriminants, if any.

To be a functional unit, the record object referenced by a given PO in this relationship must be the same record object at run-time that contains that specific PO instance. That will allow the PO instance to implement the functionality for the specific record object containing that PO instance.

Unless we arrange it, that back-reference from the protected object to the record object isn't provided. Consider the following:

```
package Q is
   protected type P is ... end P;
   type R is record
     ...
     Y : P;
   end record;
end Q;
```

During execution, whenever an object of type `Q.R` is declared or allocated, at run-time we will have two objects, instances of two distinct types — the record object and the protected object. Let's say that a client declares an object `Obj` of type R. There is only one reference direction defined, from the record denoted by `Obj` to the component protected object denoted by `Obj.Y`. This idiom, however, requires a reference in the opposite direction, from `Oby.Y` to `Obj`.

This may seem like an unrealistic situation, but it is not. An IO device type that involves interrupt handling is just one real-world example, one that we will show in detail.

The idiom context is a type because there will often be multiple real-world entities being represented in software. Representing these entities as multiple objects declared of a single type is by far the most reasonable approach.

We assume the functional unit will be implemented as an *Abstract Data Type (ADT)* (page 2001). Strictly speaking, the ADT idiom is not required here, but that is the best approach for defining major types, for the good reasons given in that idiom entry. There's no reason not to use an ADT in this case so we will.

116.2 Solution

As mentioned, the solution applies to enclosed components of both task types and protected types. We will continue the discussion in terms of protected types.

The solution has two parts:

1. An access discriminant on the PO type, designating the enclosing record's type. That part is straightforward.
2. A value given to that discriminant that designates the object of the enclosing record type, i.e., the record object that contains that PO. That part requires a relatively obscure language construct.

Given those two parts, the PO can then dereference its access discriminant to read or update the other components in the same enclosing record object.

Consider the following (very artificial) package declaration illustrating these two parts:

```
package P is
   type Enclosing is tagged limited private;
private

   protected type Controller (Instance : not null access Enclosing) is
      -- Part 1

      procedure Increment_X;
   end Controller;

   type Enclosing is tagged limited record
      X : Integer;  -- arbitrary type

      C : Controller (Instance => ...);
      -- Part 2, not fully shown yet
   end record;

end P;
```

The record type named `Enclosing` contains a component named X, arbitrarily of type **`Integer`**, and another component C that is of protected type `Controller`. Part #1 of the solution is the access discriminant on the declaration of the protected type `Controller`:

```
protected type Controller (Instance : not null access Enclosing) is
```

Given a value for the discriminant `Instance`, the code within the spec and body of type `Controller` can then reference some `Enclosing` object via that discriminant.

But not just any object of type `Enclosing` will suffice. For Part #2, we must give the `Instance` discriminant a value that refers to the current instance of the record object containing this same PO object. In the package declaration above, the value passed to `Instance`

is elided. The following is that code again, now showing just the declaration for Enclosing, but also including the construct that is actually passed. This is where the subtlety comes into play:

```
type Enclosing is tagged limited record
      ...
      C : Controller (Instance => Enclosing'Access);
end record;
```

The subtlety is the expression Enclosing'Access. Within a type declaration, usage of the type name denotes the current instance of that type. The current instance of a type is the object of the type that is associated with the execution that evaluates the type name. For example, during execution, when an object of type Enclosing is elaborated, the name Enclosing refers to that object.

It isn't compiler-defined magic, the semantics are defined by the Ada standard so it is completely portable. (There are other cases for expressing the current instance of task types, protected types, and generics.)

Therefore, within the declaration of type Enclosing, the expression Enclosing'Access provides an access value designating the current instance of that type. This is exactly what we want and is the crux of the idiom expression. With that discriminant value, the enclosed PO spec and body can reference the other record components of the same object that contains the PO.

To illustrate that, here is the package body for this trivial example. Note the value referenced in the body of procedure Increment_X:

```
package body P is

   protected body Controller is

      procedure Increment_X is
      begin
         Instance.X := Instance.X + 1;
      end Increment_X;

   end Controller;

end P;
```

Specifically, the body of procedure Increment_X can use the access discriminant Instance to get to the current instance's X component. (We could express it as Instance.**all**.X but why bother. Implicit dereferencing is a wonderful thing.)

That's the solution. Now for some necessary details.

Note that we declared type Enclosing as a limited type, first in the visible part of the package:

```
type Enclosing is tagged limited private;
```

and again in the type completion in the package private part:

```
type Enclosing is tagged limited record ... end record;
```

The type need not be tagged for this idiom solution, but if you do make it tagged, the partial and full views must always match. That is, a tagged type must be limited in both views if it is limited in either view.

For the idiom solution to be legal, the type's completion in the private part must always be *immutably limited*, meaning that it is always truly limited. There are various ways to make

that happen (see AARM22 7.5 (8.1/3)[517]) but the easiest way to is to include the reserved word **limited** in the type definition within the full view, as we did above. That is known as making the type *explicitly limited*.

Why does the compiler require the type to be immutably limited?

Recall that a (non-tagged) private type need not be limited in both views. It can be limited in the partial client view but non-limited in the private full view:

```
package Q is
   type T is limited private;
   -- the partial view for clients in package visible part
   ...
private
   type T is record -- the full view in the package private part
      ...
   end record;
end Q;
```

Clients must treat type `Q.T` as if it is limited, but `Q.T` isn't really limited because the full view defines reality. Clients simply have a more restricted view of the type than is really the case.

Types that are explicitly limited really are limited, and always have a view as a limited type. That's important because the type given in `type_name'Access` must be aliased for `'Access` to be meaningful and possible on the corresponding objects. But if the type's view could change between limited and not limited, it would be aliased in some contexts and not aliased in others. To prevent that complexity, the language requires the type's view to be permanently limited so that the type will be permanently aliased. An immutably limited type is permanently aliased. In practice, we're working with record types and type extensions, so just make the type definition explicitly limited and all will be well:

```
package Q is
   type T is limited private;
   ...
private
   type T is limited record
      ...
   end record;
end Q;
```

Then, as mentioned, you can choose whether the type will also be tagged.

116.3 Real-World Example

For a concrete, real-world example, suppose we have a serial IO device on an embedded target board. The device can be either a UART or USART[518]. For the sake of brevity let's assume we have USARTs available.

Many boards have more than one USART resident, so it makes sense to represent them in software as instances of an ADT. This example uses the USART ADT supported in the Ada Drivers Library (ADL)[519] that is named, imaginatively, USART. (We don't show package `STM32.USARTs`, but you will see it referenced in the example's context clauses.) Each of these USART devices can support either a polling implementation or an interrupt-driven implementation. We will first define a basic USART ADT, and then extend that to a new one that works with interrupts.

[517] http://www.ada-auth.org/standards/22aarm/html/AA-7-5.html
[518] https://en.wikipedia.org/wiki/Universal_synchronous_and_asynchronous_receiver-transmitter
[519] https://github.com/AdaCore/Ada_Drivers_Library

At the most basic level, to work with a given USART device we must combine it with some other hardware, specifically the IO pins that connect it to the outside world. That combination will be represented by a new ADT, the type `Device` defined in package `Serial_IO`.

Any given `Serial_IO.Device` object will be associated permanently with one USART. Therefore, type `Device` will have a discriminant named `Transceiver` designating that USART object.

There are some low-level operations that a `Serial_IO.Device` will implement, such as initializing the hardware and setting the baud rate and so forth. We can also implement the hardware-oriented input and output routines in this package because both are independent of the polling or interrupt-driven designs.

Here's the resulting package declaration for the serial IO device ADT. Parts of the package are elided for simplicity (the full code is *at the end of this idiom entry* (page 2045)):

```
with STM32;         use STM32;
with STM32.GPIO;    use STM32.GPIO;
with STM32.USARTs;  use STM32.USARTs;
with HAL;  -- the ADL's Hardware Abstraction Layer

package Serial_IO is

   type Device (Transceiver : not null access USART) is tagged limited private;

   procedure Initialize
     (This           : in out Device;
      Tx_Pin         : GPIO_Point;
      Rx_Pin         : GPIO_Point;
      ...);

   procedure Configure (This : in out Device;  Baud_Rate : Baud_Rates;  ...);
   ...
   procedure Put (This : in out Device;  Data : HAL.UInt8) with Inline;
   procedure Get (This : in out Device;  Data : out HAL.UInt8) with Inline;

private

   type Device (Transceiver : not null access USART) is tagged limited record
      Tx_Pin : GPIO_Point;
      Rx_Pin : GPIO_Point;
      ...
   end record;

end Serial_IO;
```

When called, procedure `Initialize` does the hardware setup required, such as enabling power for the USART and pins. We can ignore those details for this discussion.

Given this basic `Device` type we can then use inheritance (type extension) to define distinct types that support the polling and interrupt-driven facilities. These types will themselves be ADTs. Let's focus on the new interrupt-driven ADT, named `Serial_Port`. This type will be declared in the child package `Serial_IO.Interrupt_Driven`.

When interrupts are used, each USART raises a USART-specific interrupt for sending and receiving. Each interrupt occurrence is specific to one device. Therefore, the interrupt handler code is specific to each `Serial_Port` object instance. We use protected objects as interrupt handlers in (canonical) Ada, hence each `Serial_Port` object will contain a dedicated interrupt handling PO as a record component.

As a controller and handler for a USART's interrupts, the PO will require a way to access the USART and pins being driven. Our idiom design provides that access.

Here is the client view of the ADT for the interrupt-driven implementation:

```
with Ada.Interrupts;      use Ada.Interrupts;
with HAL;
with System; use System;

package Serial_IO.Interrupt_Driven is

   type Serial_Port
     (Transceiver  : not null access USART;
      IRQ          : Interrupt_ID;
      IRQ_Priority : Interrupt_Priority)
   is new Serial_IO.Device with private;

   --  The procedures Initialize and Configure, among others, are
   --  implicitly declared here as operations inherited from
   --  Serial_IO.Device.

   overriding
   procedure Put (This : in out Serial_Port;  Data : HAL.UInt8) with Inline;

   overriding
   procedure Get (This : in out Serial_Port;  Data : out HAL.UInt8) with Inline;

private
   ...
end Serial_IO.Interrupt_Driven;
```

The declaration of type `Serial_Port` uses *Interface Inheritance* (page 2027) to extend `Serial_IO.Device` with both visible and hidden components. The three visible extension components are the discriminants `Transceiver`, `IRQ`, and `IRQ_Priority`. `Transceiver` will designate the USART to drive (discussed in a moment). `IRQ` is the `Interrupt_ID` indicating the interrupt that the associated USART raises. `IRQ_Priority` is the priority for that interrupt. (*IRQ* in a common abbreviation for *Interrupt ReQuest*.) These two interrupt-oriented discriminants are used within the PO declaration to configure it for interrupt handling.

Clients will know which USART they are working with so they will be able to determine which interrupt ID and priority to specify, presumably by consulting the board documentation.

Now let's examine the `Serial_Port` type completion in the package's private part.

We've said we will use a PO interrupt handler as a component of the `Serial_Port` record type. This PO type, named `IO_Manager`, will include discriminants for the two interrupt-specific values it requires as an interrupt handler. It will also have a discriminant providing access to the enclosing `Serial_Port` record type.

```
protected type IO_Manager
  (IRQ          : Interrupt_ID;
   IRQ_Priority : Interrupt_Priority;
   Port         : not null access Serial_Port)
with
   Interrupt_Priority => IRQ_Priority
is
   entry Put (Datum : HAL.UInt8);
   entry Get (Datum : out HAL.UInt8);
private
   ...
   procedure IRQ_Handler with Attach_Handler => IRQ;
end IO_Manager;
```

Note how the first two discriminants are used within the type declaration to give the priority of the PO and to attach the interrupt handler procedure `IRQ_Handler` to the interrupt indicated by `IRQ`. The `Port` discriminant will be the back-reference to the enclosing record object.

We can then, finally, provide the Serial_Port type completion, in which the record object and protected object are connected whenever a Serial_Port object is declared:

```
type Serial_Port
  (Transceiver  : not null access USART;
   IRQ          : Interrupt_ID;
   IRQ_Priority : Interrupt_Priority)
is new Serial_IO.Device (Transceiver) with record
   Controller : IO_Manager (IRQ, IRQ_Priority, Serial_Port'Access);
end record;
```

The type completion repeats the declaration in the public part, up to the point where the Serial_Port.Transceiver discriminant is passed to the Serial_IO.Device.Transceiver discriminant. Type Device must be constrained with a discriminant value here, so we just pass the discriminant defined for Serial_Port.

Why does Serial_Port also have a Transceiver discriminant? Just as Serial_IO.Device is a complete wrapper for the combination of a USART and IO pins, Serial_Port is a stand-alone wrapper for Serial_IO.Device. Hence Serial_Port also needs a discriminant designating a USART to be complete.

The full definition of type Serial_Port contains the declaration of the component named Controller, of the protected type IO_Manager. The two interrupt-oriented discriminants from Serial_Port are passed to the discriminants defined for this PO component. The third IO_Manager discriminant value, Serial_Port'Access, denotes the current instance of the Serial_Port type. Thus the idiom requirements are achieved.

Let's see that back-reference in use within the protected body.

As mentioned, there is one interrupt used for both sending and receiving, per USART. Strictly speaking, the device itself does use two dedicated interrupts, one indicating that a 9-bit value has been received, and one indicating that transmission for a single 9-bit value has completed. But these two are signaled to the software on one interrupt line, and that is the value indicated by IRQ.

Therefore, there is one interrupt handling protected procedure, named IRQ_Handler. In response to this interrupt, IRQ_Handler determines which event has occurred by checking one of the Transceiver status registers. The back-reference through Port makes that possible. Other Transceiver routines are also called via Port, and Port.all is passed to the Put and Get calls:

```
procedure IRQ_Handler is
begin
   --  check for data arrival
   if Port.Transceiver.Status (Read_Data_Register_Not_Empty) and then
       Port.Transceiver.Interrupt_Enabled (Received_Data_Not_Empty)
   then  -- handle reception
      -- call the Serial_IO.Device version:
      Get (Serial_IO.Device (Port.all), Incoming);

      Await_Reception_Complete : loop
         exit when not Port.Transceiver.Status (Read_Data_Register_Not_Empty);
      end loop Await_Reception_Complete;
      Port.Transceiver.Disable_Interrupts (Received_Data_Not_Empty);
      Port.Transceiver.Clear_Status (Read_Data_Register_Not_Empty);
      Incoming_Data_Available := True;
   end if;

   --  check for transmission ready
   if Port.Transceiver.Status (Transmission_Complete_Indicated) and then
      Port.Transceiver.Interrupt_Enabled (Transmission_Complete)
   then  -- handle transmission
      -- call the Serial_IO.Device version:
```

(continues on next page)

(continued from previous page)

```
      Put (Serial_IO.Device (Port.all), Outgoing);

      Port.Transceiver.Disable_Interrupts (Transmission_Complete);
      Port.Transceiver.Clear_Status (Transmission_Complete_Indicated);
      Transmission_Pending := False;
   end if;
end IRQ_Handler;
```

In this example, although the PO only accesses the `Transceiver` component in the enclosing record object, additional functionality might need to access more components, for this example perhaps using some of the inherited IO pin components.

116.4 Pros

The solution is directly expressed, requiring only an access discriminant and the current instance semantics of `type_name'Access`.

Although the real-word example is complex — multiple discriminants are involved, and a type extension — the idiom solution itself requires little text. Interrupt handling is relatively complex in any language.

116.5 Cons

The record type must be truly a limited type, but that is not the severe limitation it was in earlier versions of Ada. Note that although access discriminants are required, there is no dynamic allocation involved.

116.6 Relationship With Other Idioms

This idiom is useful when we have a record type enclosing a PO or task object. If the *Abstract Data Machine (ADM)* (page 2009) would instead be appropriate, the necessary visibility can be achieved without requiring this idiom solution because there would be no enclosing record type. But as described in the ADM discussion, the *ADT approach* (page 2001) is usually superior.

116.7 Notes

As a wrapper abstraction for a USART, package `Serial_IO` is still more hardware-specific than absolutely necessary, as reflected in the parameters' types for procedure `Initialize` and the corresponding record component types. We could use the Hardware Abstraction Layer (HAL) to further isolate the hardware dependencies, but that doesn't affect the idiom expression itself.

116.8 Bibliography

None.

116.9 Full Source Code for Selected Units

We did not show some significant parts of the code discussed above, for the sake of not obscuring the points being made. Doing so, however, means that the interested reader cannot see how everything fits together and works, such as the actual IO using interrupts. The code below shows the relevant packages in their entirety. Note that the ADL STM32 hierarchy packages and the HAL (Hardware Abstraction Layer) package are in the Ada Drivers Library on GitHub[520].

First, the basic `Serial_IO` abstraction:

```
with STM32;          use STM32;
with STM32.GPIO;     use STM32.GPIO;
with STM32.USARTs;   use STM32.USARTs;
with HAL;

package Serial_IO is

   type Device (Transceiver : not null access USART) is tagged limited private;

   procedure Initialize
     (This           : in out Device;
      Transceiver_AF : GPIO_Alternate_Function;
      Tx_Pin         : GPIO_Point;
      Rx_Pin         : GPIO_Point;
      CTS_Pin        : GPIO_Point;
      RTS_Pin        : GPIO_Point);
   --  must be called before Configure

   procedure Configure
     (This      : in out Device;
      Baud_Rate : Baud_Rates;
      Parity    : Parities     := No_Parity;
      Data_Bits : Word_Lengths := Word_Length_8;
      End_Bits  : Stop_Bits    := Stopbits_1;
      Control   : Flow_Control := No_Flow_Control);

   procedure Set_CTS (This : in out Device; Value : Boolean) with Inline;
   procedure Set_RTS (This : in out Device; Value : Boolean) with Inline;

   procedure Put (This : in out Device;  Data : HAL.UInt8)     with Inline;
   procedure Get (This : in out Device;  Data : out HAL.UInt8) with Inline;

private

   type Device (Transceiver : not null access USART) is tagged limited record
      Tx_Pin  : GPIO_Point;
      Rx_Pin  : GPIO_Point;
      CTS_Pin : GPIO_Point;
      RTS_Pin : GPIO_Point;
   end record;

end Serial_IO;
```

[520] https://github.com/AdaCore/Ada_Drivers_Library

And the package body:

```
with STM32.Device; use STM32.Device;

package body Serial_IO is

   ----------------
   -- Initialize --
   ----------------

   procedure Initialize
     (This           : in out Device;
      Transceiver_AF : GPIO_Alternate_Function;
      Tx_Pin         : GPIO_Point;
      Rx_Pin         : GPIO_Point;
      CTS_Pin        : GPIO_Point;
      RTS_Pin        : GPIO_Point)
   is
      IO_Pins : constant GPIO_Points := Rx_Pin & Tx_Pin;
   begin
      This.Tx_Pin := Tx_Pin;
      This.Rx_Pin := Rx_Pin;
      This.CTS_Pin := CTS_Pin;
      This.RTS_Pin := RTS_Pin;

      Enable_Clock (This.Transceiver.all);

      Enable_Clock (IO_Pins);

      Configure_IO
        (IO_Pins,
         Config => (Mode_AF,
                    AF             => Transceiver_AF,
                    AF_Speed       => Speed_50MHz,
                    AF_Output_Type => Push_Pull,
                    Resistors      => Pull_Up));

      Enable_Clock (RTS_Pin & CTS_Pin);

      Configure_IO (RTS_Pin, Config => (Mode_In, Resistors => Pull_Up));

      Configure_IO
        (CTS_Pin,
         Config => (Mode_Out,
                    Speed       => Speed_50MHz,
                    Output_Type => Push_Pull,
                    Resistors   => Pull_Up));
   end Initialize;

   ---------------
   -- Configure --
   ---------------

   procedure Configure
     (This      : in out Device;
      Baud_Rate : Baud_Rates;
      Parity    : Parities     := No_Parity;
      Data_Bits : Word_Lengths := Word_Length_8;
      End_Bits  : Stop_Bits    := Stopbits_1;
      Control   : Flow_Control := No_Flow_Control)
   is
   begin
      This.Transceiver.Disable;
```

(continues on next page)

(continued from previous page)

```
      This.Transceiver.Set_Baud_Rate    (Baud_Rate);
      This.Transceiver.Set_Mode         (Tx_Rx_Mode);
      This.Transceiver.Set_Stop_Bits    (End_Bits);
      This.Transceiver.Set_Word_Length  (Data_Bits);
      This.Transceiver.Set_Parity       (Parity);
      This.Transceiver.Set_Flow_Control (Control);

      This.Transceiver.Enable;
   end Configure;

   -------------
   -- Set_CTS --
   -------------

   procedure Set_CTS (This : in out Device; Value : Boolean) is
   begin
      This.CTS_Pin.Drive (Value);
   end Set_CTS;

   -------------
   -- Set_RTS --
   -------------

   procedure Set_RTS (This : in out Device; Value : Boolean) is
   begin
      This.RTS_Pin.Drive (Value);
   end Set_RTS;

   ---------
   -- Put --
   ---------

   procedure Put (This : in out Device;  Data : HAL.UInt8) is
   begin
      This.Transceiver.Transmit (HAL.UInt9 (Data));
   end Put;

   ---------
   -- Get --
   ---------

   procedure Get (This : in out Device;  Data : out HAL.UInt8) is
      Received : HAL.UInt9;
   begin
      This.Transceiver.Receive (Received);
      Data := HAL.UInt8 (Received);
   end Get;

end Serial_IO;
```

Next, the interrupt-driven extension.

```
with Ada.Interrupts;      use Ada.Interrupts;
with HAL;
with System; use System;

package Serial_IO.Interrupt_Driven is
   pragma Elaborate_Body;

   type Serial_Port
```

(continues on next page)

(continued from previous page)

```
     (Transceiver  : not null access USART;
      IRQ          : Interrupt_ID;
      IRQ_Priority : Interrupt_Priority)
   is new Serial_IO.Device with private;
   --  A serial port that uses interrupts for I/O. Extends the Device
   --  abstraction that is itself a wrapper for the USARTs hardware.

   --  The procedures Initialize and Configure, among others, are implicitly
   --  declared here, as operations inherited from Serial_IO.Device

   overriding
   procedure Put (This : in out Serial_Port;  Data : HAL.UInt8) with Inline;
   --  Non-blocking, ie the caller can return before the Data goes out,
   --  but does block until the underlying UART is not doing any other
   --  transmitting. Does no polling. Will not interfere with any other I/O
   --  on the same device.

   overriding
   procedure Get (This : in out Serial_Port;  Data : out HAL.UInt8) with Inline;
   --  Blocks the caller until a character is available! Does no polling.
   --  Will not interfere with any other I/O on the same device.

private

   --  The protected type defining the interrupt-based I/O for sending and
   --  receiving via the USART attached to the serial port designated by
   --  Port. Each serial port object of the type defined by this package has
   --  a component of this protected type.
   protected type IO_Manager
     (IRQ          : Interrupt_ID;
      IRQ_Priority : Interrupt_Priority;
      Port         : not null access Serial_Port)
   --  with
      --  Interrupt_Priority => IRQ_Priority   -- compiler bug :-(
   is
      pragma Interrupt_Priority (IRQ_Priority);

      entry Put (Datum : HAL.UInt8);

      entry Get (Datum : out HAL.UInt8);

   private

      Outgoing : HAL.UInt8;
      Incoming : HAL.UInt8;

      Incoming_Data_Available : Boolean := False;
      Transmission_Pending    : Boolean := False;

      procedure IRQ_Handler with Attach_Handler => IRQ;

    end IO_Manager;

   type Serial_Port
     (Transceiver  : not null access USART;
      IRQ          : Interrupt_ID;
      IRQ_Priority : Interrupt_Priority)
   is
      new Serial_IO.Device (Transceiver) with
   record
      Controller : IO_Manager (IRQ, IRQ_Priority, Serial_Port'Access);
```

(continues on next page)

(continued from previous page)

```
      --  Note that Serial_Port'Access provides the Controller with a view
      --  to the current instance's components, including the discriminant
      --  components
   end record;

end Serial_IO.Interrupt_Driven;
```

And the package body:

```
with STM32.Device; use STM32.Device;

package body Serial_IO.Interrupt_Driven is

   ---------
   -- Put --
   ---------

   overriding
   procedure Put (This : in out Serial_Port;  Data : HAL.UInt8) is
   begin
      This.Controller.Put (Data);
   end Put;

   ---------
   -- Get --
   ---------

   overriding
   procedure Get (This : in out Serial_Port;  Data : out HAL.UInt8) is
   begin
      This.Transceiver.Enable_Interrupts (Received_Data_Not_Empty);
      This.Controller.Get (Data);
   end Get;

   ----------------
   -- IO_Manager --
   ----------------

   protected body IO_Manager is

      -----------------
      -- IRQ_Handler --
      -----------------

      procedure IRQ_Handler is
      begin
         --  check for data arrival
         if Port.Transceiver.Status (Read_Data_Register_Not_Empty) and then
            Port.Transceiver.Interrupt_Enabled (Received_Data_Not_Empty)
         then  -- handle reception
            -- call the Serial_IO.Device version:
            Get (Serial_IO.Device (Port.all), Incoming);

            Await_Reception_Complete : loop
               exit when not Port.Transceiver.Status (Read_Data_Register_Not_
↪Empty);
            end loop Await_Reception_Complete;
            Port.Transceiver.Disable_Interrupts (Received_Data_Not_Empty);
            Port.Transceiver.Clear_Status (Read_Data_Register_Not_Empty);
            Incoming_Data_Available := True;
         end if;
```

(continues on next page)

(continued from previous page)

```
         --  check for transmission ready
         if Port.Transceiver.Status (Transmission_Complete_Indicated) and then

end Serial_IO.Interrupt_Driven;
```

CHAPTER

SEVEN

CONTROLLING OBJECT INITIALIZATION AND CREATION

117.1 Motivation

Developers are responsible for ensuring that no uninitialized objects are read in Ada programs. Default initialization is a good way to meet this requirement because it is guaranteed to happen and requires no actions on the part of the client code. But of the many kinds of types provided by Ada, only access types have a language-defined default initial value. Fortunately, Ada supports user-defined default initialization for user-defined types.

Default initialization is conveniently expressed, especially because components of record types can have default initial values. Record types are perhaps the most commonly used non-numeric type in the language. Sometimes a given type was *wrapped* inside a record type purely for the sake of default component initialization, e.g., numeric types. That wrapping approach is less common than in earlier versions of the language, given the comparatively more recent aspect `Default_Value` for scalar types, and `Default_Component_Value` for scalar components.

These facilities are often sufficient to express an abstraction's initial state. For example, we can expect that container objects will be initially empty. Consider a bounded stack ADT. The representation is likely a record type containing an array component and a `Top` component indicating the index of the last array component used. We can default initialize objects to the empty state simply by setting `Top` to zero in the record component's declaration:

```
type Content is array (Positive range <>) of Element;
type Stack (Capacity : Positive) is record
   Values : Content (1 .. Capacity);
   Top    : Natural := 0;
end record;
```

For an unbounded container such as a simple binary tree, if the representation is an access type, the automatic default value **`null`** initializes `Tree` objects to the empty state.

```
package Binary_Trees is
   type Tree is limited private;
   Null_Tree : constant Tree;
   ...
private
   type Leaf_and_Branch is record ...
   type Tree is access Leaf_and_Branch;
   Null_Tree : constant Tree := null;
end Binary_Trees;
```

In both cases, simply declaring an object in the client code is sufficient to ensure it is initially empty.

However, not all abstractions have a meaningful default initial state. Default initialization will not suffice to fully initialize objects in these cases. Explicit initialization is required.

An explicit procedure call could be used to set the initial state of an object (passed to a mode-out parameter), but there is no guarantee that the call will occur and no way to force it.

In contrast, the declaration of the object is guaranteed to occur, and as part of the declaration the object can be given an explicit initial value. The initial value can be specified by a literal for the type, by the value of another object of that type, or by the value of that type returned from a function call.

```
declare
   X : Integer := Some_Existing_Integer_Object;
   Prompt : constant String := "Name? ";
   Reply : constant String := Response (Prompt);
begin
   ...
end;
```

The initial value can also specify constraints, if required. In the code above, the object `Prompt` has a lower bound of `Positive'First` and an upper bound set to the length of the literal. The specific bounds of `Reply` are determined by the function, and need not start at `Positive'First`.

An object cannot be used before it is declared, and since this explicit initial value is part of the declaration, the object cannot be read before it is initialized. That fact is the key to the solutions.

However, although the object declaration is guaranteed to occur, explicit initialization is optional. But unlike a procedure call, we can force the initial value to be given. There are two ways to force it, so there are two solutions presented.

In addition, a specific form of explicit initialization may be required because not all forms of initialization are necessarily appropriate for a given abstraction. Imagine a type representing a thread lock, implemented in such a way that default initialization isn't an option. Unless we prevent it, initialization by some other existing object will be possible:

```
declare
   X : Thread_Lock := Y;    --  Y is some other Thread_Lock object
begin
   --  ...
end;
```

This would amount to a copy, which might not make sense. Imagine the lock type contains a queue of pending callers...

More generally, if a type's representation includes access type components, initialization by another object will create a shallow copy of the designated objects. That is typically inappropriate.

Using an existing object for the initial value amounts to a complete copy of that other object, perhaps more of a copy than required. For example, consider a bounded container type, e.g., another stack, backed by an array and an index component named `Top`. At any time, for any stack, the contained content is in the slice of the array from 1 up to `Top`. Any array component at an index greater than `Top` has a junk value. Those components may never even have been assigned during use. Now consider the declaration of a `Stack` object, `A`, whose initial value is that of another existing `Stack` named `B`.

```
A : Stack := B;
```

The entire value of `B` is copied into `A`, so `B.Top` is copied to `A.Top`, which makes sense. But likewise, the entire array in `B` will be copied to the array in `A`. For a stack with a large backing array that might take a significant amount of time. If `B` is logically full then the time required for the full array copy is unavoidable. But if only a few values are contained by `B`, the hit could be avoided by only copying up to `Top`.

And of course, the initial value might require client-specific information.

Calling a *constructor function* (page 2017) for the initial value would be the right approach in these cases, returning an object of the type. The function might even take an existing object as a parameter, creating a new object with only the necessary parts copied.

Therefore, for some abstractions, not only do we need to guarantee explicit object initialization, we may also need to restrict the form of initial value to a function call.

The other purpose of the idiom is controlling, for some type, whether object creation itself is to be allowed by clients. As you will see, controlling object initialization can be used to control object creation.

Preventing object creation is not typical but is not unknown. The singleton design pattern[521] is an example, in which a type is defined but corresponding object creation by clients is not intended. Instead, the abstraction implementation creates a single object of the type. The abstraction is a type, rather than an *ADM* (page 2009), for the sake of potential extension via inheritance. We will illustrate this design pattern and solution using a real-world hardware device.

117.1.1 Requiring Initialization by Clients

There are two ways to force an explicit initial value as part of an object declaration. One is a matter of legality at compile-time so it is enforced by the compiler. The other is enforced by a run-time check.

Note that both solutions are type-specific, so when we say *objects* we mean objects of a type that has been designed with one of these two idiom solutions. Neither solution applies to every object of every type used in the client code. (SPARK, a formal language based closely on Ada, statically ensures all objects are initialized before read.)

The *ADT idiom* (page 2001) describes Ada *building blocks* that developers can use to compose types with semantics that we require. We can declare a type to be private, for example, so that the implementation is not compile-time visible to clients.

In addition to private types, we can decorate a type declaration with the reserved word **`limited`** so that assignment is not allowed (among other things) for client objects of the type. We can combine the two building blocks, creating a type that is both private and limited.

Throughout this discussion we will assume that these designs are based on *Abstract Data Types* (page 2001), hence we assume the use of private types. That's a general, initial design assumption but in this case private types are required by the two idiom solutions. The types are not necessarily limited as well, but in one situation they will be limited too. But in both solutions the primary types will be private types.

117.2 Solution 1: Compile-Time Legality

We can combine the private type and limited type building blocks with another, known as *unknown discriminants*, to force explicit object initialization by clients, to control the form of explicit initialization, and, when required, to control client object creation itself. Limited and private types are fairly common building blocks, but *unknown discriminants* are less common so we will first explain them, and then show how to utilize the combinations for this idiom.

Discriminants are useful for our purpose because types with discriminants are *indefinite types* (under certain circumstances). Indefinite types do not allow object declarations without also specifying some sort of constraints for those objects. Unconstrained array types,

[521] https://en.wikipedia.org/wiki/Singleton_pattern

such as **String**, are good examples. We cannot simply declare an object of type **String** without also specifying the array bounds, one way or another:

```
with Ada.Text_IO; use Ada.Text_IO;
procedure Initialization_Demo is
   S1 : String (1 .. 11) := (others => ' ');
   S2 : String := "Hello World";
   S3 : String := S1;
begin
   Put_Line ('"' & S1 & '"');
   Put_Line ('"' & S2 & '"');
   Put_Line ('"' & S3 & '"');
end Initialization_Demo;
```

In the code above, **String** objects S1, S2, and S3 all have the same constraints: a lower bound of **Positive**'First and an upper bound of 11. S1 gives the bounds directly, whereas S2 and S3 take their constraints from their initial values. A function that returned a **String** value would suffice for the initial value too and would thus serve to specify the array bounds. There are other ways to specify a constraint as well, but we can ignore them in this idiom because the building blocks we'll use preclude them.

Types with discriminants are indefinite types unless the discriminants have default values. That fact will not apply in this idiom because of the characteristics of the building blocks. You will see why in a moment. The important idea is that we can leverage the object constraint requirements of indefinite types to force explicit initialization on declarations.

Discriminants come in two flavors. So-called *known* discriminants are the most common. These discriminants are known in the sense that they are compile-time visible to client code. Clients then have everything needed for declaring objects of the corresponding type. For example, here is the type declaration for a bounded stack ADT:

```
type Stack (Capacity : Positive) is private;
```

In the above, Capacity is the physical number of components in the array backing the bounded implementation. Clients can, therefore, have different objects of the type with different capacities:

```
Trays : Stack (Capacity => 10);
Operands : Stack (100);
```

The existence of Capacity is known to clients via the partial view, so the requirement for the constraint is visible and can be expressed.

In contrast, types may have *unknown discriminants* in the client's view. The syntax reflects their confidential nature:

```
type Foo (<>) is private;
```

The parentheses are required as usual, but the *box* symbol appears inside, instead of one or more discriminant declarations. The box symbol always indicates *not specified here* so in this case no discriminants are included in the view. There may or may not be discriminants in the full view, but client's don't have compile-time visibility to that information because the type is private.

Unknown discriminants can be specified for various kinds of types, not only private types. See the *Notes section* (page 2068) for the full list. That said, combining them with private type declarations, or private type extension declarations, is the most common usage when composing abstraction definitions. For example:

```
package P is
   type Q (<>) is private;
private
```

(continues on next page)

(continued from previous page)

```
   type Q is range 0 .. 100;
end P;
```

Clients of package P must use type Q as if Q requires discriminant constraints, even though clients don't have compile-time visibility to whatever constraints are actually required, if any. In the above, Q is just an integer type in the full view. No constraint is required to create objects of type Q, but clients cannot take advantage of that fact because they only have the partial view. Only the package private part, the package body, and child units have the visibility required to treat Q as an integer type.

Q might actually be completed as an indefinite type, but the constraint required need not be a discriminant constraint. In the following, objects of type Q require an array bounds constraint:

```
package P is
   type Q (<>) is private;
private
   type Q is array  (Positive range <>) of Integer;
end P;
```

Code with the full view must respect the index bounds requirement, but the semantics of the partial view remain the same.

As illustrated, the consequence of combining indefinite types with private types is that, when declaring objects, clients must express a constraint but cannot do so directly. The constraints must instead be provided by the initial value. Hence, for these types, the initial value is now a requirement that the compiler enforces on client object declarations.

But because the type is private, the initial value cannot be specified by a literal. Instead, the initial value must be either an existing object of the type, or the result of a call to a function that returns an object of the type.

Consider the following:

```
package P is
   type Q (<>) is private;
   function F return Q;
private
   type Q is range 0 .. 100;
end P;

package body P is
   function F return Q is (42);
   --  since that is the answer to everything...
end P;

with P;
procedure Demo is
   Obj1 : P.Q;  --  not legal, requires initial value for constraint
   Obj2 : P.Q := 42;  --  not legal, per client's partial view
   Obj3 : P.Q := P.F;
   Obj4 : P.Q := Obj3;
begin
   null;
end Demo;
```

The declaration for Obj1 is illegal because no constraint is provided. Because P.Q is also private, the declaration of Obj2 is illegal because clients don't have the full view supporting integer usage. But the initial value can be provided by a function result (Obj3), thereby also specifying the required constraint. And an existing object can be used to give the constraints to other objects during their declarations (Obj4). Explicit client initialization in these two ways is required by the compiler for indefinite private types.

But as illustrated by the spin-lock example, initialization by an existing object is not always appropriate. We can restrict the initial value to a function call result by making the type limited as well as private and indefinite. Then only constructor functions can be used legally for the initial values, and the compiler will require them to be called during object declarations (e.g., `Obj3` above). That's what we'd do for the spin-lock type. We'd make the type limited in the completion too, to prevent copying in any form, including the function result. (The function result would then be built in place instead of copied.)

To recap, the primary purpose of the idiom, for a given type, is to ensure that clients initialize objects of that type as part of the object declarations. In this first solution we meet the requirement by composing the type via building blocks that:

1. require a constraint to be given when declaring any object of the type, and
2. require an initial value to give that constraint, and
3. allow only objects and function call results as the initial values, and
4. when necessary, allow only function call results to be used for the initial values.

The compiler will reject declarations that do not adhere to these rules. Explicit initialization in the client code is thus guaranteed.

For a concrete example, consider a closed loop process controller, specifically a proportional–integral–derivative (PID) controller[522]. A PID controller examines the difference between an intended value, such as the desired speed of your automobile, and the current value (the actual speed). In response to that difference the controller increases or decreases the throttle setting. This measurement and resulting control output response happens iteratively at some rate. This is a sophisticated ADT, and explaining how a PID controller actually works is beyond the scope of this document. There are numerous web sites available that describe them in detail. What you should know for our purpose is that they are used to control physical processes, such as your car's cruise control system, that affect our lives directly. Ensuring proper initialization is part of ensuring correct use.

The PID controller must be explicitly initialized because there is no default initial state that would allow subsequent safe use. Only a partial meaningful state can be defined by default. Specifically, a PID controller can be enabled and disabled by the user (the external process control engineer) at arbitrary times. We can define default initialization such that the objects are initially in the disabled state. When disabled, the output computation actually affects nothing, so starting from that state would be safe. However, there is nothing to prevent the user from enabling the controller object without first configuring it. Configuring the various parameters is essential for safe and predictable behavior.

To address that problem, we could add operation preconditions requiring the object to be in some *configured* state, but that isn't always appropriate. Such a precondition would just raise an exception, which isn't in the use-cases. (Statically proving prior configuration in the client code would be a viable alternative, but that's also beyond the scope of this document.)

Therefore, default initialization doesn't really suffice for this ADT. We need to force initialization (configuration) during object creation so that enabling the ADT output will always be safe. This idiom solution does exactly that.

The following is a cut-down version of the package declaration using this idiom solution, with some operations and record components elided for the sake of simplicity. In the full version the unit is a generic package for the sake of not hard-coding the floating point types. We use a regular package and type **`Float`** here for convenience. The full version is here:

- AdaCore/Robotics_with_Ada/src/control_systems (GitHub)[523]

[522] https://en.wikipedia.org/wiki/Proportional–integral–derivative_controller
[523] https://github.com/AdaCore/Robotics_with_Ada/blob/master/src/control_systems/

```
package Process_Control is

   type PID_Controller (<>) is tagged limited private;

   type Bounds is record
      Min, Max : Float;
   end record with
     Predicate => Min < Max;

   type Controller_Directions is (Direct, Reversed);

   type Millisecond_Units is mod 2**32;

   subtype Positive_Milliseconds is
     Millisecond_Units range 1 .. Millisecond_Units'Last;

   function Configured_Controller
     (Proportional_Gain : Float;
      Integral_Gain     : Float;
      Derivative_Gain   : Float;
      Invocation_Period : Positive_Milliseconds;
      Output_Limits     : Bounds;
      Direction         : Controller_Directions := Direct)
   return PID_Controller;

   procedure Enable
     (This             : in out PID_Controller;
      Process_Variable : Float;   --  current input value from the process
      Control_Variable : Float);  --  current output value

   procedure Disable (This : in out PID_Controller);

   procedure Compute_Output
     (This             : in out PID_Controller;
      Process_Variable : Float;          --  the input, Measured Value/Variable
      Setpoint         : Float;
      Control_Variable : in out Float);  --  the output, Manipulated Variable

   --  ...

   function Enabled (This : PID_Controller) return Boolean;

private

   type PID_Controller is tagged limited record
      --  ...
      Enabled : Boolean;
   end record;

end Process_Control;
```

As you can see, the PID controller type is indefinite limited private:

```
type PID_Controller (<>) is tagged limited private;
```

It is also tagged, primarily for the sake of the distinguished receiver call syntax. We don't really expect type extensions in this specific ADT, although nothing prevents them.

Therefore, the language requires an initial value when creating objects of the type, and because the type is limited, a function must be used for that initial value. The compiler will not compile the code containing the declaration otherwise. The only constructor function provided is `Configured_Controller` so it is guaranteed to be called. (A later child package

could add another *constructor function* (page 2017). For that matter, we probably should have declared this one in a child package. In any case one of them is guaranteed to be called.)

Here is an example declaration taken from the steering control module for an RC car written in Ada[524].

The PID controller, named `Steering_Computer`, is declared within the body of a task `Servo` that controls a motor, `Steering_Motor`, in response to requested directions from the remote control. `Steering_Motor` is an instance of an ADT named `Basic_Motors`, and is declared elsewhere. The `Servo` task is declared within the body of a package that contains various values referenced within the task, such as the various PID gain parameters, that are not shown.

```
task body Servo is
   Next_Release       : Time;
   Target_Angle       : Float;
   Current_Angle      : Float := 0.0;  --  zero for call to Steering_Computer.
 ↪Enable
   Steering_Power     : Float := 0.0;  --  zero for call to Steering_Computer.
 ↪Enable
   Motor_Power        : NXT.Motors.Power_Level;
   Rotation_Direction : NXT.Motors.Directions;
   Steering_Offset    : Float;
   Steering_Computer  : PID_Controller :=
     Configured_Controller
       (Proportional_Gain => Kp,
        Integral_Gain     => Ki,
        Derivative_Gain   => Kd,
        Invocation_Period => System_Configuration.Steering_Control_Period,
        Output_Limits     => Power_Level_Limits,
        Direction         => Closed_Loop.Direct);
begin
   Global_Initialization.Critical_Instant.Wait (Epoch => Next_Release);
   Initialize_Steering_Mechanism (Steering_Offset);
   Steering_Computer.Enable (Process_Variable => Current_Angle, Control_Variable =>
 ↪ Steering_Power);
   loop
      Current_Angle := Current_Motor_Angle (Steering_Motor) - Steering_Offset;
      Target_Angle := Float (Remote_Control.Requested_Steering_Angle);
      Limit (Target_Angle, -Steering_Offset, +Steering_Offset);
      Steering_Computer.Compute_Output
        (Process_Variable => Current_Angle,
         Setpoint         => Target_Angle,
         Control_Variable => Steering_Power);
      Convert_To_Motor_Values (Steering_Power, Motor_Power, Rotation_Direction);
      Steering_Motor.Engage (Rotation_Direction, Motor_Power);

      Next_Release := Next_Release + Period;
      delay until Next_Release;
   end loop;
end Servo;
```

Because `Steering_Computer` must be declared before it can be passed as a parameter, the call to configure the object's state necessarily precedes any other operation (e.g., `Enable`).

[524] https://blog.adacore.com/making-an-rc-car-with-ada-and-spark

117.3 Solution 2: Run-Time Checks

Ada 2022 adds another building block, `Default_Initial_Condition` (DIC), that can be used as an alternative to the unknown discriminants used above. We must still have a private type or private type extension, and the type may or may not be limited, but unknown discriminants will not be involved. The compiler would not allow the combination, in fact.

DIC is an aspect applied to a private type or private extension declaration. Developers use it to specify a developer-defined Boolean condition that will be true at run-time after the default initialization of an object of the type. Specifically, if `Default_Initial_Condition` is specified for a type, a run-time check is emitted for each object declaration of that type that uses default initialization. The check consists of the evaluation of the DIC expression. The exception `Assertion_Error` is raised if the check fails. You can think of this aspect as specifying the effects of default initialization for the type, with a verification at run-time when needed. No check is emitted for those declarations that use explicit initialization.

For example, the following is a partial definition of a `Stack` ADT. It is only a partial definition primarily because `Pop` is not provided, but other operations would be included as well. Moreover, a fully realistic version would be a generic package. We have used a subtype named `Element` as a substitute for the generic formal type what would have had that name. Note that there is a `Default_Initial_Condition` aspect specifying that any object of type `Stack` is initially empty as a result of default initialization. The *argument* to the function call is the corresponding type name, representing the current instance object, thus any object of the type.

```
package Bounded_Stacks is

   subtype Element is Integer; --  arbitrary substitute for generic formal type

   type Stack (Capacity : Positive) is limited private with
     Default_Initial_Condition => Empty (Stack);

   procedure Push (This : in out Stack; Value : Element) with
     Pre  => not Full (This),
     Post => not Empty (This);

   function Full (This : Stack) return Boolean;

   function Empty (This : Stack) return Boolean;

private

   type Contents is array (Positive range <>) of Element;

   type Stack (Capacity : Positive) is limited record
      Content : Contents (1 .. Capacity);
      Top     : Natural :=0;
   end record;

   function Full (This : Stack) return Boolean is
     (This.Top = This.Capacity);

   function Empty (This : Stack) return Boolean is
     (This.Top = 0);

end Bounded_Stacks;

package body Bounded_Stacks is

   procedure Push (This : in out Stack; Value : Element) is
   begin
```

(continues on next page)

(continued from previous page)

```
      This.Top := This.Top + 1;
      This.Content (This.Top) := Value;
   end Push;

end Bounded_Stacks;

with Ada.Text_IO;   use Ada.Text_IO;
with Bounded_Stacks; use Bounded_Stacks;

procedure Demo is
   S : Stack (Capacity => 10);
begin
   Push (S, 42);
   Put_Line ("Done");
end Demo;
```

The function Empty returns **True** when Top is zero, and zero is assigned to Top during default initialization. Consequently, Assertion_Error is not raised when Demo executes because the object S was indeed default initialized to the empty state.

We said that when DIC is applied to a type, the run-time check is emitted for all object declarations of that type that rely on default initialization. But suppose the type does not define any default initialization. We can detect these uninitialized objects at run-time if we set the DIC Boolean expression to indicate that there is no default initialization defined for this type. The checks will then fail for those objects. That's the second solution to the initialization requirement.

Specifically, we can express the lack of default initialization by a DIC condition that is hard-coded to the literal **False**. The evaluation during the check will then necessarily fail, raising Assertion_Error. Hence, for this type, explicit initialization is guaranteed in a program that does not raise Assertion_Error for this cause.

The following is an example of the DIC set to **False**:

```
package P is

   type Q is limited private with
     Default_Initial_Condition => False;

   function F return Q;

private

   type Q is range -1 .. 100;

end P;

package body P is

   function F return Q is (42);

end P;

with Ada.Text_IO;  use Ada.Text_IO;

with P; use P;

procedure Main is
   Obj1 : constant Q := F;
   Obj2 : Q;  --  triggers Assertion_Error
begin
```

(continues on next page)

(continued from previous page)

```
   Put_Line (Obj1'Image);
   Put_Line (Obj2'Image);
   Put_Line ("Done");
end Main;
```

In the above, `Assertion_Error` is raised by the elaboration of `Obj2` because the DIC check necessarily fails. There is no check on the declaration of `Obj1` because it is initialized, explicitly.

To recap, we can ensure initialization for objects of the type by detecting, during elaboration at run-time, any objects not explicitly initialized.

This approach is sufficient because when elaboration of an object declaration raises an exception, no use of that object is possible. That's guaranteed because the frame containing that declarative part is immediately abandoned and the exception is propagated up to the previous level. A local handler never can apply. But even if there is a matching handler in the previous level, there's really nothing much to be done. Re-entering the frame containing the declaration will raise the exception all over again, necessarily. Thus the code will have to be changed and recompiled, meeting the goal of the idiom.

We can illustrate this assurance using `Storage_Error`. Consider the following program, in which the main procedure calls an inner procedure P:

```
with Text_IO; use Text_IO;

procedure Main is

   procedure P (Output : out Float) is
      N : array (Positive) of Float; -- Storage_Error is likely
   begin
      Put_Line ("P's body assigns N's components and uses them");
      -- The following indexes and component values are arbitrary
      -- and used purely for illustration...
      N := (others => 0.0);
      -- other computations and assignments to N ...
      Output := N (5);
   exception
      when Storage_Error =>
         Output := N (1);
   end P;

   X : Float;

begin
   P (X);
   Put_Line (X'Image);
   Put_Line ("Done");
exception
   when Storage_Error =>
      Put_Line ("Main completes abnormally");
end Main;
```

When `Main` calls P, the elaboration of the declarative part of P almost certainly fails because there is insufficient storage to allocate to the object `P.N`, hence `Storage_Error` is raised. (If your machine can handle the above, congratulations.) Even though procedure P has a handler specifically for `Storage_Error`, that handler never applies because the declarative part is immediately abandoned. Instead, the exception is raised in the caller, where it can be caught. This behavior is essential to ensure that problematic objects are not referenced in the local handlers. In the above, the handler in P for `Storage_Error` references the object `P.N` to assign the `P.Output` parameter. If that assignment could happen — again, it cannot — what would it mean, functionally? No one knows.

Handling `Storage_Error` is a little tricky anyway. Does the OS give the program a chance to execute a handler? If so, is there sufficient storage remaining to execute the exception handler's statements? In any case you can see the problem that the declaration failure semantics preclude.

Therefore, although the DIC solution is not enforced at compile-time, it is nevertheless sufficient to ensure no uninitialized object of the type can be used.

117.3.1 Preventing Object Creation by Clients

The other idiom requirement is the ability to control object creation itself. The solution is trivially achieved using an indefinite limited private type: we can prevent client object creation simply by not providing any constructor functions. Doing so removes any means for initializing objects of the type, and since the type is indefinite there is then no way for clients to declare objects at all. The compiler again enforces this solution.

For a concrete example, we can apply the Singleton design pattern to represent the *time stamp counter* (TSC[525]) provided by x86 architectures. The TSC is a 64-bit hardware register incremented once per clock cycle, starting from zero at power-up. We can use it to make a timestamp abstraction. As explained by Wikipedia page[526], some care is required when using the register for that purpose on modern hardware, but it will suffice to illustrate the idiom solution. Note that the Singleton pattern is itself somewhat controversial in the OOP community, but that's beyond the scope of this document.

Why use the Singleton pattern in this case? Ordinarily, clients of some ADT will reasonably expect that the states of distinct objects are independent of each other. When using an ADT to represent a single piece of hardware, however, this presumption of independence will not hold because the device is shared by all the objects, unavoidably. The singleton idiom prevents the resulting problems by precluding the existence of multiple objects in the first place.

In this specific case, the time stamp counter hardware is read-only, so the lack of independence is not an issue. Multiple objects would not be a problem. But many devices are not read-only, so the singleton pattern is worth knowing.

First we'll define a singleton ADT representing the TSC register itself, then we will extend that type to add convenience operations for measuring elapsed times. We'll use the design approach of indefinite limited private types without any constructor functions in order to ensure clients cannot create objects of the type. The type will also be tagged for the sake of allowing type extensions. Adding the tagged characteristic doesn't change anything regarding the idiom solution.

```
with Interfaces;

package Timestamp is

   type Cycle_Counter (<>) is tagged limited private;

   type Cycle_Counter_Reference is access all Cycle_Counter;

   function Counter return not null Cycle_Counter_Reference;

   type Cycle_Count is new Interfaces.Unsigned_64;

   function Sample (This : not null access Cycle_Counter) return Cycle_Count;

private
```

(continues on next page)

[525] https://en.wikipedia.org/wiki/Time_Stamp_Counter
[526] https://en.wikipedia.org/wiki/Time_Stamp_Counter

(continued from previous page)

```
   type Cycle_Counter is tagged limited null record;

   function Read_TimeStamp_Counter return Cycle_Count with
     Import,
     Convention    => Intrinsic,
     External_Name => "__rdtsc",
     Inline;
   --  This gcc builtin issues the machine instruction to read the time-stamp
   --  counter, i.e., RDTSC, which returns a 64-bit count of the number of
   --  system clock cycles since power-up.

   function Sample (This : not null access Cycle_Counter) return Cycle_Count is
     (Read_TimeStamp_Counter);  --  The formal parameter This is not referenced

end Timestamp;
```

Note also that the primitive function named `Counter` is not a constructor — it doesn't return an object of the `Cycle_Counter` type. As such, it cannot be used as an initial value for a `Cycle_Counter` object declaration. Clients cannot, therefore, create their own objects of type `Cycle_Counter`.

Instead, function `Counter` returns an access value designating an object of the type. Because clients cannot declare objects themselves the function is the only way to get an object, albeit indirectly. Therefore, the function can control how many objects are created. As you will see, the function only creates a single object of the type.

The type `Cycle_Counter` is completed as a null record because the state is maintained in the hardware register we're reading.

The function `Sample` reads the timestamp counter register by calling the `Read_TimeStamp_Counter` function. That second function accesses the TSC register by executing an assembly language instruction dedicated to that purpose. We could have `Sample` issue that instruction instead, without declaring a separate function, but there is no run-time cost (due to the inlining) and separating them emphasizes that one is a member of the API and the other is an implementation artifact. Note that `Sample` does not actually reference the formal parameter `This`. The parameter exists just to make `Sample` a primitive function. Assuming we don't have a use-clause for `Timestamp`, to call `Sample` we could say:

```
TimeStamp.Counter.Sample
```

for example:

```
with Timestamp;
with Ada.Text_IO; use Ada.Text_IO;

procedure Demo_TimeStamp is
begin
   for K in 1 .. 10 loop
      Put_Line (Timestamp.Counter.Sample'Image);
   end loop;
end Demo_TimeStamp;
```

The above calls the `Timestamp.Counter` function and then implicitly dereferences the resulting access value to call the `Sample` function using the distinguished receiver syntax. The resulting number is then converted to a **`String`** value and output to `Standard_Output`.

We could have instead used positional call notation for the call to `Sample`:

```
Timestamp.Sample (Timestamp.Counter)
```

In that case we need the package name on the references, or we'd add a use-clause.

The package body is shown below. Only the function Counter has a body because Sample is completed in the package declaration's private part and Read_TimeStamp_Counter is an imported intrinsic, i.e., without a body.

```
package body Timestamp is

   The_Instance : Cycle_Counter_Reference;

   -------------
   -- Counter --
   -------------

   function Counter return not null Cycle_Counter_Reference is
   begin
      if The_Instance = null then
         The_Instance := new Cycle_Counter;
      end if;
      return The_Instance;
   end Counter;

end Timestamp;
```

Function Counter creates the single object that this singleton implementation creates. It does so by lazily allocating an object dynamically. If Counter is never called (because some subclass is used instead) then no object of type Cycle_Counter is created. At most one Cycle_Counter object is ever created.

We could instead declare The_Instance as a Cycle_Counter object in the package body, mark it as aliased, and return a corresponding access value designating it. But when objects are large, declaring one that might never be used is wasteful. The indirection avoids that wasted storage at the cost of an access object, which is small. On the other hand, now the heap is involved.

Note that we could have declared The_Instance in the private part of the package declaration. Type extensions in child packages could then use it, if needed. Presumably we'd make The_Instance be of some access to class-wide type so that extensions could use it to allocate objects of their specific type, otherwise extensions in child packages would have no need for it. But that only saves the storage for an access object in the child packages, so we leave the declaration in the parent package body. See the *Programming by Extension idiom* (page 2013) for a discussion of whether to declare an entity in the package private part or the package body.

Next, we declare a type extension in a child package. The child package body will contain its own object named The_Instance, returning an access value designating the specific extension type. The client API in the package declaration follows that of the parent type Cycle_Counter, but with additional primitives for working with samples.

```
package Timestamp.Sampling is

   type Timestamp_Sampler is new Cycle_Counter with private;

   type Timestamp_Sampler_Reference is access all Timestamp_Sampler;

   function Counter return not null Timestamp_Sampler_Reference with Inline;
   --  returns an access value designating the single instance

   procedure Take_First_Sample  (This : not null access Timestamp_Sampler) with␣
↪Inline;
   procedure Take_Second_Sample (This : not null access Timestamp_Sampler) with␣
↪Inline;

   function First_Sample  (This : not null access Timestamp_Sampler) return Cycle_
```

(continues on next page)

(continued from previous page)

```
↪Count;
   function Second_Sample (This : not null access Timestamp_Sampler) return Cycle_
↪Count;
   function Elapsed       (This : not null access Timestamp_Sampler) return Cycle_
↪Count;

private

   type Timestamp_Sampler is new Cycle_Counter with record
      First  : Cycle_Count := 0;
      Second : Cycle_Count := 0;
   end record;

end Timestamp.Sampling;

package body Timestamp.Sampling is

   The_Instance : Timestamp_Sampler_Reference;

   -------------
   -- Counter --
   -------------

   function Counter return not null Timestamp_Sampler_Reference is
   begin
      if The_Instance = null then
         The_Instance := new Timestamp_Sampler;
      end if;
      return The_Instance;
   end Counter;

   ------------------------
   -- Take_First_Sample --
   ------------------------

   procedure Take_First_Sample (This : not null access Timestamp_Sampler) is
   begin
      This.First := Sample (This);
   end Take_First_Sample;

   -------------------------
   -- Take_Second_Sample --
   -------------------------

   procedure Take_Second_Sample (This : not null access Timestamp_Sampler) is
   begin
      This.Second := Sample (This);
   end Take_Second_Sample;

   ------------------
   -- First_Sample --
   ------------------

   function First_Sample (This : not null access Timestamp_Sampler) return Cycle_
↪Count is
     (This.First);

   -------------------
   -- Second_Sample --
   -------------------
```

(continues on next page)

(continued from previous page)

```
   function Second_Sample (This : not null access Timestamp_Sampler) return Cycle_
↪Count is
      (This.Second);

   -------------
   -- Elapsed --
   -------------

   function Elapsed (This : not null access Timestamp_Sampler) return Cycle_Count␣
↪is
      (This.Second - This.First + 1);

end Timestamp.Sampling;
```

The inherited `Sample` function is called in the two procedures that take the two samples of the timestamp register. The formal parameter `This` is passed to the calls, but as mentioned earlier the argument is not referenced within `Sample`. All the formal parameter does is participate in dispatching the calls to `Sample`, in this case meaning that the inherited version of `Sample` is the one called because `This` is of the extended type.

But `Sample` is not overridden in this child package, therefore effectively we are calling the parent version. Is `Sample` ever likely to be overridden? Arguably not, because it is so directly dependent on the underlying hardware. Of course, some future type extension may override `Sample` for some unforeseen reason — that's the point of making it possible, after all. Presumably the overridden version would also call the parent version, otherwise the timestamp counter would not be accessed. Because we can't say for certain that it will never need to be overridden, we have made `Sample` a primitive function, thus overridable.

Suppose we came to the opposite conclusion, that `Timestamp.Sample` would never need to be overridden. In that case we have some options worth exploring.

Clearly function `Sample` must be part of the client API, but that doesn't force it to be a primitive function.

We could have declared `Sample` in `Timestamp` as a visible non-primitive operation, i.e., without a formal parameter or function result of the ADT type:

```
function Sample return Cycle_Count with Inline;
```

As a non-primitive function it would be neither inherited nor overridable. But we'd still be able to call it in client code.

Yet, as a non-primitive, this version looks like an implementation artifact, hence out of place as part of the visible client API. It isn't illegal by any means, it just *looks* wrong.

Furthermore, if we are going to make `Sample` a non-primitive function, why not remove it and replace it with the other non-primitive function `Read_Timestamp_Counter`? Or make the body of `Sample` call the imported intrinsic, and do away with function `Read_Timestamp_Counter`? There is no clear winner here.

An attractive alternative would be to make `Sample` be a class-wide operation. To do so, we make the formal parameter class-wide instead of removing it:

```
function Sample (This : not null access Cycle_Counter'Class) return Cycle_Count␣
↪with Inline;
```

In the version above, the formal parameter type is now (anonymous) access to `Cycle_Counter'Class`, i.e., class-wide, so in this version `Sample` can be passed a value designating an object of type `Cycle_Counter` or any type derived from it. We don't want to have a null access value passed so we add that to the parameter specification.

In this version the function is again not a primitive operation and so is neither inherited nor overridable, but because it mentions type `Cycle_Counter` it looks like a reasonable part of

an Abstract Data Type. As it happens this version of Sample also doesn't actually reference the formal parameter, so it is somewhat unusual. Ordinarily in the body we'd expect the class-wide formal to be used in dynamic dispatching calls to primitive operations, but that's not required by the language.

Ultimately whether to make Sample a primitive operation is a judgment call. We don't know that Sample will never need to be overridden so we declare it as a primitive op.

With all that said, here is an example program using the child type. Because the timestamp register is updated once per clock cycle, if we know the system clock frequency we can use the counter to measure elapsed time. In the demo below we measure the accuracy of the delay statement by delaying for a known time, with samples taken before and after the delay statement. We can then compare the known delay time to the measured elapsed time, printing the difference.

Note the constant Machine_Cycles_Per_Second. Before you run the demo you will likely need to change it in the source code to your machine's clock frequency.

```
with Timestamp.Sampling;   use Timestamp.Sampling;
with Ada.Text_IO;          use Ada.Text_IO;

procedure Demo_Sampling_Cycle_Counter is

   Delay_Interval : constant Duration := 1.0;  --  arbitrary, change if desired
   Elapsed_Time   : Duration;

   GHz : constant := 1_000_000_000;

   Machine_Cycles_Per_Second : constant := 1.9 * GHz;
   --  This is the system clock rate on the machine running this executable.
   --  It corresponds to the rate at which the time stamp counter hardware is
   --  incremented. Change it according to your target.

   use type Timestamp.Cycle_Count;  --  for "<"
begin
   Put_Line ("Using" & Machine_Cycles_Per_Second'Image & " Hertz for system clock
 ↪");

   Put_Line ("Delaying for" & Delay_Interval'Image & " second(s) ...");

   Counter.Take_First_Sample;
   delay Delay_Interval;
   Counter.Take_Second_Sample;

   Put_Line ("First sample            :" & Counter.First_Sample'Image);
   Put_Line ("Second sample           :" & Counter.Second_Sample'Image);

   if Counter.Second_Sample < Counter.First_Sample then
      Put_Line ("RDTSC counter wrapped around!?");
      return;
   end if;

   Elapsed_Time := Duration (Elapsed (Counter)) / Machine_Cycles_Per_Second;

   Put_Line ("Elapsed count           :" & Elapsed (Counter)'Image);
   Put_Line ("Specified delay interval:" & Delay_Interval'Image);
   Put_Line ("Measured delay interval :" & Elapsed_Time'Image);
end Demo_Sampling_Cycle_Counter;
```

In the above, Delay_Interval is set to 1.0 so the program will delay for 1 second, with samples taken from the TSC before and after. Delay statement semantics are such that at least the amount of time requested is delayed, so some value slightly greater than 1 second is expected. There will be overhead too, so an elapsed time slightly larger than requested

should be seen. The value of `Delay_Interval` is arbitrary, change it to whatever you like.

If you have set the `Machine_Cycles_Per_Second` properly but still get elapsed measurement values that are much larger than expected or don't make sense at all, it may be that your machine does not support using the TSC[527] this way reliably.

117.4 Pros

Ensuring explicit initialization is easily achieved. The abstraction should likely be a private type anyway, and the syntax for the required additional building blocks is light: all are just additional decorations on the declaration of the private type or private extension. The compiler does the rest, either at compile-time itself or via a generated check verified at run-time.

Likewise, ensuring that only the implementation can create objects of a type is straightforward. We take the same approach for ensuring initialization via function calls in object declarations, but then don't provide any such functions. Only the implementation will have the required visibility to create objects of the type, and can limit that number of objects to one (or any other number). Client access to this hidden object must be indirect, but that is not a heavy burden.

117.5 Cons

None.

117.6 Relationship With Other Idioms

The *Abstract Data Type* (page 2001) is assumed, in the form of a private type.

117.7 Notes

Only certain types can have unknown discriminants. For completeness here is the list:

- A private type
- A private extension
- An incomplete type
- A generic formal private type
- A generic formal private type extension
- A generic formal derived type
- Descendants of the above

The types above will either have a corresponding completion or a generic actual parameter to either define the discriminants or specify that there are none.

As we mentioned, `Default_Initial_Condition` is new in Ada 2022. The other solution, based on indefinite private types, is supported by Ada 2022 but also by earlier versions of the language. However, if the type is also limited, Ada 2005 is the earliest version allowing

[527] https://en.wikipedia.org/wiki/Time_Stamp_Counter

that solution. Prior to that version an object of a limited type could not be initialized in the object's declaration.

CHAPTER

EIGHT

INTERRUPT HANDLING

118.1 Motivation

Recall that, in Ada, protected procedures are the standard interrupt-handling mechanism. The canonical interrupt handling and management model is defined in the Systems Programming Annex, section C.3 of the Reference Manual[528]. We assume that this optional annex is supported, and indeed effectively all compilers do support it. Likewise, we assume that the Real-Time Annex, annex D[529], is supported (which would require Annex C[530] to be supported anyway). Finally, we assume that either the Ravenscar or the Jorvik usage profile is applied. These two profiles define configurations of the two annexes that are appropriate for typical embedded systems that handle interrupts.

The definition of a canonical model mitigates differences imposed by the target, but some remain. For example, the number of different priority values, including interrupt priorities, differs with the targets involved. The model supports blocking of those interrupts at a lower priority than the currently executing interrupt handler, but the hardware might not support that behavior, although many do. None of these variations affect the expression of the idioms themselves.

The response to interrupts is often arranged in logical levels. The first level is the protected procedure handler itself. In some cases, everything required to handle the interrupt is performed there. However, some applications require more extensive, asynchronous processing of the data produced by the first level interrupt handler. In this case a second-level response can be defined, consisting of a task triggered by the first level. For example, the interrupt handler could respond to the first arrival of a character on a USART[531], poll for the remainder (or not), and then notify a task to perform analysis of the entire string received.

But even if no second-level interrupt processing is required, the interrupt handler may be required to notify the application that the event has occurred. Because interrupts are asynchronous, and logically concurrent with the application code, the association of an application task to a given interrupt-driven event is convenient and common.

Hence a task is often involved. How the handler procedure notifies the task leads to a couple of different idiom solutions. In both cases notification amounts to releasing the previously suspended task for further execution.

In the Solution section below, we show how to express these three idioms: one for using protected procedures alone, and two in which a protected procedure handler notifies a task.

118.2 Solution

118.2.1 First Level Handler Alone

In this solution the interrupt handler protected procedure does everything necessary and does not require a second-level handler.

An interrupt handler that simply copies data from one location to another is a good example of a necessary and sufficient first-level handler. The enclosing application assumes the copying is occurring as required and needs no explicit notification. If the copying isn't happening the failure will be obvious.

So, given that, why discuss such a scenario? Two reasons: to show how it is done in general, and especially, to show how double-buffering can be implemented very elegantly with interrupts.

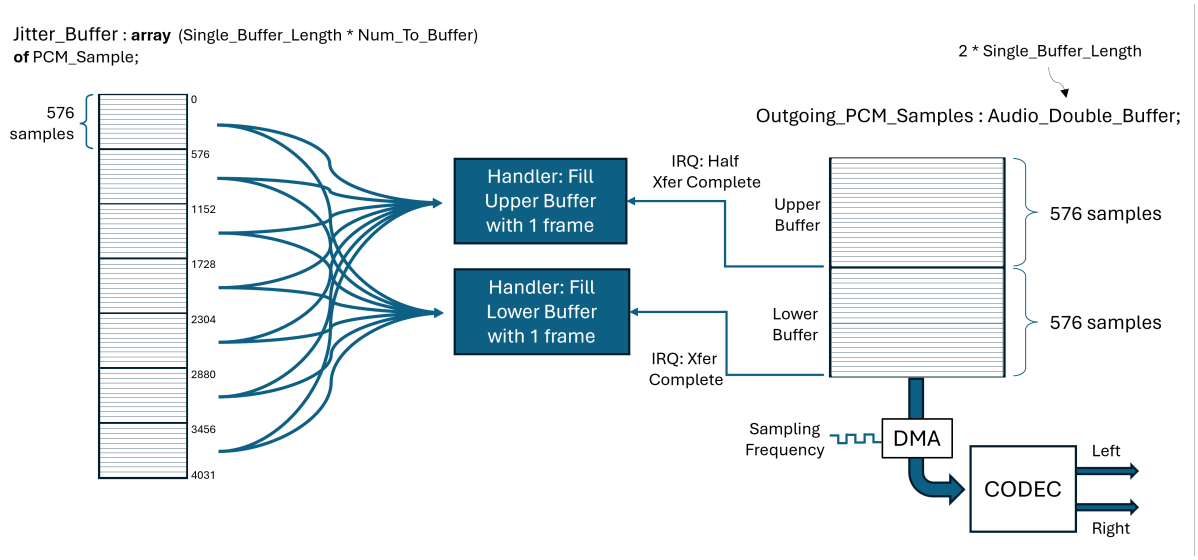
For a concrete example, consider an audio streaming device that takes PCM samples from Ethernet via incoming UDP packets and transfers them to an audio CODEC device[532] on the target board. The CODEC output is physically connected to a high-quality amplifier and speakers. No upper-level application thread requires notification of the copying: if the transfer is working the audio output occurs, otherwise it does not.

In our solution the CODEC device is *fed* from a buffer named `Outgoing_PCM_Samples`. The buffer must always have new samples available when the CODEC is ready for them, because delays or breaks would introduce audible artifacts. The timing is determined by the sampling rate used by the audio source, prior to transmission. To match that rate and to provide it efficiently, we use DMA to transfer the data from the buffer to the CODEC. In addition, `Outgoing_PCM_Samples` is double-buffered to help ensure the samples are always available upon demand.

However, the incoming UDP packets don't arrive at exact intervals. Because of this *jitter* in the arrival times, we cannot directly insert the PCM samples from these incoming packets into the `Outgoing_PCM_Samples` buffer. The delays would be audible. Therefore, we use a *jitter buffer* to deal with the arrival time variations. This jitter buffer holds the PCM samples as they arrive in the UDP packets, in sufficient amounts to de-couple the arrival time jitter from the outgoing data. A jitter buffer can do much more than this, such as correcting the order of arriving packets, but in this specific case the additional functionality is not required.

We use two DMA interrupts to copy data from the jitter buffer to the `Outgoing_PCM_Samples` buffer. The rationale for using two interrupts, rather than one, is given momentarily. The figure below illustrates the overall approach, with the jitter buffer on the left, the two interrupt handlers in the middle, and the `Outgoing_PCM_Samples` buffer on the right.

[532] https://en.wikipedia.org/wiki/Audio_codec



Each UDP packet contains 576 PCM samples, used as the *single buffer length* for the double-buffered `Outgoing_PCM_Samples` and the `Jitter_Buffer`.

The advantage of double-buffering is that the producer can be filling one buffer while the consumer is removing data from the other. These directions switch when the current output buffer becomes empty. The result is a fast, continuous output stream. Many audio and video devices use double-buffering for that reason.

To express double-buffering you could use two physically distinct array objects, switching between them when the DMA controller signals that the current outgoing buffer is empty. That would require keeping track of which buffer is being filled and which is being emptied. There is an elegant, simpler alternative that uses two different DMA interrupts instead of one. (The DMA device must support this approach directly.)

In this alternative, there is one physical array (`Outgoing_PCM_Samples`), containing twice the number of components as a single physical buffer would contain. We can then use the two interrupts to treat the one physical array as two logical buffers.

The two DMA interrupts are triggered as the DMA transfer consumes the content within this single array. One interrupt is triggered when the transfer reaches the physical half-way point in the array. The other interrupt is triggered when the transfer reaches the physical end of the array. Therefore, because the array is twice the size of a single buffer, each interrupt corresponds to one of the two logical buffers becoming empty.

Furthermore, the DMA device generating these interrupts is configured so that it does not stop. After triggering the *half transfer complete* interrupt the DMA continues reading, now from the second logical buffer. After triggering the *transfer complete* interrupt the DMA device starts over at the beginning of the array, reading from the first logical buffer again.

Therefore, we have two distinct interrupt handlers, one for each of the two interrupts. When the *half transfer complete* handler is invoked, the upper logical buffer is now empty, so the handler for that half fills it. Likewise, the *transfer complete* interrupt handler fills the lower logical buffer at the bottom half of the array. There's no need to keep track of which buffer is being filled or emptied. It's all being emptied, and the handlers always fill the same upper or lower halves of the array. As long as each handler completes filling their half before the DMA transfer begins reading it, all is well.

Here's the declaration of the protected object containing the DMA interrupt handling code.

```
protected DMA_Interrupt_Controller with
  Interrupt_Priority => DMA_Interrupt_Priority
is
private
```

(continues on next page)

(continued from previous page)

```
   procedure DMA_IRQ_Handler with
      Attach_Handler => STM32.Board.Audio_Out_DMA_Interrupt;
end DMA_Interrupt_Controller;
```

A few points are worth highlighting.

First, `DMA_Interrupt_Priority` is an application-defined constant. The actual value isn't important to this discussion. The handler procedure is attached to an interrupt that is specific to the target board, so it is defined in the package `STM32.Board` in the Ada Drivers Library. Each target board supported by the library has such a package, always with the same package name. This particular STM32 board has dedicated audio DMA support, along with the CODEC.

Second, there's nothing declared in the visible part of the PO. More to the point, everything is declared in the optional private part. That placement is a matter of style, but it's good style. No software client should ever call the protected procedure — only the hardware should call it, via the runtime library — so we make it impossible for any client to call it accidentally. That placement also informs the reader of our intent.

Third, we said there are two interrupts, but only one interrupt handler procedure is declared and attached. There's nothing inherently wrong with one routine handling multiple interrupts, although conceptually it is not ideal. In this case it is necessary because on this target both device interrupts arrive at the MCU on one external interrupt line. Therefore, the one protected procedure handler handles both device interrupts, querying the DMA status flags to see which interrupt is active. This approach is shown below. Note that there must be an enclosing package, with multiple context clauses, but we do not show them so that we can focus on the interrupt handler itself.

```
protected body DMA_Interrupt_Controller is

   procedure DMA_IRQ_Handler is
      use STM32.Board; -- for the audio DMA
   begin
      if Status (Audio_DMA, Audio_DMA_Out_Stream, DMA.Half_Transfer_Complete_
↪Indicated) then
         --  The middle of the double-buffer array has been reached by the
         --  DMA transfer, therefore the "upper half buffer" is empty.
         Fill_Logical_Buffer (Outgoing_PCM_Samples, Starting_Index => Upper_Buffer_
↪Start);
         Clear_Status (Audio_DMA, Audio_DMA_Out_Stream, DMA.Half_Transfer_Complete_
↪Indicated);
      end if;

      if Status (Audio_DMA, Audio_DMA_Out_Stream, DMA.Transfer_Complete_Indicated)␣
↪then
         --  The bottom of the double-buffer array has been reached by the
         --  DMA transfer, therefore the "lower half buffer" is empty.
         Fill_Logical_Buffer (Outgoing_PCM_Samples, Starting_Index => Lower_Buffer_
↪Start);
         Clear_Status (Audio_DMA, Audio_DMA_Out_Stream, DMA.Transfer_Complete_
↪Indicated);
      end if;
   end DMA_IRQ_Handler;

end DMA_Interrupt_Controller;
```

In both cases `Fill_Logical_Buffer` is called to insert samples from the jitter buffer into one of the logical buffers. The difference is the value passed to the formal parameter `Starting_Index`. This is the array index at which filling should begin within `Outgoing_PCM_Samples`. `Upper_Buffer_Start` corresponds to `Outgoing_PCM_Samples'First`, and `Lower_Buffer_Start` is `Outgoing_PCM_Samples'First + Single_Buffer_Length`.

That's all the software has to do. Offloading work to the hardware, in this case the DMA controller, is always a good idea, but that's especially true for less powerful targets, e.g., microcontrollers. Note that the availability of the *half transfer complete* interrupt varies across different DMA devices.

The implementation of `Fill_Logical_Buffer` is straightforward and need not be shown. However, the procedure declares a local variable named `Incoming_PCM_Samples` that has ramifications worth noting. In particular, the representation may require altering and re-building the underlying Ada run-time library.

The object `Incoming_PCM_Samples` is declared within `Fill_Logical_Buffer` like so:

```
Incoming_PCM_Samples : Jitter_Buffer.Sample_Buffer_Slice;
```

The alteration might be required because `Fill_Logical_Buffer` executes entirely in the interrupt handler procedure's context. Hence the storage used by the procedure's execution comes from the interrupt handler stack. Interrupt handlers typically do relatively little, and, as a result, a relatively small stack allocation is typically defined for them. The storage for `Incoming_PCM_Samples` might exceed that allocation.

Specifically, we said that `Fill_Logical_Buffer` fills an entire half of the double-buffer, i.e., it works in terms of `Single_Buffer_Length`. If `Sample_Buffer_Slice` is an actual array, the required storage might be considerable.

The interrupt stack allocation is set by the run-time library source code in GNAT, as is common. You could increase the allocation and rebuild the run-time.

On the other hand, `Sample_Buffer_Slice` need not be an actual array. It could be a record type containing a (read-only) pointer to the jitter buffer array and an index indicating where in that array the *slice* to be transferred begins. That representation would obviously require much less stack space, obviating the run-time library change and rebuild. Moreover, that representation would allow `Fill_Logical_Buffer` to copy directly from the jitter buffer into the final destination, i.e., `Outgoing_PCM_Samples`. If `Incoming_PCM_Samples` is an array, we'd have to copy from the jitter buffer into `Incoming_PCM_Samples`, and then again from there to `Outgoing_PCM_Samples`. That's an extra copy operation we can avoid.

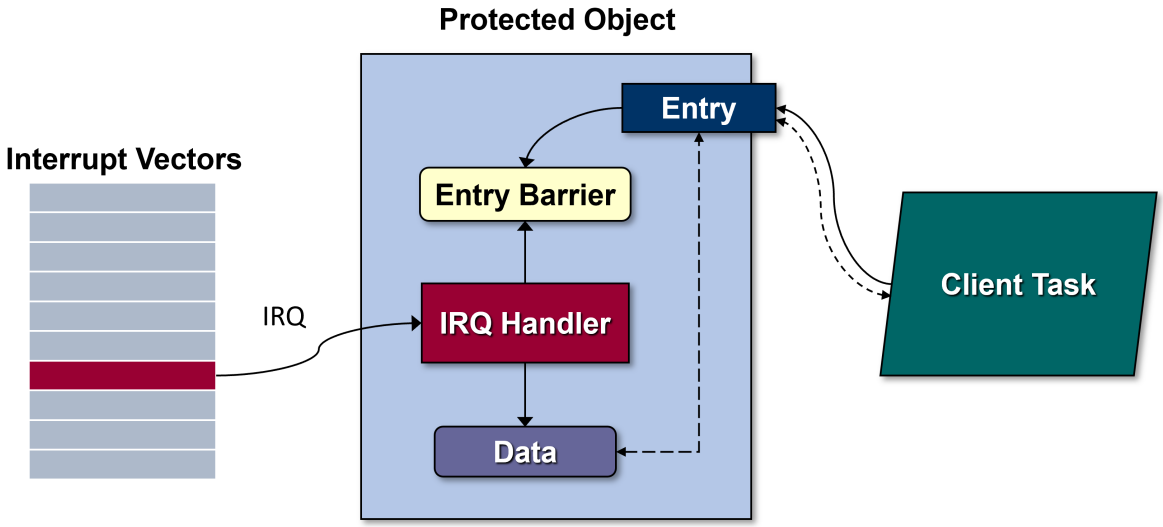
A related issue, perhaps requiring a run-time change, is the *secondary stack* allocation for interrupt handlers. The secondary stack is a common approach to implementing calls to functions that return values of unconstrained subtypes (usually, unconstrained array types, such as **`String`**). Because the result size is not known at the point of the call, using the primary call stack for holding the returned value is messy. The function's returned value would follow the stack space used for the call itself. But on return, only the call space is popped, leaving a *hole* in the stack because the value returned from the function remains on the stack. Therefore, another separate stack is commonly used for these functions. (GNAT does so.) The interrupt handler code could exhaust this allocation as well. The allocation amount is also specified in the run-time library source code. But, as with the situation above, the source code can be changed, in this case to avoid calling functions with unconstrained result types. The trade-off is whether that change is more costly than changing and rebuilding the run-time, as well as maintaining the change.

118.2.2 Task Notification Introduction

The first idiom solution did not require notifying a task, but these next idiom solutions will do so. As we mentioned earlier, how the interrupt handler achieves this notification leads to two distinct idioms. Ultimately the difference between them is whether or not the interrupt handler must communicate with the task. In both cases the handler synchronizes with the task because of the notification required.

118.2.3 Task Notification With Communication

In this solution the interrupt handler releases a task but also communicates with it when doing so. Therefore, a protected entry is used, and the entry parameters are the communication medium. The approach is depicted in the figure below:



The interrupt handler stores data within the PO and only enables the entry barrier when ready to either produce it or consume it via the entry parameters. The dashed lines in the figure represent this data flow.

By coincidence, this is the notification approach used in the idiom entry *Providing Component Access to Enclosing Record Objects* (page 2037). In that solution, client tasks call two entries to Put and Get single characters, so the data stored in the PO consists of those characters. We did not mention it there because we were focused on that other idiom, i.e., how to give visibility within a PO/task component to an enclosing record object.

Be sure to understand the code for the other idiom before exploring this one. We will repeat elided parts of the code and only discuss the parts relevant for this current idiom. Because we are focused now on the interrupt handling task notification, here is the full interrupt handler PO type declaration — `IO_Manager` — within the elided package declaration:

```
package Serial_IO.Interrupt_Driven is

   type Serial_Port ... is new Serial_IO.Device with private;

   overriding
   procedure Put (This : in out Serial_Port;  Data : HAL.UInt8) with Inline;

   overriding
   procedure Get (This : in out Serial_Port;  Data : out HAL.UInt8) with Inline;

private
```

(continues on next page)

(continued from previous page)

```
   protected type IO_Manager
     (IRQ          : Interrupt_ID;
      IRQ_Priority : Interrupt_Priority;
      Port         : not null access Serial_Port)
   with
      Interrupt_Priority => IRQ_Priority
   is

      entry Put (Datum : HAL.UInt8);

      entry Get (Datum : out HAL.UInt8);

   private

      Outgoing : HAL.UInt8;
      Incoming : HAL.UInt8;

      Incoming_Data_Available : Boolean := False;
      Transmission_Pending    : Boolean := False;

      procedure IRQ_Handler with Attach_Handler => IRQ;

    end IO_Manager;

   ...

end Serial_IO.Interrupt_Driven;
```

A protected object of type `IO_Manager` is given a discriminant value that designates the enclosing `Serial_Port` object because that `Serial_Port` has the USART device required to do the actual I/O. The other two discriminants are required for configuring the interrupt handler and attaching it to the interrupt hardware.

The two octets `Outgoing` and `Incoming` are the values sent and received via the interrupt handler's manipulation of the USART. (A USART doesn't receive characters, as such, and we're ignoring the fact that it may work with a 9-bit value instead.)

The two Boolean components `Incoming_Data_Available` and `Transmission_Pending` are used for the two barrier expressions. Their purpose is explained below.

The bodies of visible procedures `Put` and `Get` (shown below) call through to the interrupt manager's protected entries, also named `Put` and `Get`. Those entries block the callers until the interrupt manager is ready for them, via the entry barriers controlled by the interrupt handler.

```
with STM32.Device; use STM32.Device;

package body Serial_IO.Interrupt_Driven is

   ---------
   -- Put --
   ---------

   overriding
   procedure Put (This : in out Serial_Port;  Data : HAL.UInt8) is
   begin
      This.Controller.Put (Data);
   end Put;

   ---------
```

(continues on next page)

(continued from previous page)

```
   -- Get --
   ---------

   overriding
   procedure Get (This : in out Serial_Port;  Data : out HAL.UInt8) is
   begin
      This.Transceiver.Enable_Interrupts (Received_Data_Not_Empty);
      This.Controller.Get (Data);
   end Get;

   ----------------
   -- IO_Manager --
   ----------------

   protected body IO_Manager is

      -----------------
      -- IRQ_Handler --
      -----------------

      procedure IRQ_Handler is
      begin
         --  check for data arrival
         if Port.Transceiver.Status (Read_Data_Register_Not_Empty) and then
            Port.Transceiver.Interrupt_Enabled (Received_Data_Not_Empty)
         then  -- handle reception
            Get (Serial_IO.Device (Port.all), Incoming);  -- call the Serial_IO.
↪Device version!
            Await_Reception_Complete : loop
               exit when not Port.Transceiver.Status (Read_Data_Register_Not_
↪Empty);
            end loop Await_Reception_Complete;
            Port.Transceiver.Disable_Interrupts (Received_Data_Not_Empty);
            Port.Transceiver.Clear_Status (Read_Data_Register_Not_Empty);
            Incoming_Data_Available := True;
         end if;

         --  check for transmission ready
         if Port.Transceiver.Status (Transmission_Complete_Indicated) and then
            Port.Transceiver.Interrupt_Enabled (Transmission_Complete)
         then  -- handle transmission
            Put (Serial_IO.Device (Port.all), Outgoing);  -- call the Serial_IO.
↪Device version!
            Port.Transceiver.Disable_Interrupts (Transmission_Complete);
            Port.Transceiver.Clear_Status (Transmission_Complete_Indicated);
            Transmission_Pending := False;
         end if;
      end IRQ_Handler;

      ---------
      -- Put --
      ---------

      entry Put (Datum : HAL.UInt8) when not Transmission_Pending is
      begin
         Transmission_Pending := True;
         Outgoing := Datum;
         Port.Transceiver.Enable_Interrupts (Transmission_Complete);
      end Put;

      ---------
```

(continues on next page)

(continued from previous page)

```
      -- Get --
      ---------

      entry Get (Datum : out HAL.UInt8) when Incoming_Data_Available is
      begin
         Datum := Incoming;
         Incoming_Data_Available := False;
      end Get;

   end IO_Manager;

end Serial_IO.Interrupt_Driven;
```

Note how `IRQ_Handler` checks for which interrupt is active, possibly both, does whatever is necessary for that to be handled, and then sets the entry barriers accordingly. The barrier expression `Transmission_Pending` blocks `Put` callers until the current transmission, if any, completes. The barrier `Incoming_Data_Available` blocks `Get` callers until a character has been received and can be provided to the caller. The entry bodies copy the entry formal parameters to/from the internally stored characters and likewise set the entry barriers.

Note too how the body of procedure `Get` first enables the *received data available* interrupt before calling the entry. The body of the entry `Put` does something similar. They both work in concert with the handler procedure to manage the interrupts as required.

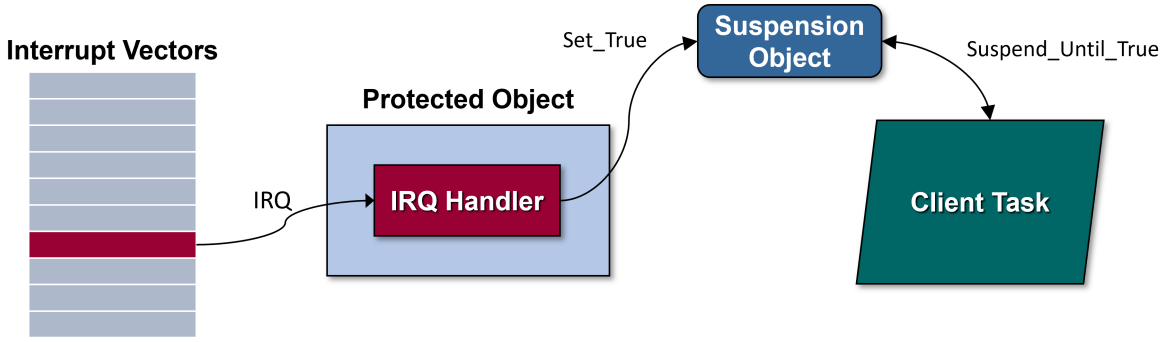
Using protected entries is ideal for this case because, after all, that is exactly what they are designed to do. Note that declaring multiple protected entries in a single protected type/object requires the Jorvik usage profile to be applied.

118.2.4 Task Notification Without Communication

In this solution, the interrupt handler procedure is not required to communicate with the task. It only needs to synchronize with it, to release it.

Therefore, we can use a `Suspension_Object`: a language-defined, thread-safe *binary flag* type defined in package `Ada.Synchronous_Task_Control`. Objects of this type have two values: **`True`** and **`False`**, with **`False`** as the default initial value. There are two primary primitive operations: procedures `Suspend_Until_True` and `Set_True`. Procedure `Set_True` does just what you think it does. Procedure `Suspend_Until_True` suspends the caller (task) until the value of the specified argument becomes **`True`**, at which point the suspended task is allowed to continue execution. (Of course, if it was already **`True`** when `Suspend_Until_True` was called, the caller returns without suspending.) Critically, procedure `Suspend_Until_True` also sets the argument back to **`False`** before returning. As a result, those are the only two routines you're likely to need, although there are others.

The interrupt handler procedure in this idiom solution simply calls `Set_True` for a `Suspension_Object` (an object of that type) visible to both the handler and the task. This arrangement is illustrated by the following figure:



The language requires the run-time library implementation to allow calls to `Set_False` and `Set_True` during any protected action, even one that has its ceiling priority in the `Interrupt_Priority` range, so this approach will work for interrupt handlers as well as tasks.

For our example we implement a facility for sending and receiving *messages* over a serial port, using interrupts. The design is similar to the solution we just explored, and thus to the *Providing Component Access to Enclosing Record Objects* (page 2037) idiom. In that solution, however, only single characters were sent and received, whereas messages will consist of one or more characters. Although there are differences, we assume that you are familiar enough with that idiom's solution that we don't need to go into all the details of the serial I/O, the USART, or the interrupt handler within a PO. We'll focus instead of the differences due to this idiom.

In this version we want to notify a task when an entire message has been sent or received, not just a single character. We'll define a message as a **`String`** that has a message-specified logical terminator character, e.g., the *nul* character. Transmission will cease when the terminator character is encountered when sending a message object. Similarly, a message is considered complete when the terminator character is received. (The terminator is not stored in message content.)

In a sense the interrupt handler is again communicating with tasks, but not directly, so entry parameters aren't applicable. Therefore, a `Suspension_Object` component is appropriate. But instead of one `Suspension_Object` variable, each `Message` object will contain two: one for notification of new content receipt, and one for notification of successful content transmission.

For the sake of the Separation of Concerns principle, the type `Message` should be an ADT of its own, in a dedicated package:

```
with Serial_IO;                      use Serial_IO;
with Ada.Synchronous_Task_Control;   use Ada.Synchronous_Task_Control;

package Message_Buffers is

   type Message (Physical_Size : Positive) is tagged limited private;

   function Content (This : Message) return String;
   function Length (This : Message) return Natural;
   procedure Set (This : in out Message;  To : String) with
     Pre  => To'Length <= This.Physical_Size,
     Post => Length (This) = To'Length and Content (This) = To;
   ...
   function Terminator (This : Message) return Character;
   procedure Await_Transmission_Complete (This : in out Message);
   procedure Await_Reception_Complete (This : in out Message);
   procedure Signal_Transmission_Complete (This : in out Message);
   procedure Signal_Reception_Complete (This : in out Message);

private
```

(continues on next page)

(continued from previous page)

```
   type Message (Physical_Size : Positive) is tagged limited record
      Content               : String (1 .. Physical_Size);
      Length                : Natural := 0;
      Reception_Complete    : Suspension_Object;
      Transmission_Complete : Suspension_Object;
      Terminator            : Character := ASCII.NUL;
   end record;

end Message_Buffers;
```

In essence, a Message object is just the usual *variable length string* abstraction with a known terminator and ways to suspend and resume clients using them. Note the two Suspension_Object components.

In this example the tasks to be notified are application tasks rather than second-level interrupt handlers. Client tasks can suspend themselves to await either transmission completion or reception completion. The Message procedures simply call the appropriate routines for the parameter's Suspension_Object components:

```
procedure Await_Transmission_Complete (This : in out Message) is
begin
   Suspend_Until_True (This.Transmission_Complete);
end Await_Transmission_Complete;
```

and likewise:

```
procedure Await_Reception_Complete (This : in out Message) is
begin
   Suspend_Until_True (This.Reception_Complete);
end Await_Reception_Complete;
```

The client task could look like the following, in this case the main program's environment task:

```
procedure Demo_Serial_Port_Nonblocking is

   Incoming : aliased Message (Physical_Size => 1024);  -- arbitrary size
   Outgoing : aliased Message (Physical_Size => 1024);  -- arbitrary size

   procedure Send (This : String) is
   begin
      Set (Outgoing, To => This);
      Start_Sending (COM, Outgoing'Unchecked_Access);
      Outgoing.Await_Transmission_Complete;
   end Send;

begin
   Initialize_Hardware (COM);
   Configure (COM, Baud_Rate => 115_200);

   Incoming.Set_Terminator (ASCII.CR);
   Send ("Enter text, terminated by CR.");
   loop
      Start_Receiving (COM, Incoming'Unchecked_Access);
      Incoming.Await_Reception_Complete;
      Send ("Received : " & Incoming.Content);
   end loop;
end Demo_Serial_Port_Nonblocking;
```

We don't show all the context clauses, for brevity, but one of the packages declares COM as the serial port. This demo doesn't exploit the nonblocking aspect because it does not

perform any other actions before suspending itself after initiating sending and receiving. But it could do so, while the I/O is happening, only later suspending to await completion of the requested operation.

The interrupt handler procedure can signal both transmission and reception completion using the two other procedures:

```
procedure Signal_Transmission_Complete (This : in out Message) is
begin
   Set_True (This.Transmission_Complete);
end Signal_Transmission_Complete;

procedure Signal_Reception_Complete (This : in out Message) is
begin
   Set_True (This.Reception_Complete);
end Signal_Reception_Complete;
```

In this version of the Serial IO facility, the interrupt handler's enclosing protected type is the type `Serial_Port` itself, rather than a PO enclosed by a record type:

```
protected type Serial_Port
  (Device       : not null access Peripheral_Descriptor;
   IRQ          : Interrupt_ID;
   IRQ_Priority : Interrupt_Priority)
with
    Interrupt_Priority => IRQ_Priority
is

   procedure Start_Sending (Msg : not null access Message);
   procedure Start_Receiving (Msg : not null access Message);

private

   Next_Out     : Positive;
   Outgoing_Msg : access Message;
   Incoming_Msg : access Message;

   procedure Handle_Transmission with Inline;
   procedure Handle_Reception    with Inline;
   procedure ISR with Attach_Handler => IRQ;

end Serial_Port;
```

Procedure ISR (*Interrupt Service Routine*) is the handler.

The two visible protected procedures, `Start_Sending` and `Start_Receiving`, are given non-null arguments when called (indirectly) by client tasks. Each argument is an access value designating a `Message` object declared by clients. The pointers are copied into the internal components, i.e., `Outgoing_Msg` and `Incoming_Msg`, for use by the interrupt handler procedure.

As with the earlier idiom above, there are multiple device interrupts, but they are all delivered on one external interrupt line. The handler procedure checks the status flags to see which interrupts are active and calls dedicated internal procedures accordingly. We don't need to see this infrastructure code again, so we can focus instead on one, the internal `Handle_Reception` procedure. The routine for transmitting is similar.

```
procedure Handle_Reception is
   Received_Char : constant Character := Character'Val (Current_Input (Device.
↪Transceiver.all));
begin
   if Received_Char /= Incoming_Msg.Terminator then
```

(continues on next page)

(continued from previous page)

```
      Incoming_Msg.Append (Received_Char);
   end if;
   if Received_Char = Incoming_Msg.Terminator or else
      Incoming_Msg.Length = Incoming_Msg.Physical_Size
   then -- reception complete
      loop
         --  wait for device to clear the status
         exit when not Status (Device.Transceiver.all, Read_Data_Register_Not_
↪Empty);
      end loop;
      Disable_Interrupts (Device.Transceiver.all, Source => Received_Data_Not_
↪Empty);
      Incoming_Msg.Signal_Reception_Complete;
      Incoming_Msg := null;
   end if;
end Handle_Reception;
```

Note the call to `Signal_Reception_Complete` for the current Message object being received, designated by `Incoming_Msg`.

The alternative to a `Suspension_Object` is a parameterless protected entry that a task calls to suspend itself. That certainly works in general, but we would need two entries, hence Jorvik. But also, the `Suspension_Object` approach can have a little better performance because it does not have the functionality that a protected entry has.

Note that type `Suspension_Object` might very well be implemented as a protected type. On a uniprocessor target, protected object mutual exclusion can be implemented via priorities, so it won't make much difference. (GNAT's bare-board run-times use that mutual exclusion implementation approach, as well as the PO implementation of type `Suspension_Object`.)

118.3 Pros

In all three idioms, the solution is directly expressed, meets the requirements, and hides the implementation details. The implementations are efficient relative to their requirements, the only reasonable metric. In particular, `Suspension_Objects` are expected to be faster than protected entries, but only support synchronization, and only with one caller at a time — there's no queue. Nor do they support communication. Protected entries have no such restrictions and are reasonably efficient given their considerable additional capabilities.

118.4 Cons

None.

118.5 Relationship With Other Idioms

The idiom showing how to connect a PO or task to an enclosing record object was illustrated by an interrupt handler PO, but that idiom is not necessary. Indeed, we used a protected type directly in the last solution.

118.6 What About Priorities?

The idiom expressions do not determine the actual priorities assigned to the protected objects containing the handler procedures, nor those of the notified tasks.

The language standard requires the priorities for interrupt handler POs to be in the range defined by the subtype `System.Interrupt_Priority`. Under the Ravenscar and Jorvik profiles they must also satisfy the Ceiling Priority Protocol requirements.

The target's interrupt hardware may dictate the specific handler priorities, or at least their floor values. You may be able to control those hardware priorities via the target board startup code.

But usually we have some freedom to choose, so what priorities should be assigned?

Often the values are arbitrary. However, a more rigorous approach may be required. A good guideline is that if you need to do a timing (schedulability) analysis for the application tasks' deadlines, you need to do it for the interrupt handlers' deadlines too. The same analyses can be used, i.e., response-time analysis, and the same priority assignment schemes, i.e., a shorter period gets a higher priority. (The interrupt *period* is the minimum interval between the interrupt occurrences.)

In addition, ensuring interrupt handler deadlines are met is part of ensuring the tasks meet their deadlines. That's because the interrupt handlers release the associated sporadic (event-driven) tasks for execution. A sporadic task triggered by a device (say) usually will have a deadline no greater than the next occurrence of the sensor-generated interrupt, that is, the interrupt period. The priority of the task will be set according to that period.

118.7 Notes

1. The *traditional* expression for an interrupt handler, i.e., a procedure, is allowed by the language as a vendor-defined extension. However, there will likely be language-oriented restrictions applied to those procedures, due to the context. That's true of other languages as well.
2. You shouldn't assign interrupt handler (PO) priorities by semantic importance, just as you shouldn't do so for task priorities. More *important* interrupt handlers shouldn't necessarily be assigned more urgent priorities.

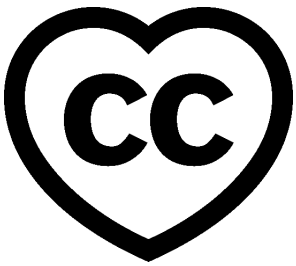
This book is published under a CC BY-SA license, which means that you can copy, redistribute, remix, transform, and build upon the content for any purpose, even commercially, as long as you give appropriate credit, provide a link to the license, and indicate if changes were made. If you remix, transform, or build upon the material, you must distribute your contributions under the same license as the original. You can find license details on this page[533]



This course will teach you advanced topics of SPARK.

Note: The code examples in this course use an 80-column limit, which is a typical limit for Ada code. Note that, on devices with a small screen size, some code examples might be difficult to read.

Note: Each code example from this book has an associated "code block metadata", which contains the name of the "project" and an MD5 hash value. This information is used to identify a single code example.

You can find all code examples in a zip file, which you can download from the learn website[534]. The directory structure in the zip file is based on the code block metadata. For example, if you're searching for a code example with this metadata:

- Project: Courses.Intro_To_Ada.Imperative_Language.Greet
- MD5: cba89a34b87c9dfa71533d982d05e6ab

you will find it in this directory:

```
projects/Courses/Intro_To_Ada/Imperative_Language/Greet/
cba89a34b87c9dfa71533d982d05e6ab/
```

In order to use this code example, just follow these steps:

1. Unpack the zip file;
2. Go to target directory;
3. Start GNAT Studio on this directory;
4. Build (or compile) the project;
5. Run the application (if a main procedure is available in the project).

SUBPROGRAM CONTRACTS

120.1 Subprogram Contracts in Ada 2012 and SPARK 2014

- Originate in Floyd-Hoare logic (1967-1969)
  - a Hoare triple {P}C{Q}
  - P is the precondition before executing command C
  - Q is the postcondition after executing command C
- Executable version by Meyer in Eiffel (1988)
  - Called Design by Contract ™
  - Precondition is checked dynamically before a routine starts
  - Postcondition is checked dynamically when a routine returns
- SPARK 2014 combines both views
  - SPARK 2005 version was only logic, Ada version is only executable

120.2 Dynamic Execution of Subprogram Contracts

- Contract on subprogram declaration
  - Different from subprogram body in general (but not always)
- Ada Reference Manual allows implementations choice
  - Contract can be checked in the caller or in the callee
  - GNAT's choice is to execute in the callee
- GNAT introduces wrappers in some cases for contracts
  - For an imported subprogram (e.g. from C) with a contract
  - For cases where contracts on static call/dispatching are different
- Contracts are not enabled by default
  - Switch `-gnata` enables dynamic checking of contracts in GNAT

120.3 Dynamic Behavior when Subprogram Contracts Fail

- Violation of contract raises an exception
  - Standard exception `Assertion_Error` is raised (same as for pragma `Assert` and all other assertions)
  - Exception cannot be caught by subprogram's own exception handler implementation choice caller/callee has no effect
  - Idiom allows to select another exception

Listing 1: show_dynamic_behavior.ads

```
with Ada.Numerics; use Ada.Numerics;

package Show_Dynamic_Behavior is

   function Sqrt (X : Float) return Float with
      Pre => X >= 0.0 or else raise Argument_Error;

end Show_Dynamic_Behavior;
```

- Control over sequencing of checks
  - Typical pre/post is a conjunction of Boolean conditions
  - Use and when no possible RTE, and then otherwise (recommended for SPARK)

120.4 Precondition

- Better alternative to defensive programming, compare

Listing 2: show_precondition.ads

```
with Ada.Numerics; use Ada.Numerics;

package Show_Precondition is

   function Sqrt (X : Float) return Float with
      Pre => X >= 0.0 or else raise Argument_Error;

end Show_Precondition;
```

and

Listing 3: show_precondition.ads

```
with Ada.Numerics; use Ada.Numerics;

package Show_Precondition is

   --  X should be non-negative or Argument_Error is raised
   function Sqrt (X : Float) return Float;

end Show_Precondition;
```

Listing 4: show_precondition.adb

```
package body Show_Precondition is

   function Sqrt (X : Float) return Float is
      Res : Float := 0.0;
   begin
      if X >= 0.0 then
         raise Argument_Error;
      end if;

      --  [...]

      return Res;
   end Sqrt;

end Show_Precondition;
```

- Preconditions can be activated alone

```
pragma Assertion_Policy (Pre => Check);
```

120.5 Postcondition

- Single place to check all return paths from the subprogram
  - Avoids duplication of checks before each return statement
  - Much more robust during maintenance
  - Only applies to normal returns (not in exception, not on abort)
- Can relate input and output values
  - Special attribute `X'Old` for referring to input value of variable X
  - Special attribute `Func'Result` for referring to result of function Func
  - Special attribute `Rec'Update` or `Arr'Update` for referring to modified value of record Rec or array `Arr`
    - replaced by delta aggregate syntax in Ada 202X: `( Rec with delta Comp => Value)`

120.6 Contract Cases

- Convenient syntax to express a contract by cases
  - Cases must be disjoint and complete (forming a partition)
  - Introduced in SPARK, planned for inclusion in Ada 202X
  - Case is (guard => consequence) with `'Old` / `'Result` in consequence
  - Can be used in combination with precondition/postcondition

Listing 5: show_contract_cases.ads

```
package Show_Contract_Cases is

   function Sqrt (X : Float) return Float with
     Contract_Cases =>
       (X > 1.0             => Sqrt'Result <= X,
        X = 1.0             => Sqrt'Result = 1.0,
        X < 1.0 and X > 0.0 => Sqrt'Result >= X,
        X = 0.0             => Sqrt'Result = 0.0);

end Show_Contract_Cases;
```

- Both a precondition and a postcondition
  - On subprogram entry, exactly one guard must hold
  - On subprogram exit, the corresponding consequence must hold

120.7 Attribute 'Old

- X'Old expresses the input value of X in postconditions
  - Same as X when variable not modified in the subprogram
  - Compiler inserts a copy of X on subprogram entry if X is large, copy can be expensive in memory footprint!
  - X can be a variable, a function call, a qualification (but not limited!)

Listing 6: show_attribute_old.ads

```
package Show_Attribute_Old is

   type Value is new Integer;

   type My_Range is range 1 .. 10;

   type My_Array is array (My_Range) of Value;

   procedure Extract (A : in out My_Array;
                      J :        My_Range;
                      V :    out Value)
     with
       Post => (if J in A'Range then V = A (J)'Old and A (J) = 0);

end Show_Attribute_Old;
```

- Expr'Old is rejected in potentially unevaluated context
  - **pragma** *Unevaluated_Use_Of_Old* (Allow) allows it
  - In Ada, user is responsible – in SPARK, user can rely on proof

120.8 Implication and Equivalence

- If-expression can be used to express an implication
  - `(if A then B)` expresses the logical implication
    - `A → B`
  - `(if A then B else C)` expresses the formula
    - `(A → B) (¬A → C)`
  - `(if A then B else C)` can also be used with B, C not of Boolean type
  - `(A <= B)` should not be used for expressing implication (same dynamic semantics, but less readable, and harmful in SPARK)
- Equality can be used to express an equivalence
  - `(A = B)` expresses the logical equivalence
    - `(A ↔ B)`
  - A double implication should not be used for expressing equivalence (same semantics, but less readable and maintainable)

120.9 Reasoning by Cases

- Case-expression can be used to reason by cases
  - Case test only on values of expressions of discrete type
  - Can sometimes be an alternative to contract cases

Listing 7: show_case_expression.ads

```
with Ada.Text_IO;

package Show_Case_Expression is

   type File_Mode is (Open, Active, Closed);

   type File is record
      F_Type : Ada.Text_IO.File_Type;
      Mode   : File_Mode;
   end record;

   procedure Open (F : in out File; Success : out Boolean) with
     Post =>
       (case F.Mode'Old is
          when Open   => Success,
          when Active => not Success,
          when Closed => Success = (F.Mode = Open));

end Show_Case_Expression;
```

- Can sometimes be used at different levels in the expression

```
procedure Open (F : in out File; Success : out Boolean) with
  Post =>
    Success = (case F.Mode'Old is
                 when Open   => True,
```

(continues on next page)

(continued from previous page)

```
                when Active => False,
                when Closed => F.Mode = Open);
```

120.10 Universal and Existential Quantification

- Quantified expressions can be used to express a property over a collection of values
  - `(for all X in A .. B => C)` expresses the universally quantified property
    - $(\forall X . X \geq A \square X \leq B \rightarrow C)$
  - `(for some X in A .. B => C)` expresses the universally quantified property
    - $(\exists X . X \geq A \square X \leq B \square C)$
- Quantified expressions translated as loops at run time
  - Control exits the loop as soon as the condition becomes false (resp. true) for a universally (resp. existentially) quantified expression
- Quantification forms over array and collection content
  - Syntax uses `(for all/some V of ... => C)`

120.11 Expression Functions

- Without abstraction, contracts can become unreadable
  - Also, use of quantifications can make them unprovable
- Expression functions provide the means to abstract contracts
  - Expression function is a function consisting in an expression
  - Definition can complete a previous declaration
  - Definition is allowed in a package spec! (crucial for proof with SPARK)

```
function Valid_Configuration return Boolean is
   (case Cur_State is
      when Piece_Falling | Piece_Blocked =>
        No_Overlap (Cur_Board, Cur_Piece),
      when Board_Before_Clean => True,
      when Board_After_Clean =>
        No_Complete_Lines (Cur_Board));
```

120.12 Code Examples / Pitfalls

120.12.1 Example #1

Listing 8: example_01.adb

```
with Ada.Assertions; use Ada.Assertions;

procedure Example_01 is

   --  Fail systematically fails a precondition and catches the
   --  resulting exception.

   procedure Fail (Condition : Boolean) with
     Pre => Condition
   is
      Bad_Condition : Boolean := False;
   begin
      Fail (Bad_Condition);
   exception
      when Assertion_Error => return;
   end Fail;
begin
   null;
end Example_01;
```

This code is not correct. The exception from the recursive call is always caught in the handler, but not the exception raised if caller of `Fail` passes **`False`** as value for `Condition`.

120.12.2 Example #2

Listing 9: example_02.ads

```
with Interfaces.C; use Interfaces.C;

package Example_02 is

   procedure Memset
     (B  : in out char_array;
      Ch :        char;
      N  :        size_t)
     with
       Import,
       Pre  => N <= B'Length,
       Post => (for all Idx in B'Range =>
                  (if Idx < B'First + N then
                         B (Idx) = Ch
                       else
                         B (Idx) = B'Old (Idx)));

end Example_02;
```

This code is correct. GNAT will create a wrapper for checking the precondition and postcondition of `Memset`, calling the imported `memset` from `libc`.

120.12.3 Example #3

Listing 10: example_03.adb

```
procedure Example_03 is

   pragma Assertion_Policy (Pre => Ignore);
   function Sqrt (X : Float) return Float with
     Pre => X >= 0.0;

   pragma Assertion_Policy (Pre => Check);
   function Sqrt (X : Float) return Float is
      Ret : Float := 0.0;
   begin
      --  missing implementation...
      return Ret;
   end Sqrt;

begin
   null;
end Example_03;
```

This code is not correct. Although GNAT inserts precondition checks in the subprogram body instead of its caller, it is the value of Pre assertion policy at the declaration of the subprogram that decides if preconditions are activated.

120.12.4 Example #4

Listing 11: example_04.adb

```
procedure Example_04 is

   function Sqrt (X : Float) return Float with
     Pre => X >= 0.0;

   function Sqrt (X : Float) return Float with
     Pre => X >= 0.0
   is
      Ret : Float := 0.0;
   begin
      --  missing implementation...
      return Ret;
   end Sqrt;

begin
   null;
end Example_04;
```

This code is not correct. Contract is allowed only on the spec of a subprogram. Hence it is not allowed on the body when a separate spec is available.

120.12.5 Example #5

Listing 12: example_05.adb

```
procedure Example_05 is

   procedure Add (X, Y : Natural; Z : out Integer) with
     Contract_Cases =>
       (X <= Integer'Last - Y => Z = X + Y,
        others                => Z = 0)
   is
   begin
      Z := 0;
      Z := X + Y;
   end Add;

begin
   null;
end Example_05;
```

This code is not correct. Postcondition is only relevant for normal returns.

120.12.6 Example #6

Listing 13: example_06.adb

```
procedure Example_06 is

   procedure Add (X, Y : Natural; Z : out Integer) with
     Post => Z = X + Y
   is
   begin
      Z := 0;
      Z := X + Y;
   end Add;
begin
   null;
end Example_06;
```

This code is correct. Procedure may raise an exception, but postcondition correctly describes normal returns.

120.12.7 Example #7

Listing 14: example_07.adb

```
procedure Example_07 is

   procedure Add (X, Y : Natural; Z : out Integer) with
     Pre  => X <= Integer'Last - Y,
     Post => Z = X + Y
   is
   begin
      Z := X + Y;
   end Add;
begin
   null;
end Example_07;
```

This code is correct. Precondition prevents exception inside Add. Postcondition is always satisfied.

120.12.8 Example #8

Listing 15: example_08.ads

```
package Example_08 is

   procedure Memset
     (B  : in out String;
      Ch :        Character;
      N  :        Natural)
     with
       Pre  => N <= B'Length,
       Post => (for all Idx in B'Range =>
                  (if Idx < B'First + N then
                      B (Idx) = Ch
                   else
                      B (Idx) = B (Idx)'Old));
end Example_08;
```

This code is not correct. `'Old` on expression including a quantified variable is not allowed.

120.12.9 Example #9

Listing 16: example_09.ads

```
package Example_09 is

   procedure Memset
     (B  : in out String;
      Ch :        Character;
      N  :        Natural)
     with
       Pre  => N <= B'Length - 1,
       Post => (for all Idx in 1 .. N => B (B'First + Idx - 1) = Ch)
                and then B (B'First + N) = B (B'First + N)'Old;

end Example_09;
```

This code is not correct. `Expr'Old` on potentially unevaluated expression is allowed only when `Expr` is a variable.

120.12.10 Example #10

Listing 17: example_10.ads

```
package Example_10 is

   procedure Memset
     (B  : in out String;
      Ch :        Character;
      N  :        Natural)
     with
       Pre  => N <= B'Length - 1,
```

(continues on next page)

(continued from previous page)

```
9         Post => (for all Idx in 1 .. N => B (B'First + Idx - 1) = Ch)
10                  and B (B'First + N) = B (B'First + N)'Old;
11
12  end Example_10;
```

This code is correct. `Expr'Old` does not appear anymore in a potentially unevaluated expression. Another solution would have been to apply `'Old` on B or to use **pragma** *Unevaluated_Use_Of_Old* (Allow).

CHAPTER

ONE

TYPE CONTRACTS

121.1 Type Contracts in Ada 2012 and SPARK 2014

- Natural evolution in Ada from previous type constraints
  - Scalar range specifies lower and upper bounds
  - Record discriminant specifies variants of the same type
- Executable type invariants by Meyer in Eiffel (1988)
  - Part of Design by Contract ™
  - Type invariant is checked dynamically when an object is created, and when an exported routine of the class returns
- Ada 2012 / SPARK 2014 support strong and weak invariants
  - A strong invariant must hold all the time
  - A weak invariant must hold outside of the scope of the type

121.2 Static and Dynamic Predicates

121.2.1 Static Predicate

- Original use case for type predicates in Ada 2012
  - Supporting non-contiguous subtypes of enumerations
  - Removes the constraint to define enumeration values in an order that allows defining interesting subtypes

Listing 1: show_static_predicate.ads

```
package Show_Static_Predicate is

   type Day is (Monday,   Tuesday, Wednesday,
                Thursday, Friday,  Saturday,
                Sunday);

   subtype Weekend is Day range Saturday .. Sunday;
   subtype Day_Off is Day with
     Static_Predicate => Day_Off in Wednesday | Weekend;

end Show_Static_Predicate;
```

- Typical use case on scalar types for holes in range

  - e.g. floats without `0.0`
- Types with static predicate are restricted
  - Cannot be used for the index of a loop or for array index (but OK for value tested in case statement)

121.2.2 Dynamic Predicate

- Extension of static predicate for any property
  - Property for static predicate must compare value to static expressions
  - Property for dynamic predicate can be anything

Listing 2: show_dynamic_predicate.ads

```
package Show_Dynamic_Predicate is

   type Day is (Monday,   Tuesday, Wednesday,
                Thursday, Friday,  Saturday,
                Sunday);

   function Check_Is_Off_In_Calendar (D : Day) return Boolean;

   subtype Day_Off is Day with
     Dynamic_Predicate => Check_Is_Off_In_Calendar (Day_Off);

end Show_Dynamic_Predicate;
```

- Various typical use cases on scalar and composite types
  - Strings that start at index 1 (`My_String'First = 1`)
  - Upper bound on record component that depends on the discriminant value (`Length <= Capacity`)
  - Ordering property on array values (`Is_Sorted (My_Array)`)

121.2.3 Restrictions on Types With Dynamic Predicate

- Types with dynamic predicate are restricted
  - Cannot be used for the index of a loop (same as static predicate)
  - Cannot be used as array index (same as static predicate)
  - Cannot be used for the value tested in a case statement
- No restriction on the property in Ada
  - Property can read the value of global variable (e.g. `Check_Is_Off_In_Calendar`)
    - what if global variable is updated?
  - Property can even have side-effects!
- Stronger restrictions on the property in SPARK
  - Property cannot read global variables or have side-effects
  - These restrictions make it possible to prove predicates

121.2.4 Dynamic Checking of Predicates

- Partly similar to other type constraints
  - Checked everywhere a range/discriminant check would be issued: assignment, parameter passing, type conversion, type qualification
  - ...but exception `Assertion_Error` is raised in case of violation
  - ...but predicates not checked by default, activated with `-gnata`
- Static predicate does not mean verification at compile time!

Listing 3: show_static_predicate_verified_at_runtime.ads

```
package Show_Static_Predicate_Verified_At_Runtime is

   type Day is (Monday,   Tuesday, Wednesday,
                Thursday, Friday,  Saturday,
                Sunday);

   subtype Weekend is Day range Saturday .. Sunday;
   subtype Day_Off is Day with
     Static_Predicate => Day_Off in Wednesday | Weekend;

   procedure Process_Day (This_Day : Day);

end Show_Static_Predicate_Verified_At_Runtime;
```

Listing 4: show_static_predicate_verified_at_runtime.adb

```
package body Show_Static_Predicate_Verified_At_Runtime is

   procedure Process_Day (This_Day : Day) is
      --  Predicate cannot be verified at compile time
      My_Day_Off : Day_Off := This_Day;
   begin
      --  missing implementation
      null;
   end Process_Day;

end Show_Static_Predicate_Verified_At_Runtime;
```

- Property should not contain calls to functions of the type
  - These functions will check the predicate on entry, leading to an infinite loop
  - GNAT compiler warns about such cases

121.2.5 Temporary Violations of the Dynamic Predicate

- Sometimes convenient to locally violate the property
  - Inside subprogram, to assign components of a record without an aggregate assignment
  - Violation even if no run-time check on component assignment
- Idiom is to define two types
  - First type does not have a predicate
  - Second type is a subtype of the first with the predicate
  - Conversions between these types at subprogram boundary

Listing 5: show_temp_violation_dyn_predicate.ads

```
package Show_Temp_Violation_Dyn_Predicate is

   type Day is (Monday,   Tuesday, Wednesday,
                Thursday, Friday,  Saturday,
                Sunday);

   type Raw_Week_Schedule is record
      Day_Off, Day_On_Duty : Day;
   end record;

   subtype Week_Schedule is Raw_Week_Schedule with
     Dynamic_Predicate =>
       Week_Schedule.Day_Off /= Week_Schedule.Day_On_Duty;

end Show_Temp_Violation_Dyn_Predicate;
```

121.3 Type Invariant

- Corresponds to the weak version of invariants
  - Predicates should hold always (only enforced with SPARK proof)
  - Type invariants should only hold outside of their defining package
- Type invariant can only be used on private types
  - Either on the private declaration
  - Or on the completion of the type in the private part of the package (makes more sense in general, only option in SPARK)

Listing 6: show_type_invariant.ads

```
package Show_Type_Invariant is

   type Day is (Monday,   Tuesday, Wednesday,
                Thursday, Friday,  Saturday,
                Sunday);

   type Week_Schedule is private;
private

   type Week_Schedule is record
      Day_Off, Day_On_Duty : Day;
   end record with
     Type_Invariant => Day_Off /= Day_On_Duty;

   procedure Internal_Adjust (WS : in out Week_Schedule);

end Show_Type_Invariant;
```

121.3.1 Dynamic Checking of Type Invariants

- Checked on outputs of public subprograms of the package
  - Checked on results of public functions
  - Checked on (**in**) **out** parameters of public subprograms
  - Checked on variables of the type, or having a part of the type
  - Exception `Assertion_Error` is raised in case of violation
  - Not checked by default, activated with `-gnata`
- No checking on internal subprograms!
  - Choice between predicate and type invariants depends on the need for such internal subprograms without checking

Listing 7: show_type_invariant.ads

```
package Show_Type_Invariant is

   type Day is (Monday,   Tuesday, Wednesday,
                Thursday, Friday,  Saturday,
                Sunday);

   type Week_Schedule is private;
private

   type Week_Schedule is record
      Day_Off, Day_On_Duty : Day;
   end record with
     Type_Invariant => Day_Off /= Day_On_Duty;

   procedure Internal_Adjust (WS : in out Week_Schedule);

end Show_Type_Invariant;
```

Listing 8: show_type_invariant.adb

```
package body Show_Type_Invariant is

   procedure Internal_Adjust (WS : in out Week_Schedule) is
   begin
      WS.Day_Off := WS.Day_On_Duty;
   end Internal_Adjust;

end Show_Type_Invariant;
```

121.4 Inheritance of Predicates and Type Invariants

- Derived types inherit the predicates of their parent type
  - Similar to other type constraints like bounds
  - Allows to structure a hierarchy of subtypes, from least to most constrained

Listing 9: show_predicate_inheritance.ads

```
package Show_Predicate_Inheritance is

   subtype String_Start_At_1 is String with
     Dynamic_Predicate => String_Start_At_1'First = 1;

   subtype String_Normalized is String_Start_At_1 with
     Dynamic_Predicate => String_Normalized'Last >= 0;

   subtype String_Not_Empty is String_Normalized with
     Dynamic_Predicate => String_Not_Empty'Length >= 1;

end Show_Predicate_Inheritance;
```

- Type invariants are typically not inherited
  - A private type cannot be derived unless it is tagged
  - Special aspect `Type_Invariant'Class` preferred for tagged types

121.5 Other Useful Gotchas on Predicates and Type Invariants

- GNAT defines its own aspects `Predicate` and `Invariant`
  - `Predicate` is the same as `Static_Predicate` if property allows it
  - Otherwise `Predicate` is the same as `Dynamic_Predicate`
  - `Invariant` is the same as `Type_Invariant`
- Referring to the *current object* in the property
  - The name of the type acts as the *current object* of that type
  - Components of records can be mentioned directly
- Type invariants on protected objects
  - Ada/SPARK do not define type invariants on protected objects

  - Idiom is to use a record type as unique component of the PO, and use a predicate for that record type

121.6 Default Initial Condition

- Aspect defined in GNAT to state a property on default initial values of a private type
  - Introduced for proof in SPARK
  - GNAT introduces a dynamic check when `-gnata` is used
  - Used in the formal containers library to state that containers are initially empty

Listing 10: show_default_init_cond.ads

```
with Ada.Containers;

package Show_Default_Init_Cond is

   type Count_Type is new Ada.Containers.Count_Type;

   type List (Capacity : Count_Type) is private with
      Default_Initial_Condition => Is_Empty (List);

   function Is_Empty (L : List) return Boolean;

private

   type List (Capacity : Count_Type) is null record;
   --  missing implementation...

end Show_Default_Init_Cond;
```

- Can also be used without a property for SPARK analysis
  - No argument specifies that the value is fully default initialized
  - Argument null specifies that there is no default initialization

121.7 Code Examples / Pitfalls

121.7.1 Example #1

Listing 11: example_01.ads

```
package Example_01 is

   type Day is (Monday,   Tuesday, Wednesday,
                Thursday, Friday,  Saturday,
                Sunday);

   subtype Weekend is Day range Saturday .. Sunday;

   subtype Day_Off is Day range Wednesday | Weekend;

end Example_01;
```

This code is not correct. The syntax of range constraints does not allow sets of values. A predicate should be used instead.

121.7.2 Example #2

Listing 12: example_02.ads

```
package Example_02 is

   type Day is (Monday,   Tuesday, Wednesday,
                Thursday, Friday,  Saturday,
                Sunday);

   subtype Weekend is Day range Saturday .. Sunday;

   subtype Day_Off is Weekend with
     Static_Predicate => Day_Off in Wednesday | Weekend;

end Example_02;
```

This code is not correct. This is accepted by GNAT, but result is not the one expected by the user. `Day_Off` has the same constraint as `Weekend`.

121.7.3 Example #3

Listing 13: example_03.ads

```
package Example_03 is

   type Day is (Monday,   Tuesday, Wednesday,
                Thursday, Friday,  Saturday,
                Sunday);

   subtype Weekend is Day range Saturday .. Sunday;

   subtype Day_Off is Day with
     Dynamic_Predicate => Day_Off in Wednesday | Weekend;

end Example_03;
```

This code is correct. It is valid to use a `Dynamic_Predicate` where a `Static_Predicate` would be allowed.

121.7.4 Example #4

Listing 14: week.ads

```
package Week is

   type Day is (Monday,   Tuesday, Wednesday,
                Thursday, Friday,  Saturday,
                Sunday);

   subtype Weekend is Day range Saturday .. Sunday;

   subtype Day_Off is Day with
```

(continues on next page)

(continued from previous page)

```
10       Static_Predicate => Day_Off in Wednesday | Weekend;
11
12    end Week;
```

Listing 15: example_04.adb

```
1  with Week; use Week;
2
3  procedure Example_04 is
4
5     function Next_Day_Off (D : Day_Off) return Day_Off is
6     begin
7        case D is
8           when Wednesday => return Saturday;
9           when Saturday  => return Sunday;
10          when Sunday    => return Wednesday;
11       end case;
12    end Next_Day_Off;
13
14 begin
15    null;
16 end Example_04;
```

This code is correct. It is valid to use a type with `Static_Predicate` for the value tested in a case statement. This is not true for `Dynamic_Predicate`.

121.7.5 Example #5

Listing 16: example_05.ads

```
1  package Example_05 is
2
3     type Day is (Monday,   Tuesday, Wednesday,
4                  Thursday, Friday,  Saturday,
5                  Sunday);
6
7     type Week_Schedule is private with
8       Type_Invariant => Valid (Week_Schedule);
9
10    function Valid (WS : Week_Schedule) return Boolean;
11
12 private
13    type Week_Schedule is record
14       Day_Off, Day_On_Duty : Day;
15    end record;
16
17    function Valid (WS : Week_Schedule) return Boolean is
18      (WS.Day_Off /= WS.Day_On_Duty);
19
20 end Example_05;
```

This code is correct. It is valid in Ada because the type invariant is not checked on entry or return from `Valid`. Also, function `Valid` is visible from the type invariant (special visibility in contracts). But it is invalid in SPARK, where private declaration cannot hold a type invariant. The reason is that the type invariant is assumed in the precondition of public functions for proof. That would lead to circular reasoning if `Valid` could be public.

121.7.6 Example #6

Listing 17: example_06.ads

```
package Example_06 is

   type Day is (Monday,   Tuesday, Wednesday,
                Thursday, Friday,  Saturday,
                Sunday);

   type Week_Schedule is private;

private

   type Week_Schedule is record
      Day_Off, Day_On_Duty : Day;
   end record with
     Type_Invariant => Valid (Week_Schedule);

   function Valid (WS : Week_Schedule) return Boolean is
     (WS.Day_Off /= WS.Day_On_Duty);

end Example_06;
```

This code is correct. This version is valid in both Ada and SPARK.

121.7.7 Example #7

Listing 18: example_07.ads

```
package Example_07 is

   subtype Sorted_String is String with
     Dynamic_Predicate =>
       (for all Pos in Sorted_String'Range =>
          Sorted_String (Pos) <= Sorted_String (Pos + 1));

   subtype Unique_String is String with
     Dynamic_Predicate =>
       (for all Pos1, Pos2 in Unique_String'Range =>
          Unique_String (Pos1) /= Unique_String (Pos2));

   subtype Unique_Sorted_String is String with
     Dynamic_Predicate =>
       Unique_Sorted_String in Sorted_String and then
       Unique_Sorted_String in Unique_String;

end Example_07;
```

This code is not correct. There are 3 problems in this code:

- there is a run-time error on the array access in `Sorted_String`;
- quantified expression defines only one variable;
- the property in `Unique_String` is true only for the empty string.

121.7.8 Example #8

Listing 19: example_08.ads

```
package Example_08 is

   subtype Sorted_String is String with
     Dynamic_Predicate =>
       (for all Pos in Sorted_String'First ..
          Sorted_String'Last - 1 =>
            Sorted_String (Pos) <= Sorted_String (Pos + 1));

   subtype Unique_String is String with
     Dynamic_Predicate =>
       (for all Pos1 in Unique_String'Range =>
          (for all Pos2 in Unique_String'Range =>
             (if Pos1 /= Pos2 then
                  Unique_String (Pos1) /= Unique_String (Pos2))));

   subtype Unique_Sorted_String is String with
     Dynamic_Predicate =>
       Unique_Sorted_String in Sorted_String and then
       Unique_Sorted_String in Unique_String;

end Example_08;
```

This code is correct. This is a correct version in Ada. For proving AoRTE in SPARK, one will need to change slightly the property of `Sorted_String`.

121.7.9 Example #9

Listing 20: example_09.ads

```
package Example_09 is

   type Day is (Monday,   Tuesday, Wednesday,
                Thursday, Friday,  Saturday,
                Sunday);

   type Week_Schedule is private with
     Default_Initial_Condition => Valid (Week_Schedule);

   function Valid (WS : Week_Schedule) return Boolean;

private

   type Week_Schedule is record
      Day_Off, Day_On_Duty : Day;
   end record;

   function Valid (WS : Week_Schedule) return Boolean is
     (WS.Day_Off /= WS.Day_On_Duty);

end Example_09;
```

This code is not correct. The default initial condition is not satisfied.

121.7.10 Example #10

Listing 21: example_10.ads

```
package Example_10 is

   type Day is (Monday,   Tuesday, Wednesday,
                Thursday, Friday,  Saturday,
                Sunday);

   type Week_Schedule is private with
     Default_Initial_Condition => Valid (Week_Schedule);

   function Valid (WS : Week_Schedule) return Boolean;

private

   type Week_Schedule is record
      Day_Off     : Day := Wednesday;
      Day_On_Duty : Day := Friday;
   end record;

   function Valid (WS : Week_Schedule) return Boolean is
     (WS.Day_Off /= WS.Day_On_Duty);

end Example_10;
```

This code is correct. This is a correct version, which can be proved with SPARK.

CHAPTER

TWO

SYSTEMS PROGRAMMING

122.1 Type Contracts in Ada 2012 and SPARK 2014

122.2 Systems Programming – What is it?

- Bare metal programming
  - bare board applications (no Operating System)
  - Operating Systems (ex: Muen separation kernel)
  - device drivers (ex: Ada Drivers Library)
  - communication stacks (ex: AdaCore TCP/IP stack)
- Specifics of Systems Programming
  - direct access to hardware: registers, memory, etc.
  - side-effects (yes!)
  - efficiency is paramount (sometimes real-time even)
  - hard/impossible to debug

122.3 Systems Programming – How can SPARK help?

- SPARK is a Systems Programming language
  - same features as Ada for accessing hardware (representation clauses, address clauses)
  - as efficient as Ada or C
- Side-effects can be modeled in SPARK
  - reads and writes to memory-mapped devices are modeled
  - concurrent interactions with environment are modeled
- SPARK can help catch problems by static analysis
  - correct flows, initialization, concurrent accesses
  - absence of run-time errors and preservation of invariants

122.4 Systems Programming – A trivial example

Listing 1: show_trivial_sys_prog.ads

```
package Show_Trivial_Sys_Prog is

   Y : Integer;

   --  Y'Address could be replaced by any
   --  external address
   X : Integer with Volatile,
     Address => Y'Address;

   procedure Get (Val : out Integer)
     with Global  => (In_Out => X),
     Depends => (Val => X,
                 X   => X);

end Show_Trivial_Sys_Prog;
```

Listing 2: show_trivial_sys_prog.adb

```
package body Show_Trivial_Sys_Prog is

   procedure Get (Val : out Integer) is
   begin
      Val := X;
   end Get;

end Show_Trivial_Sys_Prog;
```

- Comments:
  - X is volatile
  - X is also an output; output X depends on input X
  - X is only read

122.5 Volatile Variables and Volatile Types

- Variables whose reads/writes cannot be optimized away
- Identified through multiple aspects (or pragmas)
  - aspect `Volatile`
  - but also aspect `Atomic`
  - and GNAT aspect `Volatile_Full_Access`
  - all the above aspects can be set on type or object
- Other aspects are useful on volatile variables
  - aspect **`Address`** to specify location in memory
  - aspect `Import` to skip definition/initialization

```
type T is new Integer with Volatile;

X : Integer with Atomic, Import, Address => ... ;
```

122.6 Flavors of Volatile Variables

122.6.1 Using Async_Readers / Async_Writers

- Boolean aspects describing asynchronous behavior
  - Async_Readers if variable may be read asynchronously
  - Async_Writers if variable may be written asynchronously
- Effect of Async_Readers on flow analysis
- Effect of Async_Writers on flow analysis & proof
  - always initialized, always has an unknown value

Listing 3: volatile_vars.ads

```
package Volatile_Vars is

   pragma Elaborate_Body;

   Ext : array (1 .. 2) of Integer;

   X : Integer with Volatile,
     Address => Ext (1)'Address,
     Async_Readers;

   Y : Integer with Volatile,
     Address => Ext (2)'Address,
     Async_Writers;

   procedure Set;
end Volatile_Vars;
```

Listing 4: volatile_vars.adb

```
package body Volatile_Vars is

   procedure Set is
      U, V : constant Integer := Y;
   begin
      pragma Assert (U = V);
      X := 0;
      X := 1;
   end Set;
begin
   Ext := (others => 0);
end Volatile_Vars;
```

Listing 5: show_volatile_vars.adb

```
with Volatile_Vars;

procedure Show_Volatile_Vars is
begin
   Volatile_Vars.Set;
end Show_Volatile_Vars;
```

122.6.2 Using Effective_Reads / Effective_Writes

- Boolean aspects distinguishing values & sequences
  - `Effective_Reads` if reading the variable has an effect on its value
  - `Effective_Writes` if writing the variable has an effect on its value
- Effect of both on proof and flow dependencies
  - Final value of variable is seen as a sequence of values it took

Listing 6: volatile_vars.ads

```
package Volatile_Vars is

   pragma Elaborate_Body;

   Ext : array (1 .. 2) of Integer;

   X : Integer with Volatile,
     Address => Ext (1)'Address,
     Async_Readers,
     Effective_Writes;

   Y : Integer with Volatile,
     Address => Ext (2)'Address,
     Async_Writers,
     Effective_Reads;

   procedure Set with
      Depends => (X => Y,
                  Y => Y);
end Volatile_Vars;
```

Listing 7: volatile_vars.adb

```
package body Volatile_Vars is

   procedure Set is
   begin
      X := Y;
      X := 0;
   end Set;

begin
   Ext := (others => 0);
end Volatile_Vars;
```

Listing 8: show_volatile_vars.adb

```
with Volatile_Vars;

procedure Show_Volatile_Vars is
begin
   Volatile_Vars.Set;
end Show_Volatile_Vars;
```

122.6.3 Combinations of Flavors of Volatile Variables

- All four flavors can be set independently
  - Default for Volatile/Atomic is all four `True`
  - When some aspects set, all others default to `False`
- Only half the possible combinations are legal
  - `Async_Readers` and/or `Async_Writers` is set
  - `Effective_Reads = True` forces `Async_Writers = True`
  - `Effective_Writes = True` forces `Async_Readers = True`
  - sensor: AW=`True`
  - actuator: AR=`True`
  - input port: AW=`True`, ER=`True`
  - output port: AR=`True`, EW=`True`

122.7 Constraints on Volatile Variables

- Volatile variables must be defined at library level
- Expressions (and functions) cannot have side-effects
  - read of variable with AW=`True` must appear alone on *rhs* of assign
  - a function cannot read a variable with ER=`True`

Listing 9: volatile_vars.ads

```
package Volatile_Vars is

   pragma Elaborate_Body;

   Ext : array (1 .. 4) of Integer;

   AR : Integer with Volatile,
     Address => Ext (1)'Address,
     Async_Readers;

   AW : Integer with Volatile,
     Address => Ext (2)'Address,
     Async_Writers;

   ER : Integer with Volatile,
     Address => Ext (3)'Address,
```

(continues on next page)

(continued from previous page)

```
      Async_Writers,
      Effective_Reads;

   EW : Integer with Volatile,
     Address => Ext (4)'Address,
      Async_Readers,
      Effective_Writes;

   procedure Read_All;

   function Read_ER return Integer;

   procedure Set (V : Integer);

end Volatile_Vars;
```

Listing 10: volatile_vars.adb

```
package body Volatile_Vars is

   procedure Read_All is
      Tmp : Integer := 0;
   begin
      Tmp := Tmp + AR;
      Tmp := Tmp + AW;
      EW := Tmp;
      Set (ER);
   end Read_All;

   function Read_ER return Integer is
      Tmp : Integer := ER;
   begin
      return Tmp;
   end Read_ER;

   procedure Set (V : Integer) is
   begin
      AW := V;
   end Set;

begin
   Ext := (others => 0);
end Volatile_Vars;
```

Listing 11: show_volatile_vars.adb

```
with Volatile_Vars;

procedure Show_Volatile_Vars is
   V : Integer;
begin
   Volatile_Vars.Read_All;
   V := Volatile_Vars.Read_ER;
end Show_Volatile_Vars;
```

- Comments:
  - AW not alone on rhs
  - ER not alone on rhs
  - ER output of Read_ER

122.8 Constraints on Volatile Functions

- Functions should have mathematical interpretation
  - a function reading a variable with AW=**True** is marked as volatile with aspect `Volatile_Function`
  - calls to volatile functions are restricted like reads of `Async_Writers`

Listing 12: volatile_vars.ads

```
package Volatile_Vars is

   pragma Elaborate_Body;

   Ext : array (1 .. 4) of Integer;

   AR : Integer with Volatile,
     Address => Ext (1)'Address,
     Async_Readers;

   AW : Integer with Volatile,
     Address => Ext (2)'Address,
     Async_Writers;

   ER : Integer with Volatile,
     Address => Ext (3)'Address,
     Async_Writers,
     Effective_Reads;

   EW : Integer with Volatile,
     Address => Ext (4)'Address,
     Async_Readers,
     Effective_Writes;

   function Read_Non_Volatile
     return Integer;

   function Read_Volatile
     return Integer
     with Volatile_Function;

   function Read_ER
     return Integer
     with Volatile_Function;

end Volatile_Vars;
```

Listing 13: volatile_vars.adb

```
package body Volatile_Vars is

   function Read_Non_Volatile
     return Integer is
      Tmp : Integer := 0;
   begin
      --  reads AR, AW, EW
      --  ERROR: not a volatile function
      Tmp := Tmp + AR;
      Tmp := Tmp + AW;
      Tmp := Tmp + EW;

```

(continues on next page)

(continued from previous page)

```
      return Tmp;
   end Read_Non_Volatile;

   function Read_Volatile
     return Integer is
      Tmp : Integer := 0;
   begin
      --  reads AR, AW, EW
      --  OK for volatile function
      Tmp := Tmp + AR;
      Tmp := Tmp + AW;
      Tmp := Tmp + EW;

      return Tmp;
   end Read_Volatile;

   function Read_ER
     return Integer is
      Tmp : Integer := ER;
   begin
      --  reads ER
      --  ERROR: ER output of Read_ER
      return Tmp;
   end Read_ER;

begin
   Ext := (others => 0);
end Volatile_Vars;
```

Listing 14: show_volatile_vars.adb

```
with Volatile_Vars;

procedure Show_Volatile_Vars is
   V : Integer;
begin
   V := Volatile_Vars.Read_Non_Volatile;
   V := Volatile_Vars.Read_Volatile;
   V := Volatile_Vars.Read_ER;
end Show_Volatile_Vars;
```

122.9 State Abstraction on Volatile Variables

- Abstract state needs to be identified as `External`
- Flavors of volatility can be specified
  - Default if none specified is all True

Listing 15: p1.ads

```
package P1 with
  Abstract_State => (S with External)
is
   procedure Process (Data : out Integer) with
     Global => (In_Out => S);

end P1;
```

Listing 16: p2.ads

```
package P2 with
  Abstract_State => (S with External =>
                        (Async_Writers,
                         --  OK if refined into AW, ER
                         Effective_Reads)
                         --  not OK if refined into AR, EW
                     )
is
   procedure Process (Data : out Integer) with
     Global => (In_Out => S);

end P2;
```

122.10 Constraints on Address Attribute

- Address of volatile variable can be specified

Listing 17: show_address_attribute.ads

```
package Show_Address_Attribute is

   Ext : array (1 .. 2) of Integer;

   X : Integer with Volatile,
     Address => Ext (1)'Address;

   Y : Integer with Volatile;
   for Y'Address use Ext (2)'Address;

end Show_Address_Attribute;
```

- Address attribute not allowed in expressions
- Overlays are allowed
  - GNATprove does not check absence of overlays
  - GNATprove does not model the resulting aliasing

Listing 18: show_address_overlay.adb

```
procedure Show_Address_Overlay is

   X : Integer := 1;
   Y : Integer := 0
     with Address => X'Address;

   pragma Assert (X = 1);
   --  assertion wrongly proved
begin
   null;

end Show_Address_Overlay;
```

122.11 Can something be known of volatile variables?

- Variables with `Async_Writers` have no known value
- ... but they have a known type!
  - type range, ex: `0 .. 360`
  - type predicate, ex: `0 .. 15 | 17 .. 42 | 43 .. 360`
- Variables without `Async_Writers` have a known value
- GNATprove also assumes all values are valid (`X'Valid`)

Listing 19: show_provable_volatile_var.ads

```
package Show_Provable_Volatile_Var is

   X : Integer with Volatile, Async_Readers;

   procedure Read_Value;

end Show_Provable_Volatile_Var;
```

Listing 20: show_provable_volatile_var.adb

```
package body Show_Provable_Volatile_Var is

   procedure Read_Value is
   begin
      X := 42;
      pragma Assert (X = 42);
      --  proved!
   end Read_Value;

end Show_Provable_Volatile_Var;
```

122.12 Other Concerns in Systems Programming

- Software startup state ⟶ elaboration rules
  - SPARK follows Ada static elaboration model
  - ... with additional constraints for ensuring correct initialization
  - ... but GNATprove follows the relaxed GNAT static elaboration
- Handling of faults ⟶ exception handling
  - raising exceptions is allowed in SPARK
  - ... but exception handlers are `SPARK_Mode => Off`
  - ... typically the last-chance-handler is used instead
- Concurrency inside the application ⟶ tasking support
  - Ravenscar and Extended_Ravenscar profiles supported in SPARK

122.13 Code Examples / Pitfalls

122.13.1 Example #1

Listing 21: example_01.ads

```
package Example_01 is

   Ext : Integer;

   X   : Integer with Volatile,
     Address => Ext'Address;

   procedure Get (Val : out Integer)
     with Global  => (Input => X),
     Depends => (Val => X);

end Example_01;
```

Listing 22: example_01.adb

```
package body Example_01 is

   procedure Get (Val : out Integer) is
   begin
      Val := X;
   end Get;

end Example_01;
```

This code is not correct. X has `Effective_Reads` set by default, hence it is also an output.

122.13.2 Example #2

Listing 23: example_02.ads

```
package Example_02 is

   Ext : Integer;

   X : Integer with Volatile, Address => Ext'Address,
     Async_Readers, Async_Writers, Effective_Writes;

   procedure Get (Val : out Integer)
     with Global  => (Input => X),
     Depends => (Val => X);

end Example_02;
```

Listing 24: example_02.adb

```
package body Example_02 is

   procedure Get (Val : out Integer) is
   begin
      Val := X;
   end Get;

end Example_02;
```

This code is correct. X has `Effective_Reads = False`, hence it is only an input.

122.13.3 Example #3

Listing 25: example_03.ads

```
package Example_03 is

   Speed : Float with Volatile, Async_Writers;
   Motor : Float with Volatile, Async_Readers;

   procedure Adjust with
     Depends => (Motor =>+ Speed);

end Example_03;
```

Listing 26: example_03.adb

```
package body Example_03 is

   procedure Adjust is
      Cur_Speed : constant Float := Speed;
   begin
      if abs (Cur_Speed) > 100.0 then
         Motor := Motor - 1.0;
      end if;
   end Adjust;

end Example_03;
```

This code is correct. Speed is an input only, `Motor` is both an input and output. Note how the current value of Speed is first copied to be tested in a larger expression.

122.13.4 Example #4

Listing 27: example_04.ads

```
package Example_04 is

   Raw_Data : Float with Volatile,
     Async_Writers, Effective_Reads;
   Data     : Float with Volatile,
     Async_Readers, Effective_Writes;

   procedure Smooth with
     Depends => (Data => Raw_Data);

end Example_04;
```

Listing 28: example_04.adb

```
package body Example_04 is

   procedure Smooth is
      Data1 : constant Float := Raw_Data;
      Data2 : constant Float := Raw_Data;
   begin
      Data := Data1;
      Data := (Data1 + Data2) / 2.0;
      Data := Data2;
   end Smooth;

end Example_04;
```

This code is not correct. Raw_Data has `Effective_Reads` set, hence it is also an output.

122.13.5 Example #5

Listing 29: example_05.ads

```
package Example_05 is

   type Regval is new Integer with Volatile;
   type Regnum is range 1 .. 32;
   type Registers is array (Regnum) of Regval;

   Regs : Registers with Async_Writers, Async_Readers;

   function Reg (R : Regnum) return Integer is
     (Integer (Regs (R))) with Volatile_Function;

end Example_05;
```

This code is not correct. Regs has Async_Writers set, hence it cannot appear as the expression in an expression function.

122.13.6 Example #6

Listing 30: example_06.ads

```
package Example_06 is

   type Regval is new Integer with Volatile;
   type Regnum is range 1 .. 32;
   type Registers is array (Regnum) of Regval;

   Regs : Registers with Async_Writers, Async_Readers;

   function Reg (R : Regnum) return Integer
     with Volatile_Function;

end Example_06;
```

Listing 31: example_06.adb

```
package body Example_06 is

   function Reg (R : Regnum) return Integer is
      V : Regval := Regs (R);
   begin
      return Integer (V);
   end Reg;

end Example_06;
```

This code is not correct. Regval is a volatile type, hence variable V is volatile and cannot be declared locally.

122.13.7 Example #7

Listing 32: example_07.ads

```
package Example_07 is

   type Regval is new Integer with Volatile;
   type Regnum is range 1 .. 32;
   type Registers is array (Regnum) of Regval;

   Regs : Registers with Async_Writers, Async_Readers;

   function Reg (R : Regnum) return Integer
     with Volatile_Function;

end Example_07;
```

Listing 33: example_07.adb

```
package body Example_07 is

   function Reg (R : Regnum) return Integer is
   begin
      return Integer (Regs (R));
   end Reg;

end Example_07;
```

This code is correct. Regs has `Effective_Reads = False` hence can be read in a function. Function Reg is marked as volatile with aspect `Volatile_Function`. No volatile variable is declared locally.

122.13.8 Example #8

Listing 34: example_08.ads

```
package Example_08 with
  Abstract_State => (State with External),
    Initializes => State
is
   procedure Dummy;
end Example_08;
```

Listing 35: example_08.adb

```
package body Example_08 with
  Refined_State => (State => (X, Y, Z))
is
   X : Integer with Volatile, Async_Readers;
   Y : Integer with Volatile, Async_Writers;
   Z : Integer := 0;

   procedure Dummy is
   begin
      null;
   end Dummy;

end Example_08;
```

This code is not correct. X has `Async_Writers = False`, hence is not considered as always initialized. As aspect `Initializes` specifies that `State` should be initialized after elaboration, this is an error. Note that is allowed to bundle volatile and non-volatile variables in an external abstract state.

122.13.9 Example #9

Listing 36: example_09.ads

```
package Example_09 is

   type Pair is record
      U, V : Natural;
   end record
     with Predicate => U /= V;

   X : Pair with Atomic, Async_Readers, Async_Writers;

   function Max return Integer with
     Volatile_Function,
     Post => Max'Result /= 0;

end Example_09;
```

Listing 37: example_09.adb

```
package body Example_09 is

   function Max return Integer is
      Val1 : constant Natural := X.U;
      Val2 : constant Natural := X.V;
   begin
```

(continues on next page)

(continued from previous page)

```
      return Natural'Max (Val1, Val2);
   end Max;

end Example_09;
```

This code is not correct. `X` has `Async_Writers` set, hence it may have been written between the successive reads of `X.U` and `X.V`.

122.13.10 Example #10

Listing 38: example_10.ads

```
package Example_10 is

   type Pair is record
      U, V : Natural;
   end record
     with Predicate => U /= V;

   X : Pair with Atomic, Async_Readers, Async_Writers;

   function Max return Integer with
     Volatile_Function,
     Post => Max'Result /= 0;

end Example_10;
```

Listing 39: example_10.adb

```
package body Example_10 is

   function Max return Integer is
      P    : constant Pair := X;
      Val1 : constant Natural := P.U;
      Val2 : constant Natural := P.V;
   begin
      return Natural'Max (Val1, Val2);
   end Max;

end Example_10;
```

This code is correct. Values of `P.U` and `P.V` are provably different, and the postcondition is proved.

CHAPTER

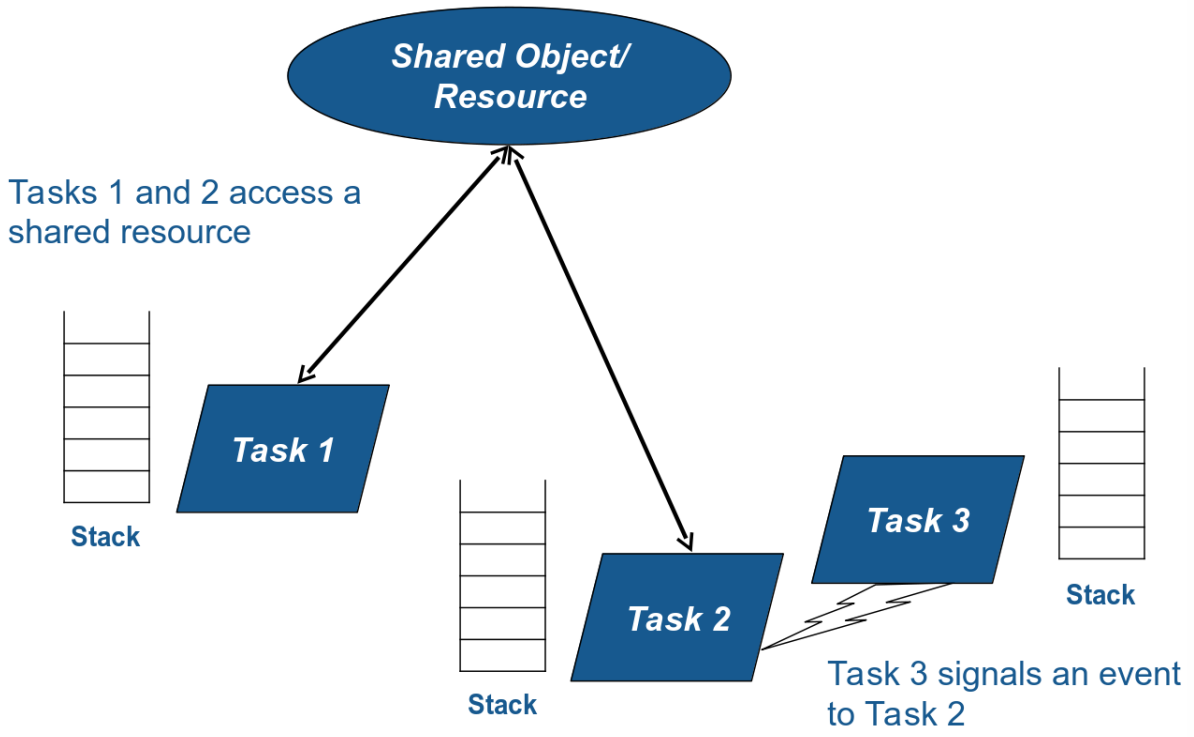
THREE

CONCURRENCY

123.1 Concurrency ≠ Parallelism

- Concurrency allows to create a well structured program
- Parallelism allows to create a high performance program
- Multiple cores/processors are...
  - possible for concurrent programs
  - essential to parallelism
- What about Ada and SPARK?
  - GNAT runtimes for concurrency available on single core & multicore (for SMP platforms)
  - parallel features scheduled for inclusion in Ada and SPARK 202x

123.2 Concurrent Program Structure in Ada



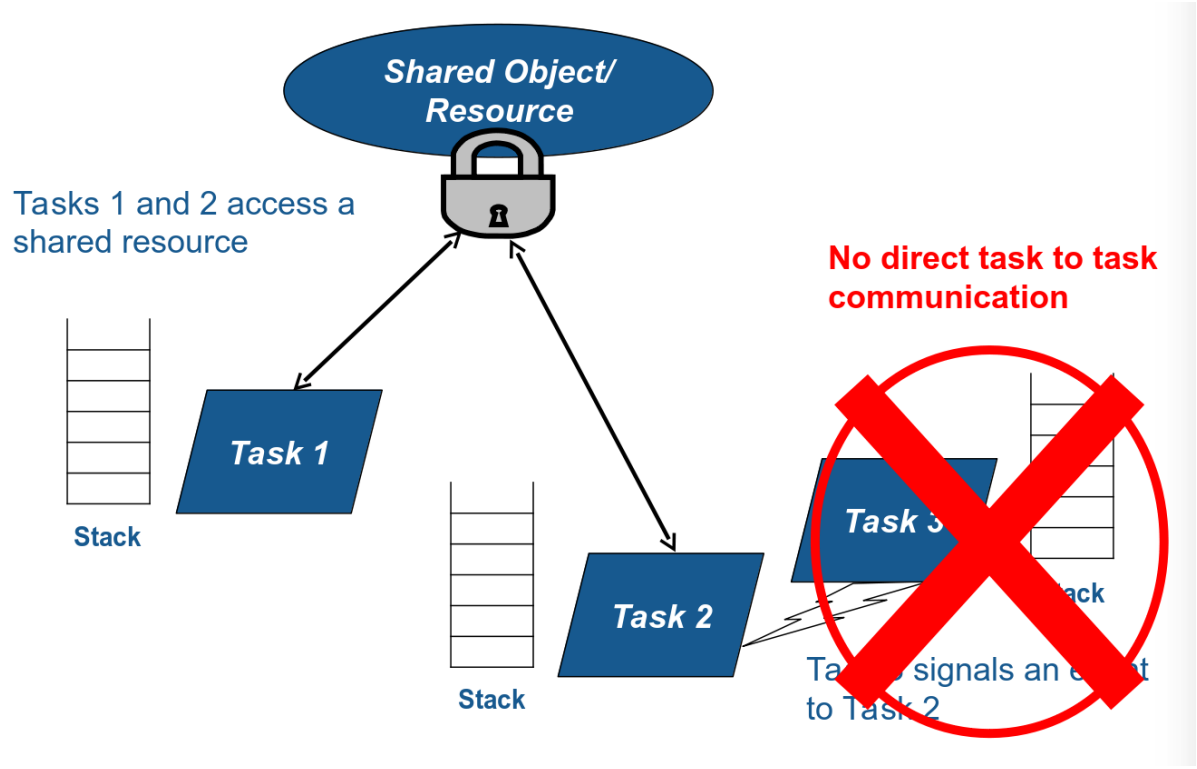
123.3 The problems with concurrency

- Control and data flow become much more complex
  - possibly nondeterministic even
  - actual behavior is one of many possible interleavings of tasks
- Data may be corrupted by concurrent accesses
  - so called data races or race conditions
- Control may block indefinitely, or loop indefinitely
  - so called deadlocks and livelocks
- Scheduling and memory usage are harder to compute

123.4 Ravenscar – the Ada solution to concurrency problems

- Ravenscar profile restricts concurrency in Ada
  - ensures deterministic behavior at every point in time
  - recommends use of protected objects to avoid data races
  - prevents deadlocks with Priority Ceiling Protocol
  - allows use of scheduling analysis techniques (RMA, RTA)
  - facilitates computation of memory usage with static tasks
- GNAT Extended Ravenscar profile lifts some restrictions
  - still same benefits as Ravenscar profile
  - removes painful restrictions for some applications

123.5 Concurrent Program Structure in Ravenscar



123.6 Ravenscar – the SPARK solution to concurrency problems

- Ravenscar and Extended_Ravenscar profiles supported in SPARK
- Data races prevented by flow analysis
  - ensures no problematic concurrent access to unprotected data
  - flow analysis also ensures non-termination of tasks
- Run-time errors prevented by proof
  - includes violations of the Priority Ceiling Protocol

123.7 Concurrency – A trivial example

Listing 1: show_trivial_task.ads

```
1 package Show_Trivial_Task is
2
3    type Task_Id is new Integer;
4
5    task type T (Id : Task_Id);
6
7    T1 : T (0);
8    T2 : T (1);
9 end Show_Trivial_Task;
```

Listing 2: show_trivial_task.adb

```
package body Show_Trivial_Task is
   task body T is
      Current_Task : Task_Id := Id;
   begin
      loop
         delay 1.0;
      end loop;
   end T;
end Show_Trivial_Task;
```

- Id can be written by T1 and T2 at the same time

123.8 Setup for using concurrency in SPARK

- Any unit using concurrency features (tasks, protected objects, etc.) must set the profile

```
pragma Profile (Ravenscar);
--  or
pragma Profile (GNAT_Extended_Ravenscar);
```

- ... plus an additional pragma
  - that ensures tasks start after the end of elaboration

```
pragma Partition_Elaboration_Policy (Sequential);
```

- ... which are checked by GNAT partition-wide
  - pragmas needed for verification even it not for compilation

123.9 Tasks in Ravenscar

- A task can be either a singleton object or a type
  - no declarations of entries for rendez-vous

```
task T;
task type TT;
```

- ... completed by a body
  - infinite loop to prevent termination

```
task body T is
begin
   loop
      ...
   end loop;
end T;
```

- Tasks are declared at library-level
- ... as standalone objects or inside records/arrays

```
type TA is array (1 .. 3) of TT;
type TR is record
   A, B : TT;
end record;
```

123.10 Communication Between Tasks in Ravenscar

- Tasks can communicate through protected objects
- A protected object is either a singleton object or a type
  - all PO private data initialized by default in SPARK

Listing 3: show_protected_object.ads

```
package Show_Protected_Object is

   protected P is
      procedure Set (V : Natural);
      function Get return Natural;
   private
      The_Data : Natural := 0;
   end P;

end Show_Protected_Object;
```

Listing 4: show_protected_object.adb

```
package body Show_Protected_Object is

   protected body P is
      procedure Set (V : Natural) is
      begin
         The_Data := V;
      end Set;
      function Get return Natural is
        (The_Data);
   end P;

end Show_Protected_Object;
```

123.11 Protected Objects in Ravenscar

- Protected objects are declared at library-level
- ... as standalone objects or inside records/arrays
  - The record type needs to be volatile, as a non-volatile type cannot contain a volatile component. The array type is implicitly volatile when its component type is volatile.

Listing 5: show_protected_object_ravenscar.ads

```
package Show_Protected_Object_Ravenscar is

   protected type PT is
```

(continues on next page)

(continued from previous page)

```
      procedure Set (V : Natural);
      function Get return Natural;
   private
      The_Data : Natural := 0;
   end PT;

   P : PT;

   type PAT is array (1 .. 3) of PT;
   PA : PAT;

   type PRT is record
      A, B : PT;
   end record with Volatile;
   PR : PRT;

end Show_Protected_Object_Ravenscar;
```

Listing 6: show_protected_object_ravenscar.adb

```
package body Show_Protected_Object_Ravenscar is

   protected body PT is
      procedure Set (V : Natural) is
      begin
         The_Data := V;
      end Set;
      function Get return Natural is
        (The_Data);
   end PT;

end Show_Protected_Object_Ravenscar;
```

123.12 Protected Communication with Procedures & Functions

- CREW enforced (Concurrent-Read-Exclusive-Write)
  - procedures have exclusive read-write access to PO
  - functions have shared read-only access to PO
- Actual mechanism depends on target platform
  - scheduler enforces policy on single core
  - locks used on multicore (using CAS instructions)
  - lock-free transactions used for simple PO (again using CAS)
- Mechanism is transparent to user
  - user code simply calls procedures/functions
  - task may be queued until PO is released by another task

123.13 Blocking Communication with Entries

- Only protected objects have entries in Ravenscar
- Entry = procedure with **entry** guard condition
  - second level of queues, one for each entry, on a given PO
  - task may be queued until guard is True and PO is released
  - at most one entry in Ravenscar
  - guard is a **Boolean** component of PO in Ravenscar

Listing 7: show_blocking_communication.ads

```
package Show_Blocking_Communication is

   protected type PT is
      entry Reset;
   private
      Is_Not_Null : Boolean := False;
      The_Data    : Integer := 1000;
   end PT;

end Show_Blocking_Communication;
```

Listing 8: show_blocking_communication.adb

```
package body Show_Blocking_Communication is

   protected body PT is
      entry Reset when Is_Not_Null is
      begin
         The_Data := 0;
      end Reset;
   end PT;

end Show_Blocking_Communication;
```

123.14 Relaxed Constraints on Entries with Extended Ravenscar

- Proof limitations with Ravenscar
  - not possible to relate guard to other components with invariant
- GNAT Extended Ravenscar profile lifts these constraints
  - and allows multiple tasks to call the same entry

Listing 9: show_relaxed_constraints_on_entries.ads

```
package Show_Relaxed_Constraints_On_Entries is

   protected type Mailbox is
      entry Publish;
      entry Retrieve;
   private
      Num_Messages : Natural := 0;
```

(continues on next page)

(continued from previous page)

```
   end Mailbox;

end Show_Relaxed_Constraints_On_Entries;
```

Listing 10: show_relaxed_constraints_on_entries.adb

```
package body Show_Relaxed_Constraints_On_Entries is

   Max : constant := 100;

   protected body Mailbox is
      entry Publish when Num_Messages < Max is
      begin
         Num_Messages := Num_Messages + 1;
      end Publish;

      entry Retrieve when Num_Messages > 0 is
      begin
         Num_Messages := Num_Messages - 1;
      end Retrieve;
   end Mailbox;

end Show_Relaxed_Constraints_On_Entries;
```

123.15 Interrupt Handlers in Ravenscar

- Interrupt handlers are parameterless procedures of PO
  - with aspect `Attach_Handler` specifying the corresponding signal
  - with aspect `Interrupt_Priority` on the PO specifying the priority

Listing 11: show_interrupt_handlers.ads

```
with System; use System;
with Ada.Interrupts.Names; use Ada.Interrupts.Names;

package Show_Interrupt_Handlers is

    protected P with
      Interrupt_Priority =>
        System.Interrupt_Priority'First
    is
       procedure Signal with
         Attach_Handler => SIGHUP;
    end P;

end Show_Interrupt_Handlers;
```

- Priority of the PO should be in `System.Interrupt_Priority`
  - default is OK – in the range of `System.Interrupt_Priority`
  - checked by proof (default or value of `Priority` or `Interrupt_Priority`)

123.16 Other Communications Between Tasks in SPARK

- Tasks must communicate through synchronized objects
  - atomic objects
  - protected objects
  - suspension objects (standard `Boolean` protected objects)
- Constants are considered as synchronized
  - this includes variables constant after elaboration (specified with aspect `Constant_After_Elaboration`)
- Single task or PO can access an unsynchronized object
  - exclusive relation between object and task/PO must be specified with aspect `Part_Of`

123.17 Data and Flow Dependencies of Tasks

- Input/output relation can be specified for a task
  - as task never terminates, output is understood while task runs
  - task itself is both an input and an output
  - implicit `In_Out => T`
  - explicit dependency

Listing 12: show_data_and_flow_dependencies.ads

```
package Show_Data_And_Flow_Dependencies is

   X, Y, Z : Integer;

   task T with
     Global => (Input  => X,
                Output => Y,
                In_Out => Z),
     Depends => (T    => T,
                 Z    => X,
                 Y    => X,
                 null => Z);
end Show_Data_And_Flow_Dependencies;
```

123.18 State Abstraction over Synchronized Variables

- Synchronized objects can be abstracted in synchronized abstract state with aspect `Synchronous`

Listing 13: show_state_abstraction.ads

```
package Show_State_Abstraction with
  Abstract_State => (State with Synchronous, External)
is

```

(continues on next page)

(continued from previous page)

```
   protected type Protected_Type is
      procedure Reset;
   private
      Data : Natural := 0;
   end Protected_Type;

   task type Task_Type;

end Show_State_Abstraction;
```

Listing 14: show_state_abstraction.adb

```
package body Show_State_Abstraction with
  Refined_State => (State => (A, P, T))
is
   A : Integer with Atomic, Async_Readers, Async_Writers;
   P : Protected_Type;
   T : Task_Type;

   protected body Protected_Type is
      procedure Reset is
      begin
         Data := 0;
      end Reset;
   end Protected_Type;

   task body Task_Type is
   begin
      P.Reset;
      A := 0;
   end Task_Type;

end Show_State_Abstraction;
```

- Synchronized state is a form of external state
  - Synchronous same as `External => (Async_Readers, Async_Writers)`
  - tasks are not volatile and can be part of regular abstract state

123.19 Synchronized Abstract State in the Standard Library

- Standard library maintains synchronized state
  - the tasking runtime maintains state about running tasks
  - the real-time runtime maintains state about current time

```
package Ada.Task_Identification with
  SPARK_Mode,
  Abstract_State =>
    (Tasking_State with Synchronous,
       External => (Async_Readers, Async_Writers)),
  Initializes    => Tasking_State

package Ada.Real_Time with
  SPARK_Mode,
  Abstract_State =>
```

(continues on next page)

(continued from previous page)

```
    (Clock_Time with Synchronous,
       External => (Async_Readers, Async_Writers)),
  Initializes    => Clock_Time
```

- API of these units refer to **Task**ing_State and Clock_Time

123.20 Code Examples / Pitfalls

123.20.1 Example #1

Listing 15: rendezvous.adb

```
procedure Rendezvous is
   task T1 is
      entry Start;
   end T1;

   task body T1 is
   begin
      accept Start;
   end T1;

begin
   T1.Start;
end Rendezvous;
```

This code is not correct. Task rendezvous is not allowed; violation of restriction Max_Task_Entries = 0. A local task is not allowed; violation of restriction No_Task_Hierarchy

123.20.2 Example #2

Listing 16: example_02.ads

```
package Example_02 is

   protected P is
      entry Reset;
   end P;

private
   Data : Boolean := False;
end Example_02;
```

Listing 17: example_02.adb

```
package body Example_02 is

   protected body P is
      entry Reset when Data is
      begin
         null;
      end Reset;
   end P;
```

(continues on next page)

(continued from previous page)

```
9
10 end Example_02;
```

This code is not correct. Global data in entry guard is not allowed. Violation of restriction `Simple_Barriers` (for Ravenscar) or `Pure_Barriers` (for Extended Ravenscar)

123.20.3 Example #3

Listing 18: example_03.ads

```
1  package Example_03 is
2
3     protected P is
4        procedure Set (Value : Integer);
5     end P;
6
7  private
8     task type TT;
9
10    T1, T2 : TT;
11
12 end Example_03;
```

Listing 19: example_03.adb

```
1  package body Example_03 is
2
3     Data : Integer := 0;
4
5     protected body P is
6        procedure Set (Value : Integer) is
7        begin
8           Data := Value;
9        end Set;
10    end P;
11
12    task body TT is
13       Local : Integer := 0;
14    begin
15       loop
16          Local := (Local + 1) mod 100;
17          P.Set (Local);
18       end loop;
19    end TT;
20
21 end Example_03;
```

This code is not correct. Global unprotected data accessed in protected object shared between tasks

123.20.4 Example #4

Listing 20: example_04.ads

```
package Example_04 is

   protected P is
      procedure Set (Value : Integer);
   end P;

private
   Data : Integer := 0 with Part_Of => P;

   task type TT;

   T1, T2 : TT;

end Example_04;
```

Listing 21: example_04.adb

```
package body Example_04 is

   protected body P is
      procedure Set (Value : Integer) is
      begin
         Data := Value;
      end Set;
   end P;

   task body TT is
      Local : Integer := 0;
   begin
      loop
         Local := (Local + 1) mod 100;
         P.Set (Local);
      end loop;
   end TT;

end Example_04;
```

This code is correct. Data is part of the protected object state. The only accesses to Data are through P.

123.20.5 Example #5

Listing 22: example_05.ads

```
package Example_05 is

   protected P1 with Priority => 3 is
      procedure Set (Value : Integer);
   private
      Data : Integer := 0;
   end P1;

   protected P2 with Priority => 2 is
      procedure Set (Value : Integer);
   end P2;
```

(continues on next page)

(continued from previous page)

```
12
13 private
14    task type TT with Priority => 1;
15
16    T1, T2 : TT;
17
18 end Example_05;
```

Listing 23: example_05.adb

```
1  package body Example_05 is
2
3     protected body P1 is
4        procedure Set (Value : Integer) is
5        begin
6           Data := Value;
7        end Set;
8     end P1;
9
10    protected body P2 is
11       procedure Set (Value : Integer) is
12       begin
13          P1.Set (Value);
14       end Set;
15    end P2;
16
17    task body TT is
18       Local : constant Integer := 0;
19    begin
20       loop
21          P2.Set (Local);
22       end loop;
23    end TT;
24
25 end Example_05;
```

This code is correct. `Ceiling_Priority` policy is respected. Task never accesses a protected object with lower priority than its active priority. Note that PO can call procedure or function from another PO, but not an entry (possibly blocking).

123.20.6 Example #6

Listing 24: example_06.ads

```
1  package Example_06 is
2
3     protected type Mailbox is
4        entry Publish;
5        entry Retrieve;
6     private
7        Not_Empty    : Boolean := True;
8        Not_Full     : Boolean := False;
9        Num_Messages : Natural := 0;
10    end Mailbox;
11
12 end Example_06;
```

Listing 25: example_06.adb

```
package body Example_06 is

   Max : constant := 100;

   protected body Mailbox is
      entry Publish when Not_Full is
      begin
         Num_Messages := Num_Messages + 1;
         Not_Empty := True;
         if Num_Messages = Max then
            Not_Full := False;
         end if;
      end Publish;

      entry Retrieve when Not_Empty is
      begin
         Num_Messages := Num_Messages - 1;
         Not_Full := True;
         if Num_Messages = 0 then
            Not_Empty := False;
         end if;
      end Retrieve;
   end Mailbox;

end Example_06;
```

This code is not correct. Integer range cannot be proved correct.

123.20.7 Example #7

Listing 26: example_07.ads

```
package Example_07 is

   protected type Mailbox is
      entry Publish;
      entry Retrieve;
   private
      Num_Messages : Natural := 0;
   end Mailbox;

end Example_07;
```

Listing 27: example_07.adb

```
package body Example_07 is

   Max : constant := 100;

   protected body Mailbox is
      entry Publish when Num_Messages < Max is
      begin
         Num_Messages := Num_Messages + 1;
      end Publish;

      entry Retrieve when Num_Messages > 0 is
      begin
```

(continues on next page)

(continued from previous page)

```
         Num_Messages := Num_Messages - 1;
      end Retrieve;
   end Mailbox;

end Example_07;
```

This code is correct. Precise range obtained from entry guards allows to prove checks.

123.20.8 Example #8

Listing 28: example_08.ads

```
package Example_08 is

   Max : constant := 100;

   type Content is record
      Not_Empty    : Boolean := False;
      Not_Full     : Boolean := True;
      Num_Messages : Natural := 0;
   end record with Predicate =>
     Num_Messages in 0 .. Max
     and Not_Empty = (Num_Messages > 0)
     and Not_Full = (Num_Messages < Max);

   protected type Mailbox is
      entry Publish;
      entry Retrieve;
   private
      C : Content;
   end Mailbox;

end Example_08;
```

Listing 29: example_08.adb

```
package body Example_08 is

   protected body Mailbox is
      entry Publish when C.Not_Full is
         Not_Full     : Boolean := C.Not_Full;
         Num_Messages : Natural := C.Num_Messages;
      begin
         Num_Messages := Num_Messages + 1;
         if Num_Messages = Max then
            Not_Full := False;
         end if;
         C := (True, Not_Full, Num_Messages);
      end Publish;

      entry Retrieve when C.Not_Empty is
         Not_Empty    : Boolean := C.Not_Empty;
         Num_Messages : Natural := C.Num_Messages;
      begin
         Num_Messages := Num_Messages - 1;
         if Num_Messages = 0 then
            Not_Empty := False;
         end if;
         C := (Not_Empty, True, Num_Messages);
```

(continues on next page)

(continued from previous page)

```
      end Retrieve;
   end Mailbox;

end Example_08;
```

This code is correct. Precise range obtained from predicate allows to prove checks. Predicate is preserved.

123.20.9 Example #9

Listing 30: example_09.ads

```
--% src_file: Example_09.ads
--% cflags: -gnaty
--% make_flags: -gnaty -gnata

package Example_09 is

   package Service with
     Abstract_State => (State with External)
   is
      procedure Extract (Data : out Integer) with
        Global => (In_Out => State);
   end Service;

private
   task type T;
   T1, T2 : T;

end Example_09;
```

Listing 31: example_09.adb

```
package body Example_09 is

   package body Service with
     Refined_State => (State => Extracted)
   is
      Local_Data : constant Integer := 100;
      Extracted  : Boolean := False;

      procedure Extract (Data : out Integer) is
      begin
         if not Extracted then
            Data := Local_Data;
            Extracted := True;
         else
            Data := Integer'First;
         end if;
      end Extract;
   end Service;

   task body T is
      X : Integer;
   begin
      loop
         Service.Extract (X);
      end loop;
```

(continues on next page)

(continued from previous page)

```
   end T;

end Example_09;
```

This code is not correct. Unsynchronized state cannot be accessed from multiple tasks or protected objects.

123.20.10 Example #10

Listing 32: example_10.ads

```
package Example_10 is

   package Service with
     Abstract_State => (State with Synchronous, External)
   is
      procedure Extract (Data : out Integer) with
        Global => (In_Out => State);
   private
      protected type Service_Extracted is
         procedure Set;
         function Get return Boolean;
      private
         Extracted : Boolean := False;
      end Service_Extracted;
   end Service;

private
   task type T;
   T1, T2 : T;

end Example_10;
```

Listing 33: example_10.adb

```
package body Example_10 is

   package body Service with
     Refined_State => (State => Extracted)
   is
      Local_Data : constant Integer := 100;

      Extracted : Service_Extracted;

      protected body Service_Extracted is
         procedure Set is
         begin
            Extracted := True;
         end Set;

        function Get return Boolean is
           (Extracted);
      end Service_Extracted;

      procedure Extract (Data : out Integer) is
         Is_Extracted : constant Boolean := Extracted.Get;
      begin
         if not Is_Extracted then
```

(continues on next page)

(continued from previous page)

```
            Data := Local_Data;
            Extracted.Set;
         else
            Data := Integer'First;
         end if;
      end Extract;
   end Service;

   task body T is
      X : Integer;
   begin
      loop
         Service.Extract (X);
      end loop;
   end T;

end Example_10;
```

This code is correct. Abstract state is synchronized, hence can be accessed from multiple tasks and protected objects.

CHAPTER

FOUR

OBJECT-ORIENTED PROGRAMMING

124.1 What is Object Oriented Programming?

> Object-oriented software construction is the building of software systems as structured collections of [...] abstract data type implementations.
>
> Bertrand Meyer, "Object Oriented Software Construction"

- Object Oriented Programming is about:
  - isolating clients from implementation details (abstraction)
  - isolating clients from the choice of data types (dynamic dispatching)
- Object Oriented Programming is not:
  - the same as prototype programming (class and objects)
  - the same as scoping (class as the scope for methods)
  - the same as code reuse (use a component in a record in SPARK)

124.2 Prototypes and Scopes in SPARK

- Types in SPARK come with methods aka primitive operations

Listing 1: show_type_primitives.ads

```
package Show_Type_Primitives is

   type Int is range 1 .. 10;
   function Equal (Arg1, Arg2 : Int) return Boolean;
   procedure Bump (Arg : in out Int);

   type Approx_Int is new Int;
   --  implicit definition of Equal and Bump for Approx_Int

end Show_Type_Primitives;
```

- Scope for the prototype is current declarative region
  - ... or up to the first freezing point – point at which the type must be fully defined, e.g. when defining an object of the type
- OOP without dynamic dispatching = Abstract Data Types

124.3 Classes in SPARK

- Classes in SPARK are tagged records

Listing 2: show_classes.ads

```
package Show_Classes is

   type Int is tagged record
      Min, Max, Value : Integer;
   end record;

   function Equal (Arg1, Arg2 : Int) return Boolean;
   procedure Bump (Arg : in out Int);

   type Approx_Int is new Int with record
      Precision : Natural;
   end record;
   --  implicit definition of Equal and Bump for Approx_Int

end Show_Classes;
```

- Derived types are specializations of the root type
  - typically with more components
  - inheriting the methods on the parent type
  - can add their own methods

124.4 Methods in SPARK

- Derived methods can be overriding or not

Listing 3: show_derived_methods.ads

```
package Show_Derived_Methods is

   pragma Elaborate_Body;

   type Int is tagged record
      Min, Max, Value : Integer := 0;
   end record;

   function Equal (Arg1, Arg2 : Int) return Boolean;
   procedure Bump (Arg : in out Int);

   type Approx_Int is new Int with record
      Precision : Natural := 0;
   end record;

   overriding function Equal (Arg1, Arg2 : Approx_Int)
                              return Boolean;
   overriding procedure Bump (Arg : in out Approx_Int);

   not overriding procedure Blur (Arg : in out Approx_Int);

end Show_Derived_Methods;
```

Listing 4: show_derived_methods.adb

```
package body Show_Derived_Methods is

   function Equal (Arg1, Arg2 : Int) return Boolean is
     (Arg1 = Arg2);

   procedure Bump (Arg : in out Int) is
      Next : constant Integer := (if Arg.Value < Integer'Last
                                  then Arg.Value + 1
                                  else Integer'Last);
   begin
      if Next <= Arg.Max then
         Arg.Value := Next;
      end if;
   end Bump;

   overriding function Equal (Arg1, Arg2 : Approx_Int)
                              return Boolean is
     (Arg1 = Arg2);

   overriding procedure Bump (Arg : in out Approx_Int) is
   begin
      Bump (Int (Arg));
   end Bump;

   not overriding procedure Blur (Arg : in out Approx_Int) is
      Prev : constant Integer := (if Arg.Value > Integer'First
                                  then Arg.Value - 1
                                  else Integer'First);
   begin
      if Arg.Value >= Prev then
         Arg.Value := Prev;
      end if;
   end Blur;

end Show_Derived_Methods;
```

- Method called depends on static type

Listing 5: use_derived_methods.adb

```
with Show_Derived_Methods; use Show_Derived_Methods;

procedure Use_Derived_Methods is
   I  : Int;
   AI : Approx_Int;
begin
   Bump (I); -- call to Int.Bump
   I.Bump; -- call to Int.Bump (object.method notation)

   Bump (AI); -- call to Approx_Int.Bump
   Bump (Int (AI)); -- call to Int.Bump
end Use_Derived_Methods;
```

124.5 Dynamic dispatching in SPARK

- Class-wide types
  - type of object that triggers dispatching
  - method called depends on dynamic type

Listing 6: use_dynamic_dispatching.adb

```
with Show_Derived_Methods; use Show_Derived_Methods;

procedure Use_Dynamic_Dispatching is

   I  : Int;
   AI : Approx_Int;
begin
   declare
      IC : Int'Class := Int'Class (I);
   begin
      IC.Bump; -- call to Int.Bump
   end;

   declare
      IC : Int'Class := Int'Class (AI);
   begin
      IC.Bump; -- call to Approx_Int.Bump
   end;
end Use_Dynamic_Dispatching;
```

- Class-wide views of objects
  - in Ada, usually manipulated through pointers
  - in SPARK, manipulated through parameter passing

Listing 7: use_classwide_dispatching.adb

```
with Show_Derived_Methods; use Show_Derived_Methods;

procedure Use_Classwide_Dispatching is

   procedure Call_Bump (Arg : in out Int'Class) is
   begin
      Arg.Bump;
```

(continues on next page)

(continued from previous page)

```
   end Call_Bump;

   I  : Int;
   AI : Approx_Int;

begin
   Call_Bump (Int'Class (I));  -- calls Int.Bump(I)
   Call_Bump (Int'Class (AI)); -- calls Approx_Int.Bump(AI)
end Use_Classwide_Dispatching;
```

124.5.1 A trivial example

- what is called here?

Listing 8: show_trivial_example.adb

```
procedure Show_Trivial_Example is

   package Pkg_Trivial is
      type Int is tagged record
         Min, Max, Value : Integer;
      end record;

      procedure Bump (Arg : in out Int) is null;
   end Pkg_Trivial;

   use Pkg_Trivial;

   procedure Call_Bump
     (Arg : in out Int'Class) is
   begin
      Arg.Bump;
   end Call_Bump;

begin
   null;
end Show_Trivial_Example;
```

124.5.2 The problems with dynamic dispatching

- Control and data flow are not known statically
  - control flow – which subprogram is called when dispatching
  - data flow – what data this subprogram is accessing
  - similar to callbacks through subprogram pointers
- Avionics standard DO-178C lists 3 verification options
  - run all tests on parent type where derived type is used instead
  - cover all possible methods at dispatching calls
  - prove type substitutability (Liskov Substitution Principle aka LSP)

124.6 LSP – the SPARK solution to dynamic dispatching problems

- Class-wide contracts on methods
  - `Pre'Class` specifies strongest precondition for the hierarchy
  - `Post'Class` specifies weakest postcondition for the hierarchy

Listing 9: show_lsp.ads

```
package Show_LSP is

   type Int is tagged record
      Min, Max, Value : Integer := 0;
   end record;

   procedure Bump (Arg : in out Int) with
     Pre'Class  => Arg.Value < Arg.Max - 10,
     Post'Class => Arg.Value > Arg.Value'Old;

   type Approx_Int is new Int with record
      Precision : Natural := 0;
   end record;

   overriding procedure Bump (Arg : in out Approx_Int) with
     Pre'Class  => Arg.Value > 100,
     Post'Class => Arg.Value = Arg.Value'Old;

end Show_LSP;
```

Listing 10: show_lsp.ads

```
package Show_LSP is

   type Int is tagged record
      Min, Max, Value : Integer := 0;
   end record;

   procedure Bump (Arg : in out Int) with
     Pre'Class  => Arg.Value < Arg.Max - 10,
     Post'Class => Arg.Value > Arg.Value'Old;

   type Approx_Int is new Int with record
      Precision : Natural := 0;
   end record;

   overriding procedure Bump (Arg : in out Approx_Int) with
     Pre'Class  => True,
     Post'Class => Arg.Value = Arg.Value'Old + 10;

end Show_LSP;
```

Listing 11: show_lsp.ads

```
package Show_LSP is

   type Int is tagged record
      Min, Max, Value : Integer := 0;
   end record;

```

(continues on next page)

(continued from previous page)

```
   procedure Bump (Arg : in out Int) with
     Pre'Class  => Arg.Value < Arg.Max - 10,
     Post'Class => Arg.Value > Arg.Value'Old;

   type Approx_Int is new Int with record
      Precision : Natural := 0;
   end record;

   overriding procedure Bump (Arg : in out Approx_Int);
   --  inherited Pre'Class from Int.Bump
   --  inherited Post'Class from Int.Bump

end Show_LSP;
```

124.6.1 Verification of dynamic dispatching calls

- Class-wide contracts used for dynamic dispatching calls

Listing 12: show_dynamic_dispatching_verification.adb

```
with Show_LSP; use Show_LSP;

procedure Show_Dynamic_Dispatching_Verification is

   procedure Call_Bump (Arg : in out Int'Class) with
     Pre  => Arg.Value < Arg.Max - 10,
     Post => Arg.Value > Arg.Value'Old
   is
   begin
      Arg.Bump;
   end Call_Bump;

begin
   null;
end Show_Dynamic_Dispatching_Verification;
```

- LSP applies to data dependencies too
  - overriding method cannot read more global variables
  - overriding method cannot write more global variables
  - overriding method cannot have new input-output flows
  - SPARK RM defines `Global'Class` and `Depends'Class` (not yet implemented ⟶ use `Global` and `Depends` instead)

124.6.2 Class-wide contracts and data abstraction

- Abstraction can be used in class-wide contracts
- Typically use expression functions for abstraction

Listing 13: show_classwide_contracts.ads

```
package Show_Classwide_Contracts is

   type Int is tagged private;

```

(continues on next page)

(continued from previous page)

```
   function Get_Value (Arg : Int) return Integer;

   function Small (Arg : Int) return Boolean with Ghost;

   procedure Bump (Arg : in out Int) with
     Pre'Class  => Arg.Small,
     Post'Class => Arg.Get_Value > Arg.Get_Value'Old;

private

   type Int is tagged record
      Min, Max, Value : Integer := 0;
   end record;

   function Get_Value (Arg : Int) return Integer is
     (Arg.Value);
   function Small (Arg : Int) return Boolean is
     (Arg.Value < Arg.Max - 10);

end Show_Classwide_Contracts;
```

124.6.3 Class-wide contracts, data abstraction and overriding

- Abstraction functions can be overridden freely
  - overriding needs not be weaker or stronger than overridden

Listing 14: show_contract_override.ads

```
package Show_Contract_Override is

   type Int is tagged record
      Min, Max, Value : Integer := 0;
   end record;

   function Small (Arg : Int) return Boolean is
     (Arg.Value < Arg.Max - 10);

   type Approx_Int is new Int with record
      Precision : Natural := 0;
   end record;

   overriding function Small (Arg : Approx_Int) return Boolean is
     (True);

end Show_Contract_Override;
```

Listing 15: show_contract_override.ads

```
package Show_Contract_Override is

   type Int is tagged record
      Min, Max, Value : Integer := 0;
   end record;

   function Small (Arg : Int) return Boolean is
     (Arg.Value < Arg.Max - 10);

   type Approx_Int is new Int with record
```

(continues on next page)

(continued from previous page)

```
      Precision : Natural := 0;
   end record;

   function Small (Arg : Approx_Int) return Boolean is
     (Arg.Value in 1 .. 100);

end Show_Contract_Override;
```

- Inherited contract reinterpreted for derived class

Listing 16: show_contract_override.ads

```
package Show_Contract_Override is

   type Int is tagged record
      Min, Max, Value : Integer := 0;
   end record;

   procedure Bump (Arg : in out Int) with
     Pre'Class  => Arg.Value < Arg.Max - 10,
     Post'Class => Arg.Value > Arg.Value'Old;

   type Approx_Int is new Int with record
      Precision : Natural := 0;
   end record;

   overriding procedure Bump (Arg : in out Approx_Int);
   --  inherited Pre'Class uses Approx_Int.Small
   --  inherited Post'Class uses Approx_Int.Get_Value

end Show_Contract_Override;
```

124.7 Dynamic semantics of class-wide contracts

- Class-wide precondition is the disjunction (or) of
  - own class-wide precondition, and
  - class-wide preconditions of all overridden methods
- Class-wide postcondition is the conjunction (and) of
  - own class-wide postcondition, and
  - class-wide postconditions of all overridden methods
- Plain `Post` + class-wide `Pre` / `Post` can be used together
- Proof guarantees no violation of contracts at runtime
  - LSP guarantees stronger than dynamic semantics

124.8 Redispatching and Extensions_Visible aspect

- Redispatching is dispatching after class-wide conversion
  - formal parameter cannot be converted to class-wide type when Extensions_Visible is **False**

Listing 17: show_redispatching.adb

```
with Show_Contract_Override; use Show_Contract_Override;

procedure Show_Redispatching is

   procedure Re_Call_Bump (Arg : in out Int) is
   begin
      Int'Class (Arg).Bump;
   end Re_Call_Bump;
begin
   null;

end Show_Redispatching;
```

- Aspect Extensions_Visible allows class-wide conversion
  - parameter mode used also for hidden components

Listing 18: show_redispatching.adb

```
with Show_Contract_Override; use Show_Contract_Override;

procedure Show_Redispatching is

   procedure Re_Call_Bump (Arg : in out Int)
     with Extensions_Visible is
   begin
      Int'Class (Arg).Bump;
   end Re_Call_Bump;
begin
   null;

end Show_Redispatching;
```

124.9 Code Examples / Pitfalls

124.9.1 Example #1

Listing 19: oo_example_01.ads

```
package OO_Example_01 is

   type Int is record
      Min, Max, Value : Integer;
   end record;

   procedure Bump (Arg : in out Int) with
     Pre'Class  => Arg.Value < Arg.Max - 10,
     Post'Class => Arg.Value > Arg.Value'Old;
```

(continues on next page)

(continued from previous page)

```
10
11 end OO_Example_01;
```

This code is not correct. Class-wide contracts are only allowed on tagged records.

124.9.2 Example #2

Listing 20: oo_example_02.ads

```
1  package OO_Example_02 is
2
3     type Int is tagged record
4        Min, Max, Value : Integer;
5     end record;
6
7     procedure Bump (Arg : in out Int) with
8       Pre  => Arg.Value < Arg.Max - 10,
9       Post => Arg.Value > Arg.Value'Old;
10
11 end OO_Example_02;
```

This code is not correct. Plain precondition on dispatching subprogram is not allowed in SPARK. Otherwise it would have to be both weaker and stronger than the class-wide precondition (because they are both checked dynamically on both plain calls and dispatching calls).

Plain postcondition is allowed, and should be stronger than class-wide postcondition (plain postcondition used for plain calls).

124.9.3 Example #3

Listing 21: oo_example_03.ads

```
1  package OO_Example_03 is
2
3     pragma Elaborate_Body;
4
5     type Int is tagged record
6        Min, Max, Value : Integer;
7     end record;
8
9     procedure Bump (Arg : in out Int) with
10      Pre'Class  => Arg.Value < Arg.Max - 10,
11      Post'Class => Arg.Value > Arg.Value'Old;
12
13    type Approx_Int is new Int with record
14       Precision : Natural := 0;
15    end record;
16
17    overriding procedure Bump (Arg : in out Approx_Int) with
18      Post'Class => Arg.Value = Arg.Value'Old + 10;
19
20 end OO_Example_03;
```

Listing 22: oo_example_03.adb

```
package body OO_Example_03 is

   procedure Bump (Arg : in out Int) is
   begin
      Arg.Value := Arg.Value + 10;
   end Bump;

   overriding procedure Bump (Arg : in out Approx_Int) is
   begin
      Arg.Value := Arg.Value + 10;
   end Bump;

end OO_Example_03;
```

This code is correct. Class-wide precondition of `Int.Bump` is inherited by `Approx_Int.Bump`. Class-wide postcondition of `Approx_Int.Bump` is stronger than the one of `Int.Bump`.

124.9.4 Example #4

Listing 23: oo_example_04.ads

```
package OO_Example_04 is

   type Int is tagged record
      Min, Max, Value : Integer;
   end record;

   function "+" (Arg1, Arg2 : Int) return Int with
     Pre'Class => Arg1.Min = Arg2.Min
                  and Arg1.Max = Arg2.Max;

   type Approx_Int is new Int with record
      Precision : Natural;
   end record;

   --  inherited function “+”

end OO_Example_04;
```

This code is not correct. A type must be declared abstract or `"+"` overridden.

124.9.5 Example #5

Listing 24: oo_example_05.ads

```
package OO_Example_05 is

   type Int is tagged record
      Min, Max, Value : Integer;
   end record;

   procedure Reset (Arg : out Int);

   type Approx_Int is new Int with record
      Precision : Natural;
```

(continues on next page)

(continued from previous page)

```
11    end record;
12
13    --  inherited procedure Reset
14
15 end OO_Example_05;
```

This code is not correct. A type must be declared abstract or Reset overridden Reset is subject to Extensions_Visible **False**.

124.9.6 Example #6

Listing 25: oo_example_06.ads

```
1  package OO_Example_06 is
2
3     type Int is tagged record
4        Min, Max, Value : Integer;
5     end record;
6
7     procedure Reset (Arg : out Int) with Extensions_Visible;
8
9     type Approx_Int is new Int with record
10       Precision : Natural;
11    end record;
12
13    --  inherited procedure Reset
14
15 end OO_Example_06;
```

Listing 26: oo_example_06.adb

```
1  package body OO_Example_06 is
2
3     procedure Reset (Arg : out Int) is
4     begin
5        Arg := Int'(Min   => -100,
6                    Max   => 100,
7                    Value => 0);
8     end Reset;
9
10 end OO_Example_06;
```

This code is not correct. High: extension of Arg is not initialized in Reset.

124.9.7 Example #7

Listing 27: oo_example_07.ads

```
1  package OO_Example_07 is
2
3     pragma Elaborate_Body;
4
5     type Int is tagged record
6        Min, Max, Value : Integer;
7     end record;
8
```

(continues on next page)

(continued from previous page)

```
   function Zero return Int;

   procedure Reset (Arg : out Int) with Extensions_Visible;

   type Approx_Int is new Int with record
      Precision : Natural;
   end record;

   overriding function Zero return Approx_Int;

   --  inherited procedure Reset

end OO_Example_07;
```

Listing 28: oo_example_07.adb

```
package body OO_Example_07 is

   function Zero return Int is
      ((0, 0, 0));

   procedure Reset (Arg : out Int) is
   begin
      Int'Class (Arg) := Zero;
   end Reset;

   function Zero return Approx_Int is
       ((0, 0, 0, 0));

end OO_Example_07;
```

This code is correct. Redispatching ensures that Arg is fully initialized on return.

124.9.8 Example #8

Listing 29: file_system.ads

```
package File_System is

   type File is tagged private;

   function Closed (F : File) return Boolean;
   function Is_Open (F : File) return Boolean;

   procedure Create (F : out File) with
     Post'Class => F.Closed;

   procedure Open_Read (F : in out File) with
     Pre'Class  => F.Closed,
     Post'Class => F.Is_Open;

   procedure Close (F : in out File) with
     Pre'Class  => F.Is_Open,
     Post'Class => F.Closed;

private
   type File is tagged record
      Closed  : Boolean := True;
      Is_Open : Boolean := False;
```

(continues on next page)

(continued from previous page)

```
   end record;

   function Closed (F : File) return Boolean is
     (F.Closed);

   function Is_Open (F : File) return Boolean is
     (F.Is_Open);

end File_System;
```

Listing 30: file_system.adb

```
package body File_System is

   procedure Create (F : out File) is
   begin
      F.Closed  := True;
      F.Is_Open := False;
   end Create;

   procedure Open_Read (F : in out File) is
   begin
      F.Is_Open := True;
   end Open_Read;

   procedure Close (F : in out File) is
   begin
      F.Closed := True;
   end Close;

end File_System;
```

Listing 31: oo_example_08.adb

```
with File_System; use File_System;

procedure OO_Example_08 is

   procedure Use_File_System (F : out File'Class) is
   begin
      F.Create;
      F.Open_Read;
      F.Close;
   end Use_File_System;

begin
   null;
end OO_Example_08;
```

This code is correct. State automaton encoded in class-wide contracts is respected.

124.9.9 Example #9

Listing 32: file_system-sync.ads

```
package File_System.Sync is

   type File is new File_System.File with private;

   function Is_Synchronized (F : File) return Boolean;

   procedure Create (F : out File) with
     Post'Class => F.Closed;

   procedure Open_Read (F : in out File) with
     Pre'Class  => F.Closed,
     Post'Class => F.Is_Open and F.Is_Synchronized;

   procedure Close (F : in out File) with
     Pre'Class  => F.Is_Open and F.Is_Synchronized,
     Post'Class => F.Closed;

private
   type File is new File_System.File with record
      In_Synch : Boolean := True;
   end record;

   function Is_Synchronized (F : File) return Boolean is
     (F.In_Synch);

end File_System.Sync;
```

Listing 33: file_system-sync.adb

```
package body File_System.Sync is

   procedure Create (F : out File) is
   begin
      File_System.File (F).Create;
      F.In_Synch := True;
   end Create;

   procedure Open_Read (F : in out File) is
   begin
      File_System.File (F).Open_Read;
      F.In_Synch := True;
   end Open_Read;

   procedure Close (F : in out File) is
   begin
      File_System.File (F).Close;
      F.Closed := True;
   end Close;

end File_System.Sync;
```

Listing 34: oo_example_09.adb

```
with File_System.Sync; use File_System.Sync;

procedure OO_Example_09 is

```

(continues on next page)

(continued from previous page)

```
   procedure Use_File_System (F : out File'Class) is
   begin
      F.Create;
      F.Open_Read;
      F.Close;
   end Use_File_System;

begin
   null;
end OO_Example_09;
```

This code is not correct. Medium: class-wide precondition might be stronger than overridden one

124.9.10 Example #10

Listing 35: file_system-sync.ads

```
package File_System.Sync is

   type File is new File_System.File with private;

   function Is_Synchronized (F : File) return Boolean;

   procedure Create (F : out File) with
     Post'Class => F.Closed;

   procedure Open_Read (F : in out File) with
     Pre'Class  => F.Closed,
     Post'Class => F.Is_Open;

   procedure Close (F : in out File) with
     Pre'Class  => F.Is_Open,
     Post'Class => F.Closed;

private
   type File is new File_System.File with record
      In_Synch : Boolean;
   end record with
     Predicate => File_System.File (File).Closed
                  or In_Synch;

   function Is_Synchronized (F : File) return Boolean is
     (F.In_Synch);

end File_System.Sync;
```

Listing 36: file_system-sync.adb

```
package body File_System.Sync is

   procedure Create (F : out File) is
   begin
      File_System.File (F).Create;
      F.In_Synch := True;
   end Create;

   procedure Open_Read (F : in out File) is
```

(continues on next page)

(continued from previous page)

```
   begin
      File_System.File (F).Open_Read;
      F.In_Synch := True;
   end Open_Read;

   procedure Close (F : in out File) is
   begin
      File_System.File (F).Close;
      F.Closed := True;
   end Close;

end File_System.Sync;
```

Listing 37: oo_example_10.adb

```
with File_System.Sync; use File_System.Sync;

procedure OO_Example_10 is

   procedure Use_File_System (F : out File'Class) is
   begin
      F.Create;
      F.Open_Read;
      F.Close;
   end Use_File_System;

begin
   null;
end OO_Example_10;
```

This code is correct. Predicate encodes the additional constraint on opened files. Type invariants are not yet supported on tagged types in SPARK.

CHAPTER

FIVE

GHOST CODE

125.1 What is ghost code?

ghost code is part of the program that is added for the purpose of specification

Why3 team, “The Spirit of Ghost Code”

... or verification

addition by SPARK team

- Examples of ghost code:
  - contracts (`Pre`, `Post`, `Contract_Cases`, etc.)
  - assertions (`pragma Assert`, loop (in)variants, etc.)
  - special values `Func'Result`, `Var'Old`, `Var'Loop_Entry`
- Is it enough?

125.2 Ghost code – A trivial example

- how to express it?

Listing 1: show_trivial_example.ads

```
package Show_Trivial_Example is

   type Data_Array is array (1 .. 10) of Integer;

   Data : Data_Array;
   Free : Natural;

   procedure Alloc;

end Show_Trivial_Example;
```

Listing 2: show_trivial_example.adb

```
package body Show_Trivial_Example is

   procedure Alloc is
   begin
      --  some computations here
      --
      --  assert that Free “increases”
      null;
```

(continues on next page)

(continued from previous page)

```
   end Alloc;

end Show_Trivial_Example;
```

125.3 Ghost variables – aka auxiliary variables

- Variables declared with aspect `Ghost`
  - declaration is discarded by compiler when ghost code ignored
- Ghost assignments to ghost variables
  - assignment is discarded by compiler when ghost code ignored

Listing 3: show_ghost_variable.ads

```
package Show_Ghost_Variable is

   type Data_Array is array (1 .. 10) of Integer;

   Data : Data_Array;
   Free : Natural;

   procedure Alloc;

end Show_Ghost_Variable;
```

Listing 4: show_ghost_variable.adb

```
package body Show_Ghost_Variable is

   procedure Alloc is
      Free_Init : Natural with Ghost;
   begin
      Free_Init := Free;
      --  some computations here
      pragma Assert (Free > Free_Init);
   end Alloc;

end Show_Ghost_Variable;
```

125.4 Ghost variables – non-interference rules

- Ghost variable cannot be assigned to non-ghost one
  - `Free := Free_Init;`
- Ghost variable cannot indirectly influence assignment to non-ghost one

```
if Free_Init < Max then
   Free := Free + 1;
end if;
```

Listing 5: show_non_interference.adb

```
procedure Show_Non_Interference is

   type Data_Array is array (1 .. 10) of Integer;

   Data : Data_Array;
   Free : Natural;

   Free_Init : Natural with Ghost;

   procedure Alloc is
   begin
      Free_Init := Free;
      --  some computations here
      pragma Assert (Free > Free_Init);
   end Alloc;

   procedure Assign (From : Natural; To : out Natural) is
   begin
      To := From;
   end Assign;

begin
   Assign (From => Free_Init, To => Free);
end Show_Non_Interference;
```

125.5 Ghost statements

- Ghost variables can only appear in ghost statements
  - assignments to ghost variables
  - assertions and contracts
  - calls to ghost procedures

Listing 6: show_ghost_statements.adb

```
procedure Show_Ghost_Statements is

   type Data_Array is array (1 .. 10) of Integer;

   Data : Data_Array;
   Free : Natural;

   Free_Init : Natural with Ghost;

   procedure Alloc is
   begin
      Free_Init := Free;
      --  some computations here
      pragma Assert (Free > Free_Init);
   end Alloc;

   procedure Assign (From : Natural; To : out Natural)
     with Ghost
   is
   begin
```

(continues on next page)

(continued from previous page)

```
      To := From;
   end Assign;

begin
   Assign (From => Free, To => Free_Init);
end Show_Ghost_Statements;
```

```
procedure Show_Ghost_Statements is
begin
   --  Non-ghost variable "Free" cannot appear as actual in
   --  call to ghost procedure
   Assign (From => Free_Init, To => Free);
end Show_Ghost_Statements;
```

125.6 Ghost procedures

- Ghost procedures cannot write into non-ghost variables

```
procedure Assign (Value : Natural) with Ghost is
begin
   --  "Free" is a non-ghost variable
   Free := Value;
end Assign;
```

- Used to group statements on ghost variables
  - in particular statements not allowed in non-ghost procedures

```
procedure Assign_Cond (Value : Natural) with Ghost is
begin
   if Condition then
      Free_Init := Value;
   end if;
end Assign_Cond;
```

- Can have `Global` (including `Proof_In`) & `Depends` contracts

125.7 Ghost functions

- Functions for queries used only in contracts
- Typically implemented as expression functions
  - in private part – proof of client code can use expression
  - or in body – only proof of unit can use expression

Listing 7: show_ghost_function.ads

```
package Show_Ghost_Function is

   type Data_Array is array (1 .. 10) of Integer;

   Data : Data_Array;
   Free : Natural;

```

(continues on next page)

(continued from previous page)

```
   Free_Init : Natural with Ghost;

   procedure Alloc with
     Pre  => Free_Memory > 0,
     Post => Free_Memory < Free_Memory'Old;

   function Free_Memory return Natural with Ghost;

private

   --  Completion of ghost function declaration
   function Free_Memory return Natural is
     (0); -- dummy implementation

   --  If function body as declaration:
   --
   --     function Free_Memory return Natural is (...) with Ghost;

end Show_Ghost_Function;
```

125.8 Imported ghost functions

- Ghost functions without a body
  - cannot be executed

```
function Free_Memory return Natural with Ghost, Import;
```

- Typically used with abstract ghost private types
  - definition in `SPARK_Mode(Off)`
    - type is abstract for GNATprove

Listing 8: show_imported_ghost_function.ads

```
package Show_Imported_Ghost_Function
  with SPARK_Mode => On is

   type Memory_Chunks is private;

   function Free_Memory return Natural with Ghost;

   function Free_Memory return Memory_Chunks
      with Ghost, Import;

private
   pragma SPARK_Mode (Off);

   type Memory_Chunks is null record;

end Show_Imported_Ghost_Function;
```

- Definition of ghost types/functions given in proof
  - either in Why3 using `External_Axiomatization`
  - or in an interactive prover (Coq, Isabelle, etc.)

125.9 Ghost packages and ghost abstract state

- Every entity in a ghost package is ghost
  - local ghost package can group all ghost entities
  - library-level ghost package can be withed/used in regular units
- Ghost abstract state can only represent ghost variables

Listing 9: show_ghost_package.ads

```
package Show_Ghost_Package
  with Abstract_State => (State with Ghost) is

   function Free_Memory return Natural with Ghost;

end Show_Ghost_Package;
```

Listing 10: show_ghost_package.adb

```
package body Show_Ghost_Package
  with Refined_State => (State => (Data, Free, Free_Init)) is

   type Data_Array is array (1 .. 10) of Integer;

   Data : Data_Array with Ghost;
   Free : Natural with Ghost;

   Free_Init : Natural with Ghost;

   function Free_Memory return Natural is
     (0);  --  dummy implementation

end Show_Ghost_Package;
```

- Non-ghost abstract state can contain both ghost and non-ghost variables

125.10 Executing ghost code

- Ghost code can be enabled globally
  - using compilation switch `-gnata` (for all assertions)
- Ghost code can be enabled selectively
  - using `pragma Assertion_Policy (Ghost => Check)`
  - SPARK rules enforce consistency – in particular no write disabled

Listing 11: show_exec_ghost_code.ads

```
package Show_Exec_Ghost_Code is

   pragma Assertion_Policy (Ghost => Check);
   --  pragma Assertion_Policy (Ghost => Ignore, Pre => Check);

   procedure Alloc with
     Pre => Free_Memory > 0;

   function Free_Memory return Natural with Ghost;
```

(continues on next page)

(continued from previous page)

```
10
11 end Show_Exec_Ghost_Code;
```

- GNATprove analyzes all ghost code and assertions

125.11 Examples of use

125.11.1 Encoding a state automaton

- Tetris in SPARK
  - at Tetris[535]
- Global state encoded in global ghost variable
  - updated at the end of procedures of the API

```
type State is (Piece_Falling, ...) with Ghost;
Cur_State : State with Ghost;
```

- Properties encoded in ghost functions

```
function Valid_Configuration return Boolean is
   (case Cur_State is
      when Piece_Falling => ...,
      when ...)
with Ghost;
```

125.11.2 Expressing useful lemmas

- GCD in SPARK
  - at GCD[536]
- Lemmas expressed as ghost procedures

```
procedure Lemma_Not_Divisor (Arg1, Arg2 : Positive) with
   Ghost,
   Global => null,
   Pre  => Arg1 in Arg2 / 2 + 1 .. Arg2 - 1,
   Post => not Divides (Arg1, Arg2);
```

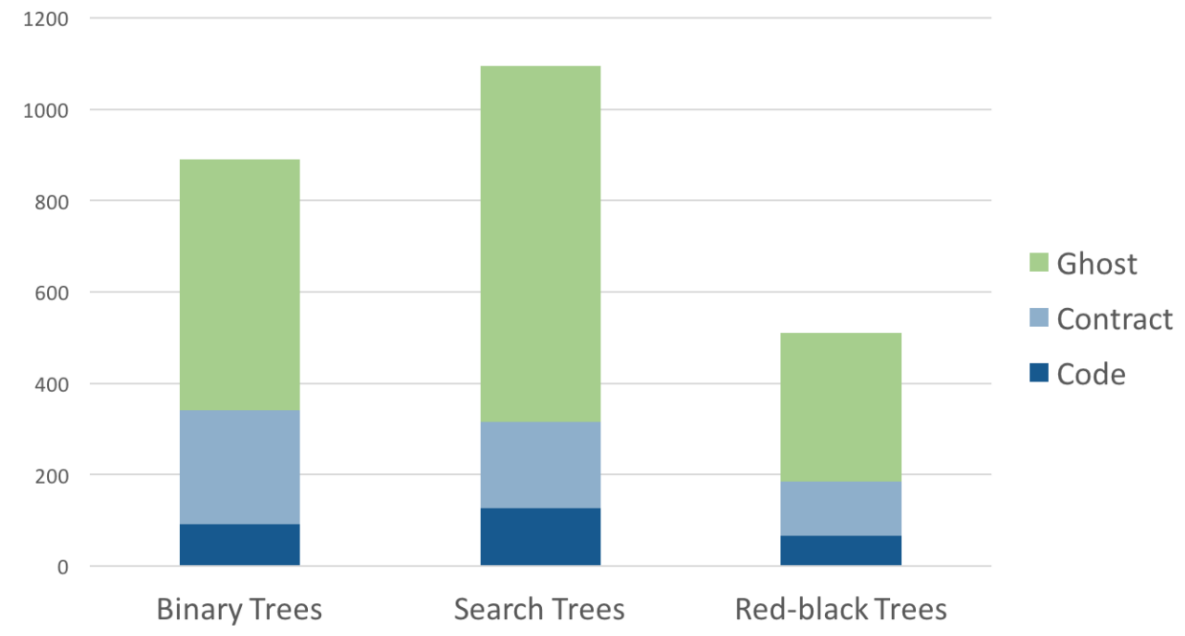
- Most complex lemmas further refined into other lemmas
  - code in procedure body used to guide proof (e.g. for induction)

[535] http://blog.adacore.com/tetris-in-spark-on-arm-cortex-m4
[536] http://www.spark-2014.org/entries/detail/gnatprove-tips-and-tricks-proving-the-ghost-common-denominator-gcd

125.11.3 Specifying an API through a model

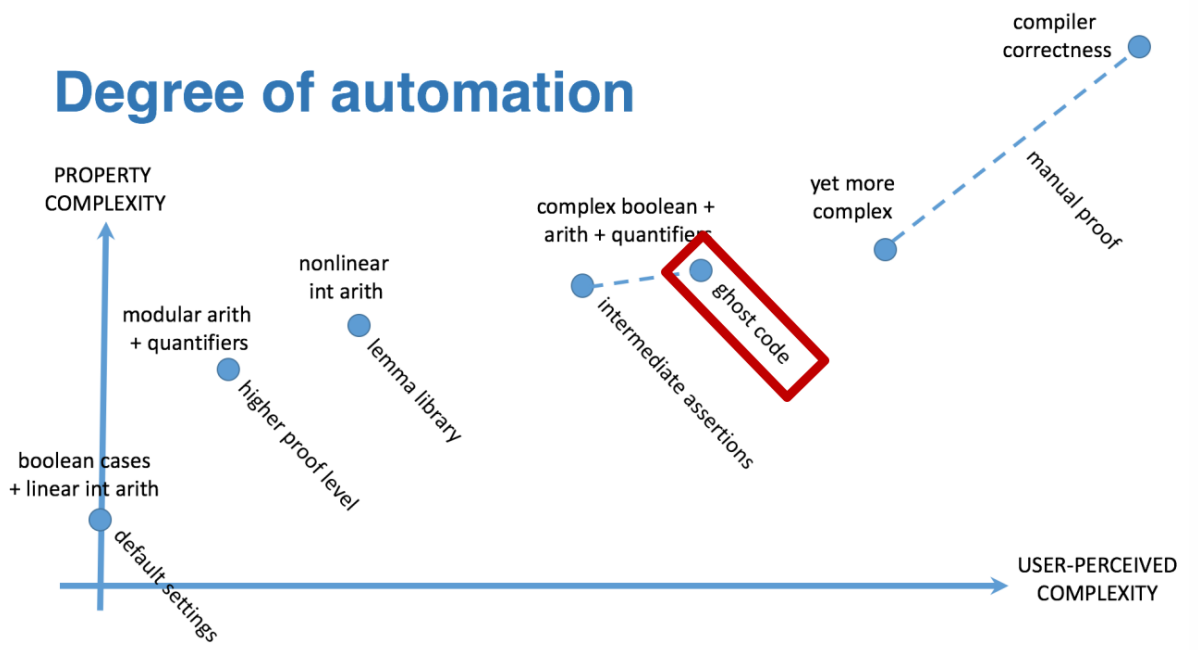
- Red black trees in SPARK
  - at Red black trees[537]
- Invariants of data structures expressed as ghost functions
  - using `Type_Invariant` on private types
- Model of data structures expressed as ghost functions
  - called from `Pre` / `Post` of subprograms from the API
- Lemmas expressed as ghost procedures
  - sometimes without contracts to benefit from inlining in proof

125.12 Extreme proving with ghost code – red black trees in SPARK



[537] http://www.spark-2014.org/entries/detail/research-corner-auto-active-verification-in-spark

125.13 Positioning ghost code in proof techniques



125.14 Code Examples / Pitfalls

125.14.1 Example #1

Listing 12: example_01.adb

```
procedure Example_01 is

   type Data_Array is array (1 .. 10) of Integer;

   Data : Data_Array;
   Free : Natural;

   procedure Alloc is
      Free_Init : Natural with Ghost;
   begin
      Free_Init := Free;
      --  some computations here
      if Free <= Free_Init then
         raise Program_Error;
      end if;
   end Alloc;
begin
   null;

end Example_01;
```

This code is not correct. A ghost entity cannot appear in this context.

125.14.2 Example #2

Listing 13: example_02.adb

```
procedure Example_02 is

   type Data_Array is array (1 .. 10) of Integer;

   Data : Data_Array;
   Free : Natural;

   procedure Alloc is
      Free_Init : Natural with Ghost;

      procedure Check with Ghost is
      begin
         if Free <= Free_Init then
            raise Program_Error;
         end if;
      end Check;
   begin
      Free_Init := Free;
      --  some computations here
      Check;
   end Alloc;
begin
   null;

end Example_02;
```

This code is correct. Note that procedure Check is inlined for proof (no contract).

125.14.3 Example #3

Listing 14: example_03.ads

```
package Example_03 is

   type Data_Array is array (1 .. 10) of Integer;

   Data : Data_Array;
   Free : Natural;

   pragma Assertion_Policy (Pre => Check);

   procedure Alloc with
     Pre => Free_Memory > 0;

   function Free_Memory return Natural with Ghost;

end Example_03;
```

This code is not correct. Incompatible ghost policies in effect during compilation, as ghost code is ignored by default. Note that GNATprove accepts this code as it enables all ghost code and assertions.

125.14.4 Example #4

Listing 15: example_04.ads

```
package Example_04 is

   procedure Alloc with
     Post => Free_Memory < Free_Memory'Old;

   function Free_Memory return Natural with Ghost;

end Example_04;
```

Listing 16: example_04.adb

```
package body Example_04 is

   Free : Natural;

   Max : constant := 1000;

   function Free_Memory return Natural is
   begin
      return Max - Free + 1;
   end Free_Memory;

   procedure Alloc is
   begin
      Free := Free + 10;
   end Alloc;

end Example_04;
```

This code is not correct. No postcondition on `Free_Memory` that would allow proving the postcondition on `Alloc`.

125.14.5 Example #5

Listing 17: example_05.ads

```
package Example_05 is

   procedure Alloc with
     Post => Free_Memory < Free_Memory'Old;

   function Free_Memory return Natural with Ghost;

end Example_05;
```

Listing 18: example_05.adb

```
package body Example_05 is

   Free : Natural;

   Max : constant := 1000;

   function Free_Memory return Natural is (Max - Free + 1);

   procedure Alloc is
   begin
      Free := Free + 10;
   end Alloc;

end Example_05;
```

This code is correct. Free_Memory has an implicit postcondition as an expression function.

125.14.6 Example #6

Listing 19: example_06.adb

```
procedure Example_06 is

   subtype Resource is Natural range 0 .. 1000;
   subtype Num is Natural range 0 .. 6;
   subtype Index is Num range 1 .. 6;
   type Data is array (Index) of Resource;

   function Sum (D : Data; To : Num) return Natural is
     (if To = 0 then 0 else D (To) + Sum (D, To - 1))
       with Ghost;

   procedure Create (D : out Data) with
     Post => Sum (D, D'Last) < 42
   is
   begin
      for J in D'Range loop
         D (J) := J;
         pragma Loop_Invariant (2 * Sum (D, J) <= J * (J + 1));
      end loop;
   end Create;

begin
   null;
end Example_06;
```

This code is not correct. Info: expression function body not available for proof (Sum may not return).

125.14.7 Example #7

Listing 20: example_07.adb

```
procedure Example_07 is

   subtype Resource is Natural range 0 .. 1000;
   subtype Num is Natural range 0 .. 6;
   subtype Index is Num range 1 .. 6;
   type Data is array (Index) of Resource;

   function Sum (D : Data; To : Num) return Natural is
     (if To = 0 then 0 else D (To) + Sum (D, To - 1))
       with Ghost, Annotate => (GNATprove, Terminating);

   procedure Create (D : out Data) with
     Post => Sum (D, D'Last) < 42
   is
   begin
      for J in D'Range loop
         D (J) := J;
         pragma Loop_Invariant (2 * Sum (D, J) <= J * (J + 1));
      end loop;
   end Create;

begin
   null;
end Example_07;
```

This code is correct. Note that GNATprove does not prove the termination of Sum here.

125.14.8 Example #8

Listing 21: example_08.adb

```
procedure Example_08 is

   subtype Resource is Natural range 0 .. 1000;
   subtype Num is Natural range 0 .. 6;
   subtype Index is Num range 1 .. 6;
   type Data is array (Index) of Resource;

   function Sum (D : Data; To : Num) return Natural is
     (if To = 0 then 0 else D (To) + Sum (D, To - 1))
       with Ghost, Annotate => (GNATprove, Terminating);

   procedure Create (D : out Data) with
     Post => Sum (D, D'Last) < 42
   is
   begin
      for J in D'Range loop
         D (J) := J;
      end loop;
   end Create;

```

(continues on next page)

(continued from previous page)

```
begin
   null;
end Example_08;
```

This code is correct. The loop is unrolled by GNATprove here, as `D'Range` is `0 .. 6`. The automatic prover unrolls the recursive definition of `Sum`.

125.14.9 Example #9

Listing 22: example_09.adb

```
with Ada.Containers.Functional_Vectors;

procedure Example_09 is

   subtype Resource is Natural range 0 .. 1000;
   subtype Index is Natural range 1 .. 42;

   package Seqs is new
     Ada.Containers.Functional_Vectors (Index, Resource);
   use Seqs;

   function Create return Sequence with
     Post => (for all K in 1 .. Last (Create'Result) =>
                 Get (Create'Result, K) = K)
   is
      S : Sequence;
   begin
      for K in 1 .. 42 loop
         S := Add (S, K);
      end loop;
      return S;
   end Create;

begin
   null;
end Example_09;
```

This code is not correct. Loop requires a loop invariant to prove the postcondition.

125.14.10 Example #10

Listing 23: example_10.adb

```
with Ada.Containers.Functional_Vectors;

procedure Example_10 is

   subtype Resource is Natural range 0 .. 1000;
   subtype Index is Natural range 1 .. 42;

   package Seqs is new
     Ada.Containers.Functional_Vectors (Index, Resource);
   use Seqs;

   function Create return Sequence with
     Post => (for all K in 1 .. Last (Create'Result) =>
```

(continues on next page)

(continued from previous page)

```
                  Get (Create'Result, K) = K)
   is
      S : Sequence;
   begin
      for K in 1 .. 42 loop
         S := Add (S, K);
         pragma Loop_Invariant (Integer (Length (S)) = K);
         pragma Loop_Invariant
           (for all J in 1 .. K => Get (S, J) = J);
      end loop;
      return S;
   end Create;

begin
   null;
end Example_10;
```

This code is correct.

CHAPTER

SIX

TEST AND PROOF

126.1 Various Combinations of Tests and Proofs

- Overall context is functional verification of code
- Combination can take various forms:
  - Test before Proof – contracts used first in test, possibly later in proof
  - Test for Proof – contracts executed in test to help with development of proof
  - Test alongside Proof – some modules are tested and other modules are proved
  - Test as Proof – exhaustive test as good as proof
  - Test on top of Proof – proof at unit level completed with test at integration level, also using contracts

126.2 Test (be)for(e) Proof

126.2.1 Activating Run-time Checks

- Need to activate run-time checks in executable
- `Constraint_Error` exceptions activated by default
  - Use `-gnat-p` to revert effect of previous `-gnatp` (say in project file)
  - Use `-gnato` to activate overflow checking (default since GNAT 7.3)
- Special handling of floating-point computations
  - Use `-gnateF` to activate bound checking on standard float types
  - Use `-msse2 -mfpmath=sse` to forbid use of 80bits registers and FMA on x86 processors
  - Runtime/BSP should enforce use of Round-Nearest-tie-to-Even (RNE) rounding mode

126.2.2 Activating Assertions

- Need to activate assertions in executable
- `Assertion_Error` exceptions deactivated by default
  - Use `-gnata` to activate globally
  - Use pragma `Assertion_Policy` to activate file-by-file
  - Use `-gnateE` to get more precise error messages (`Contract_Cases`)
- Special assertions checked at run time
  - `Contract_Cases` ⟶ checks one and only one case activated
  - `Loop_Invariant` ⟶ checks assertion holds (even if not inductive)
  - `Assume` ⟶ checks assertion holds (even if not subject to proof)
  - `Loop_Variant` ⟶ checks variant decreases wrt previous iteration

126.2.3 Activating Ghost Code

- Need to activate ghost code in executable
- Ghost code, like assertions, is deactivated by default
  - Use `-gnata` to activate globally
  - Use pragma `Assertion_Policy (Ghost => Check)` to activate locally
- Inconsistent combinations will be rejected by GNAT
  - Ignored ghost entity in activated assertion
  - Ignored ghost assignment to activated ghost variable

126.3 Test for Proof

126.3.1 Overflow Checking Mode

- Problem: ignore overflow checks in assertions/contracts
  - Only applies to signed integer arithmetic
  - Does not apply inside an expression function returning an integer
- Solution: use unbounded arithmetic in assertions/contracts
  - Will use 64bits signed arithmetic when sufficient
  - Otherwise use a run-time library for unbounded arithmetic
- Two ways to activate unbounded arithmetic
  - Use `-gnato13` compiler switch
  - Use pragma `Overflow_Mode` with arguments `(General => Strict, Assertions => Eliminated)` in configuration pragma file

126.4 Test alongside Proof

126.4.1 Checking Proof Assumptions

- Need to check dynamically the assumptions done in proof
  - Postcondition of tested subprogram called in proved subprogram
  - Precondition of proved subprogram called in tested subprogram
- Other assumptions beyond pre- and postconditions
  - Global variables read and written by tested subprogram
  - Non-aliasing of inputs and outputs of proved subprogram
  - No run-time errors in tested subprogram
- GNATprove can list assumptions used in proof
  - Switch `--assumptions` adds info in `gnatprove.out` file
- See "Explicit Assumptions - A Prenup for Marrying Static and Dynamic Program Verification"

126.4.2 Rules for Defining the Boundary

- `SPARK_Mode` defines a simple boundary test vs. proof
  - Subprograms with `SPARK_Mode (On)` should be proved
  - Subprograms with `SPARK_Mode (Off)` should be tested
- `SPARK_Mode` can be used at different levels
  - Project-wise switch in configuration pragma file (with value `On`) ⟶ explicit exemptions of units/subprograms in the code
  - Distinct GNAT project with `SPARK_Mode (On)` for proof on subset of units
  - Explicit `SPARK_Mode (On)` on units that should be proved
- Unproved checks inside proved subprograms are justified
  - Use of pragma `Annotate` inside the code

126.4.3 Special Compilation Switches

- Validity checking for reads of uninitialized data
  - Compilation switch `-gnatVa` enables validity checking
  - pragma `Initialize_Scalars` uses invalid default values
  - Compilation switch `-gnateV` enables validity checking for composite types (records, arrays) ⟶ extra checks to detect violation of SPARK stronger data initialization policy
- Non-aliasing checks for parameters
  - Compilation switch `-gnateA` enables non-aliasing checks between parameters
  - Does not apply to aliasing between parameters and globals

126.5 Test as Proof

126.5.1 Feasibility of Exhaustive Testing

- Exhaustive testing covers all possible input values
  - Typically possible for numerical computations involving few values
  - e.g. OK for 32 bits values, not for 64 bits ones
    - binary op on 16 bits ⟶ 1 second with 4GHz
    - unary op on 32 bits ⟶ 1 second with 4GHz
    - binary op on 32 bits ⟶ 2 years with 64 cores at 4GHz
  - In practice, this can be feasible for trigonometric functions on 32 bits floats
- Representative/boundary values may be enough
  - Partitioning of the input state in equivalent classes
  - Relies on continuous/linear behavior inside a partition

126.6 Test on top of Proof

126.6.1 Combining Unit Proof and Integration Test

- Unit Proof of AoRTE combined with Integration Test
  - Combination used by Altran UK on several projects
  - Unit Proof assumes subprogram contracts
  - Integration Test verifies subprogram contracts
- Unit Proof of Contracts combined with Integration Test
  - Test exercises the assumptions made in proof
  - One way to show Property Preservation between Source Code and Executable Object Code from DO-178C/DO-333
    - Integration Test performed twice: once with contracts to show they are verified in EOC, once without to show final executable behaves the same

126.7 Test Examples / Pitfalls

126.7.1 Example #1

I am stuck with an unproved assertion. My options are:

- switch --level to 4 and --timeout to 360
- open a ticket on GNAT Tracker
- justify the unproved check manually

Evaluation: This approach is not correct. Why not, but only after checking this last option:

- run tests to see if the assertion actually holds

126.7.2 Example #2

The same contracts are useful for test and for proof, so it's useful to develop them for test initially.

Evaluation: This approach is not correct. In fact, proof requires more contracts that test, as each subprogram is analyzed separately. But these are a superset of the contracts used for test.

126.7.3 Example #3

Assertions need to be activated explicitly at compilation for getting the corresponding run-time checks.

Evaluation: This approach is correct. Use switch `-gnata` to activate assertions.

126.7.4 Example #4

When assertions are activated, loop invariants are checked to be inductive on specific executions.

Evaluation: This approach is not correct. Loop invariants are checked dynamically exactly like assertions. The inductive property is not something that can be tested.

126.7.5 Example #5

Procedure P which is proved calls function T which is tested. To make sure the assumptions used in the proof of P are verified, we should check dynamically the precondition of T.

Evaluation: This approach is not correct. The precondition is proved at the call site of T in P. But we should check dynamically the postcondition of T.

126.7.6 Example #6

Function T which is tested calls procedure P which is proved. To make sure the assumptions used in the proof of P are verified, we should check dynamically the precondition of P.

Evaluation: This approach is correct. The proof of P depends on its precondition being satisfied at every call.

126.7.7 Example #7

However procedure P (proved) and function T (tested) call each other, we can verify the assumptions of proof by checking dynamically all preconditions and postconditions during tests of T.

Evaluation: This approach is not correct. That covers only functional contracts. There are other assumptions made in proof, related to initialization, effects and non-aliasing.

126.7.8 Example #8

Proof is superior to test in every aspect.

Evaluation: This approach is not correct. Maybe for the aspects `Pre` and `Post`. But not in other aspects of verification: non-functional verification (memory footprint, execution time), match with hardware, integration in environment... And testing can even be exhaustive sometimes!

126.7.9 Example #9

When mixing test and proof at different levels, proof should be done at unit level and test at integration level.

Evaluation: This approach is not correct. This is only one possibility that has been used in practice. The opposite could be envisioned: test low-level functionalities (e.g. crypto in hardware), and prove correct integration of low-level functionalities.

126.7.10 Example #10

There are many ways to mix test and proof, and yours may not be in these slides.

Evaluation: This approach is correct. YES! (and show me yours)

CHAPTER

SEVEN

IMPERATIVE LANGUAGE

For the exercises below (except for the first one), don't worry about the details of the `Main` procedure. You should just focus on implementing the application in the subprogram specified by the exercise.

127.1 Hello World

Goal: create a "Hello World!" application.

Steps:

1. Complete the `Main` procedure.

Requirements:

1. The application must display the message "Hello World!".

Listing 1: main.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Main is
begin
   --  Implement the application here!
   null;
end Main;
```

127.2 Greetings

Goal: create an application that greets a person.

Steps:

1. Complete the `Greet` procedure.

Requirements:

1. Given an input string <name>, procedure `Greet` must display the message "Hello <name>!".
    1. For example, if the name is "John", it displays the message "Hello John!".

Remarks:

1. You can use the concatenation operator (`&`).

Listing 2: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;

procedure Main is

   procedure Greet (Name : String) is
   begin
      --  Implement the application here!
      null;
   end Greet;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Greet (Argument (1));
end Main;
```

127.3 Positive Or Negative

Goal: create an application that classifies integer numbers.

Steps:

1. Complete the `Classify_Number` procedure.

Requirements:

1. Given an integer number `X`, procedure `Classify_Number` must classify `X` as positive, negative or zero and display the result:
    1. If `X > 0`, it displays `Positive`.
    2. If `X < 0`, it displays `Negative`.
    3. If `X = 0`, it displays `Zero`.

Listing 3: classify_number.ads

```
procedure Classify_Number (X : Integer);
```

Listing 4: classify_number.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Classify_Number (X : Integer) is
begin
   --  Implement the application here!
   null;
end Classify_Number;
```

Listing 5: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;

with Classify_Number;

procedure Main is
   A : Integer;
begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   A := Integer'Value (Argument (1));

   Classify_Number (A);
end Main;
```

127.4 Numbers

Goal: create an application that displays numbers in a specific order.

Steps:

1. Complete the `Display_Numbers` procedure.

Requirements:

1. Given two integer numbers, `Display_Numbers` displays all numbers in the range starting with the smallest number.

Listing 6: display_numbers.ads

```
procedure Display_Numbers (A, B : Integer);
```

Listing 7: display_numbers.adb

```
procedure Display_Numbers (A, B : Integer) is
begin
   --  Implement the application here!
   null;
end Display_Numbers;
```

Listing 8: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;

with Display_Numbers;

procedure Main is
   A, B : Integer;
begin
   if Argument_Count < 2 then
      Put_Line ("ERROR: missing arguments! Exiting...");
```

(continues on next page)

(continued from previous page)

```
      return;
   elsif Argument_Count > 2 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   A := Integer'Value (Argument (1));
   B := Integer'Value (Argument (2));

   Display_Numbers (A, B);
end Main;
```

CHAPTER

EIGHT

SUBPROGRAMS

128.1 Subtract procedure

Goal: write a procedure that subtracts two numbers.

Steps:

1. Complete the procedure `Subtract`.

Requirements:

1. `Subtract` performs the operation `A - B`.

Listing 1: subtract.ads

```
--  Write the correct parameters for the procedure below.
procedure Subtract;
```

Listing 2: subtract.adb

```
procedure Subtract is
begin
   --  Implement the procedure here.
   null;
end Subtract;
```

Listing 3: main.adb

```
with Ada.Command_Line;     use Ada.Command_Line;
with Ada.Text_IO;          use Ada.Text_IO;

with Subtract;

procedure Main is
   type Test_Case_Index is
     (Sub_10_1_Chk,
      Sub_10_100_Chk,
      Sub_0_5_Chk,
      Sub_0_Minus_5_Chk);

   procedure Check (TC : Test_Case_Index) is
      Result : Integer;
   begin
      case TC is
      when Sub_10_1_Chk =>
         Subtract (10, 1, Result);
         Put_Line ("Result: " & Integer'Image (Result));
      when Sub_10_100_Chk =>
         Subtract (10, 100, Result);
```

(continues on next page)

(continued from previous page)

```
         Put_Line ("Result: " & Integer'Image (Result));
      when Sub_0_5_Chk =>
         Subtract (0, 5, Result);
         Put_Line ("Result: " & Integer'Image (Result));
      when Sub_0_Minus_5_Chk =>
         Subtract (0, -5, Result);
         Put_Line ("Result: " & Integer'Image (Result));
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

128.2 Subtract function

Goal: write a function that subtracts two numbers.

Steps:

1. Rewrite the `Subtract` procedure from the previous exercise as a function.

Requirements:

1. `Subtract` performs the operation `A - B` and returns the result.

Listing 4: subtract.ads

```
--  Write the correct signature for the function below.
--  Don't forget to replace the keyword "procedure" by "function."
procedure Subtract;
```

Listing 5: subtract.adb

```
procedure Subtract is
begin
   --  Implement the function here!
   null;
end Subtract;
```

Listing 6: main.adb

```
with Ada.Command_Line;     use Ada.Command_Line;
with Ada.Text_IO;          use Ada.Text_IO;

with Subtract;

procedure Main is
   type Test_Case_Index is
     (Sub_10_1_Chk,
      Sub_10_100_Chk,
      Sub_0_5_Chk,
```

(continues on next page)

(continued from previous page)

```
      Sub_0_Minus_5_Chk);

   procedure Check (TC : Test_Case_Index) is
      Result : Integer;
   begin
      case TC is
      when Sub_10_1_Chk =>
         Result := Subtract (10, 1);
         Put_Line ("Result: " & Integer'Image (Result));
      when Sub_10_100_Chk =>
         Result := Subtract (10, 100);
         Put_Line ("Result: " & Integer'Image (Result));
      when Sub_0_5_Chk =>
         Result := Subtract (0, 5);
         Put_Line ("Result: " & Integer'Image (Result));
      when Sub_0_Minus_5_Chk =>
         Result := Subtract (0, -5);
         Put_Line ("Result: " & Integer'Image (Result));
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

128.3 Equality function

Goal: write a function that compares two values and returns a flag.

Steps:

1. Complete the `Is_Equal` subprogram.

Requirements:

1. `Is_Equal` returns a flag as a **`Boolean`** value.
2. The flag must indicate whether the values are equal (flag is **`True`**) or not (flag is **`False`**).

Listing 7: is_equal.ads

```
--  Write the correct signature for the function below.
--  Don't forget to replace the keyword "procedure" by "function."
procedure Is_Equal;
```

Listing 8: is_equal.adb

```
procedure Is_Equal is
begin
   --  Implement the function here!
   null;
end Is_Equal;
```

Listing 9: main.adb

```
with Ada.Command_Line;     use Ada.Command_Line;
with Ada.Text_IO;          use Ada.Text_IO;

with Is_Equal;

procedure Main is
   type Test_Case_Index is
     (Equal_Chk,
      Inequal_Chk);

   procedure Check (TC : Test_Case_Index) is

      procedure Display_Equal (A, B  : Integer;
                               Equal : Boolean) is
      begin
         Put (Integer'Image (A));
         if Equal then
            Put (" is equal to ");
         else
            Put (" isn't equal to ");
         end if;
         Put_Line (Integer'Image (B) & ".");
      end Display_Equal;

      Result : Boolean;
   begin
      case TC is
      when Equal_Chk =>
         for I in 0 .. 10 loop
            Result := Is_Equal (I, I);
            Display_Equal (I, I, Result);
         end loop;
      when Inequal_Chk =>
         for I in 0 .. 10 loop
            Result := Is_Equal (I, I - 1);
            Display_Equal (I, I - 1, Result);
         end loop;
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

128.4 States

Goal: write a procedure that displays the state of a machine.

Steps:

1. Complete the procedure `Display_State`.

Requirements:

1. The states can be set according to the following numbers:

Number	State
0	Off
1	On: Simple Processing
2	On: Advanced Processing

2. The procedure `Display_State` receives the number corresponding to a state and displays the state (indicated by the table above) as a user message.

Remarks:

1. You can use a case statement to implement this procedure.

Listing 10: display_state.ads

```
procedure Display_State (State : Integer);
```

Listing 11: display_state.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Display_State (State : Integer) is
begin
   null;
end Display_State;
```

Listing 12: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;

with Display_State;

procedure Main is
   State : Integer;
begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   State := Integer'Value (Argument (1));

   Display_State (State);
end Main;
```

128.5 States #2

Goal: write a function that returns the state of a machine.

Steps:

1. Implement the function `Get_State`.

Requirements:

1. Implement same state machine as in the previous exercise.
2. Function `Get_State` must return the state as a string.

Remarks:

1. You can implement a function returning a string by simply using quotes in a return statement. For example:

Listing 13: get_hello.ads

```
function Get_Hello return String;
```

Listing 14: get_hello.adb

```
function Get_Hello return String is
begin
   return "Hello";
end Get_Hello;
```

Listing 15: main.adb

```
with Ada.Text_IO;      use Ada.Text_IO;
with Get_Hello;

procedure Main is
   S : constant String := Get_Hello;
begin
   Put_Line (S);
end Main;
```

2. You can reuse your previous implementation and replace it by a case expression.
    1. For values that do not correspond to a state, you can simply return an empty string (`""`).

Listing 16: get_state.ads

```
function Get_State (State : Integer) return String;
```

Listing 17: get_state.adb

```
function Get_State (State : Integer) return String is
begin
   return "";
end Get_State;
```

Listing 18: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;

with Get_State;
```

(continues on next page)

(continued from previous page)

```
5
6  procedure Main is
7     State : Integer;
8  begin
9     if Argument_Count < 1 then
10       Put_Line ("ERROR: missing arguments! Exiting...");
11       return;
12    elsif Argument_Count > 1 then
13       Put_Line ("Ignoring additional arguments...");
14    end if;
15
16    State := Integer'Value (Argument (1));
17
18    Put_Line (Get_State (State));
19 end Main;
```

128.6 States #3

Goal: implement an on/off indicator for a state machine.

Steps:

1. Implement the function `Is_On`.
2. Implement the procedure `Display_On_Off`.

Requirements:

1. Implement same state machine as in the previous exercise.
2. Function `Is_On` returns:
   - `True` if the machine is on;
   - otherwise, it returns `False`.
3. Procedure `Display_On_Off` displays the message
   - "On" if the machine is on, or
   - "Off" otherwise.
4. `Is_On` must be called in the implementation of `Display_On_Off`.

Remarks:

1. You can implement both subprograms using if expressions.

Listing 19: is_on.ads

```
1  function Is_On (State : Integer) return Boolean;
```

Listing 20: is_on.adb

```
1  function Is_On (State : Integer) return Boolean is
2  begin
3     return False;
4  end Is_On;
```

Listing 21: display_on_off.ads

```
1  procedure Display_On_Off (State : Integer);
```

Listing 22: display_on_off.adb

```
with Ada.Text_IO; use Ada.Text_IO;
with Is_On;

procedure Display_On_Off (State : Integer) is
begin
   Put_Line ("");
end Display_On_Off;
```

Listing 23: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;

with Display_On_Off;
with Is_On;

procedure Main is
   State : Integer;
begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   State := Integer'Value (Argument (1));

   Display_On_Off (State);
   Put_Line (Boolean'Image (Is_On (State)));
end Main;
```

128.7 States #4

Goal: implement a procedure to update the state of a machine.

Steps:

1. Implement the procedure `Set_Next`.

Requirements:

1. Implement the same state machine as in the previous exercise.
2. Procedure `Set_Next` updates the machine's state with the next one in a *circular* manner:
   - In most cases, the next state of `N` is simply the next number (`N + 1`).
   - However, if the state is the last one (which is 2 for our machine), the next state must be the first one (in our case: 0).

Remarks:

1. You can use an if expression to implement `Set_Next`.

Listing 24: set_next.ads

```
procedure Set_Next (State : in out Integer);
```

Listing 25: set_next.adb

```
procedure Set_Next (State : in out Integer) is
begin
   null;
end Set_Next;
```

Listing 26: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;

with Set_Next;

procedure Main is
   State : Integer;
begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   State := Integer'Value (Argument (1));

   Set_Next (State);
   Put_Line (Integer'Image (State));
end Main;
```

CHAPTER

NINE

MODULAR PROGRAMMING

129.1 Months

Goal: create a package to display the months of the year.

Steps:

1. Convert the `Months` procedure below to a package.
2. Create the specification and body of the `Months` package.

Requirements:

1. `Months` must contain the declaration of strings for each month of the year, which are stored in three-character constants based on the month's name.
    - For example, the string `"January"` is stored in the constant `Jan`. These strings are then used by the `Display_Months` procedure, which is also part of the `Months` package.

Remarks:

1. The goal of this exercise is to create the `Months` package.
    1. In the code below, `Months` is declared as a procedure.
        - Therefore, we need to *convert* it into a real package.
    2. You have to modify the procedure declaration and implementation in the code below, so that it becomes a package specification and a package body.

Listing 1: months.ads

```
--  Create specification for Months package, which includes
--  the declaration of the Display_Months procedure.
--
procedure Months;
```

Listing 2: months.adb

```
--  Create body of Months package, which includes
--  the implementation of the Display_Months procedure.
--
procedure Months is

   procedure Display_Months is
   begin
      Put_Line ("Months:");
      Put_Line ("- " & Jan);
      Put_Line ("- " & Feb);
      Put_Line ("- " & Mar);
```

(continues on next page)

(continued from previous page)

```
      Put_Line ("- " & Apr);
      Put_Line ("- " & May);
      Put_Line ("- " & Jun);
      Put_Line ("- " & Jul);
      Put_Line ("- " & Aug);
      Put_Line ("- " & Sep);
      Put_Line ("- " & Oct);
      Put_Line ("- " & Nov);
      Put_Line ("- " & Dec);
   end Display_Months;

begin
   null;
end Months;
```

Listing 3: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;

with Months;           use Months;

procedure Main is

   type Test_Case_Index is
     (Months_Chk);

   procedure Check (TC : Test_Case_Index) is
   begin
      case TC is
         when Months_Chk =>
            Display_Months;
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

129.2 Operations

Goal: create a package to perform basic mathematical operations.

Steps:

1. Implement the `Operations` package.
    1. Declare and implement the `Add` function.
    2. Declare and implement the `Subtract` function.
    3. Declare and implement the `Multiply`: function.

    4. Declare and implement the `Divide` function.
2. Implement the `Operations.Test` package
    1. Declare and implement the `Display` procedure.

Requirements:

1. Package `Operations` contains functions for each of the four basic mathematical operations for parameters of **`Integer`** type:
    1. Function `Add` performs the addition of `A` and `B` and returns the result;
    2. Function `Subtract` performs the subtraction of `A` and `B` and returns the result;
    3. Function `Multiply` performs the multiplication of `A` and `B` and returns the result;
    4. Function `Divide` performs the division of `A` and `B` and returns the result.
2. Package `Operations.Test` contains the test environment:
    1. Procedure `Display` must use the functions from the parent (`Operations`) package as indicated by the template in the code below.

Listing 4: operations.ads

```
package Operations is

   --  Create specification for Operations package, including the
   --  declaration of the functions mentioned above.
   --

end Operations;
```

Listing 5: operations.adb

```
package body Operations is

   --  Create body of Operations package.
   --

end Operations;
```

Listing 6: operations-test.ads

```
package Operations.Test is

   --  Create specification for Operations package, including the
   --  declaration of the Display procedure:
   --
   --   procedure Display (A, B : Integer);
   --

end Operations.Test;
```

Listing 7: operations-test.adb

```
package body Operations.Test is

   --  Implement body of Operations.Test package.
   --

   procedure Display (A, B : Integer) is
      A_Str : constant String := Integer'Image (A);
      B_Str : constant String := Integer'Image (B);
```

(continues on next page)

(continued from previous page)

```
   begin
      Put_Line ("Operations:");
      Put_Line (A_Str & " + " & B_Str & " = "
                & Integer'Image (Add (A, B))
                & ",");
      --  Use the line above as a template and add the rest of the
      --  implementation for Subtract, Multiply and Divide.
   end Display;

end Operations.Test;
```

Listing 8: main.adb

```

with Operations;
with Operations.Test;  use Operations.Test;

procedure Main is

   type Test_Case_Index is
     (Operations_Chk,
      Operations_Display_Chk);

   procedure Check (TC : Test_Case_Index) is
   begin
      case TC is
         when Operations_Chk =>
            Put_Line ("Add (100, 2) = "
                      & Integer'Image (Operations.Add (100, 2)));
            Put_Line ("Subtract (100, 2) = "
                      & Integer'Image (Operations.Subtract (100, 2)));
            Put_Line ("Multiply (100, 2) = "
                      & Integer'Image (Operations.Multiply (100, 2)));
            Put_Line ("Divide (100, 2) = "
                      & Integer'Image (Operations.Divide (100, 2)));
         when Operations_Display_Chk =>
            Display (10, 5);
            Display ( 1, 2);
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

STRONGLY TYPED LANGUAGE

130.1 Colors

Goal: create a package to represent HTML colors in hexadecimal form and its corresponding names.

Steps:

1. Implement the `Color_Types` package.
    1. Declare the `HTML_Color` enumeration.
    2. Declare the `Basic_HTML_Color` enumeration.
    3. Implement the `To_Integer` function.
    4. Implement the `To_HTML_Color` function.

Requirements:

1. Enumeration `HTML_Color` has the following colors:
    - Salmon
    - Firebrick
    - Red
    - Darkred
    - Lime
    - Forestgreen
    - Green
    - Darkgreen
    - Blue
    - Mediumblue
    - Darkblue
2. Enumeration `Basic_HTML_Color` has the following colors: Red, Green, Blue.
3. Function `To_Integer` converts from the `HTML_Color` type to the HTML color code — as integer values in hexadecimal notation.
    - You can find the HTML color codes in the table below.
4. Function `To_HTML_Color` converts from `Basic_HTML_Color` to `HTML_Color`.
5. This is the table to convert from an HTML color to a HTML color code in hexadecimal notation:

Color	HTML color code (hexa)
Salmon	#FA8072
Firebrick	#B22222
Red	#FF0000
Darkred	#8B0000
Lime	#00FF00
Forestgreen	#228B22
Green	#008000
Darkgreen	#006400
Blue	#0000FF
Mediumblue	#0000CD
Darkblue	#00008B

Remarks:

1. In order to express the hexadecimal values above in Ada, use the following syntax: 16#<hex_value># (e.g.: `16#FFFFFF#`).
2. For function `To_Integer`, you may use a **`case`** for this.

Listing 1: color_types.ads

```
package Color_Types is

   --  Include type declaration for HTML_Color!
   --
   --  type HTML_Color is [...]
   --

   --  Include function declaration for:
   --  function To_Integer (C : HTML_Color) return Integer;

   --  Include type declaration for Basic_HTML_Color!
   --
   --  type Basic_HTML_Color is [...]
   --

   --  Include function declaration for:
   --  - Basic_HTML_Color => HTML_Color
   --
   --  function To_HTML_Color [...];
   --
end Color_Types;
```

Listing 2: color_types.adb

```
package body Color_Types is

   --  Implement the conversion from HTML_Color to Integer here!
   --
   --  function To_Integer (C : HTML_Color) return Integer is
   --  begin
   --  --  Hint: use 'case' for the HTML colors;
   --  --        use 16#...# for the hexadecimal values.
   --  end To_Integer;

   --  Implement the conversion from Basic_HTML_Color to HTML_Color here!
   --
   --  function To_HTML_Color [...] is
```

(continues on next page)

(continued from previous page)

```
   --
end Color_Types;
```

Listing 3: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;
with Ada.Integer_Text_IO;

with Color_Types; use Color_Types;

procedure Main is
   type Test_Case_Index is
     (HTML_Color_Range,
      HTML_Color_To_Integer,
      Basic_HTML_Color_To_HTML_Color);

   procedure Check (TC : Test_Case_Index) is
   begin
      case TC is
         when HTML_Color_Range =>
            for I in HTML_Color'Range loop
               Put_Line (HTML_Color'Image (I));
            end loop;
         when HTML_Color_To_Integer =>
            for I in HTML_Color'Range loop
               Ada.Integer_Text_IO.Put (Item  => To_Integer (I),
                                        Width => 6,
                                        Base  => 16);
               New_Line;
            end loop;
         when Basic_HTML_Color_To_HTML_Color =>
            for I in Basic_HTML_Color'Range loop
               Put_Line (HTML_Color'Image (To_HTML_Color (I)));
            end loop;
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

130.2 Integers

Goal: implement a package with various integer types.

Steps:

1. Implement the `Int_Types` package.
    1. Declare the integer type `I_100`.
    2. Declare the modular type `U_100`.
    3. Implement the `To_I_100` function to convert from the `U_100` type.
    4. Implement the `To_U_100` function to convert from the `I_100` type.
    5. Declare the derived type `D_50`.
    6. Declare the subtype `S_50`.
    7. Implement the `To_D_50` function to convert from the `I_100` type.
    8. Implement the `To_S_50` function to convert from the `I_100` type.
    9. Implement the `To_I_100` function to convert from the `D_50` type.

Requirements:

1. Types `I_100` and `U_100` have values between 0 and 100.
    1. Type `I_100` is an integer type.
    2. Type `U_100` is a modular type.
2. Function `To_I_100` converts from the `U_100` type to the `I_100` type.
3. Function `To_U_100` converts from the `I_100` type to the `U_100` type.
4. Types `D_50` and `S_50` have values between 10 and 50 and use `I_100` as a base type.
    1. `D_50` is a derived type.
    2. `S_50` is a subtype.
5. Function `To_D_50` converts from the `I_100` type to the `D_50` type.
6. Function `To_S_50` converts from the `I_100` type to the `S_50` type.
7. Functions `To_D_50` and `To_S_50` saturate the input values if they are out of range.
    - If the input is less than 10 the output should be 10.
    - If the input is greater than 50 the output should be 50.
8. Function `To_I_100` converts from the `D_50` type to the `I_100` type.

Remarks:

1. For the implementation of functions `To_D_50` and `To_S_50`, you may use the type attributes `D_50'First` and `D_50'Last`:
    1. `D_50'First` indicates the minimum value of the `D_50` type.
    2. `D_50'Last` indicates the maximum value of the `D_50` type.
    3. The same attributes are available for the `S_50` type (`S_50'First` and `S_50'Last`).
2. We could have implemented a function `To_I_100` as well to convert from `S_50` to `I_100`. However, we skip this here because explicit conversions are not needed for subtypes.

Listing 4: int_types.ads

```
package Int_Types is

   --  Include type declarations for I_100 and U_100!
   --
   --  type I_100 is [...]
   --  type U_100 is [...]
   --

   function To_I_100 (V : U_100) return I_100;

   function To_U_100 (V : I_100) return U_100;

   --  Include type declarations for D_50 and S_50!
   --
   --  [...] D_50 is [...]
   --  [...] S_50 is [...]
   --

   function To_D_50 (V : I_100) return D_50;

   function To_S_50 (V : I_100) return S_50;

   function To_I_100 (V : D_50) return I_100;

end Int_Types;
```

Listing 5: int_types.adb

```
package body Int_Types is

   function To_I_100 (V : U_100) return I_100 is
   begin
      --  Implement the conversion from U_100 to I_100 here!
      --
      null;
   end To_I_100;

   function To_U_100 (V : I_100) return U_100 is
   begin
      --  Implement the conversion from I_100 to U_100 here!
      --
      null;
   end To_U_100;

   function To_D_50 (V : I_100) return D_50 is
      Min : constant I_100 := I_100 (D_50'First);
      Max : constant I_100 := I_100 (D_50'Last);
   begin
      --  Implement the conversion from I_100 to D_50 here!
      --
      --  Hint: using the constants above simplifies the checks needed for
      --        this function.
      --
      null;
   end To_D_50;

   function To_S_50 (V : I_100) return S_50 is
   begin
      --  Implement the conversion from I_100 to S_50 here!
```

(continues on next page)

(continued from previous page)

```
      --

(continued from previous page)

```
102 end Main;
```

130.3 Temperatures

Goal: create a package to handle temperatures in Celsius and Kelvin.

Steps:

1. Implement the `Temperature_Types` package.
    1. Declare the `Celsius` type.
    2. Declare the `Int_Celsius` type.
    3. Implement the `To_Celsius` function.
    4. Implement the `To_Int_Celsius` function.
    5. Declare the `Kelvin` type.
    6. Implement the `To_Celsius` function to convert from the `Kelvin` type.
    7. Implement the `To_Kelvin` function.

Requirements:

1. The custom floating-point types declared in `Temperature_Types` must use a precision of six digits.
2. Types `Celsius` and `Int_Celsius` are used for temperatures in Celsius:
    1. `Celsius` is a floating-point type with a range between -273.15 and 5504.85.
    2. `Int_Celsius` is an integer type with a range between -273 and 5505.
3. Functions `To_Celsius` and `To_Int_Celsius` are used for type conversion:
    1. `To_Celsius` converts from `Int_Celsius` to `Celsius` type.
    2. `To_Int_Celsius` converts from `Celsius` and `Int_Celsius` types:
4. `Kelvin` is a floating-point type for temperatures in Kelvin using a range between 0.0 and 5778.0.
5. The functions `To_Celsius` and `To_Kelvin` are used to convert between temperatures in `Kelvin` and `Celsius`.
    1. In order to convert temperatures in Celsius to Kelvin, you must use the formula $K = C + 273.15$, where:
        - *K* is the temperature in Kelvin, and
        - *C* is the temperature in Celsius.

Remarks:

1. When implementing the `To_Celsius` function for the `Int_Celsius` type:
    1. You'll need to check for the minimum and maximum values of the input values because of the slightly different ranges.
    2. You may use variables of floating-point type (`Float`) for intermediate values.
2. For the implementation of the functions `To_Celsius` and `To_Kelvin` (used for converting between `Kelvin` and `Celsius`), you may use a variable of floating-point type (`Float`) for intermediate values.

Listing 7: temperature_types.ads

```
package Temperature_Types is

   --  Include type declaration for Celsius!
   --
   --  Celsius is [...];
       --  Int_Celsius is [...];
   --

   function To_Celsius (T : Int_Celsius) return Celsius;

   function To_Int_Celsius (T : Celsius) return Int_Celsius;

   --  Include type declaration for Kelvin!
   --
   --  type Kelvin is [...];
   --

   --  Include function declarations for:
   --  - Kelvin  => Celsius
   --  - Celsius => Kelvin
   --
   --  function To_Celsius [...];
   --  function To_Kelvin  [...];
   --
end Temperature_Types;
```

CHAPTER

ONE

RECORDS

131.1 Directions

Goal: create a package that handles directions and geometric angles.

Steps:

1. Implement the `Directions` package.
    1. Declare the `Ext_Angle` record.
    2. Implement the `Display` procedure.
    3. Implement the `To_Ext_Angle` function.

Requirements:

1. Record `Ext_Angle` stores information about the extended angle (see remark about *extended angles* below).
2. Procedure `Display` displays information about the extended angle.
    1. You should use the implementation that has been commented out (see code below) as a starting point.
3. Function `To_Ext_Angle` converts a simple angle value to an extended angle (`Ext_Angle` type).

Remarks:

1. We make use of the algorithm implemented in the `Check_Direction` procedure (*chapter on imperative language* (page 9)).
2. For the sake of this exercise, we use the concept of *extended angles*. This includes the actual geometric angle and the corresponding direction (North, South, Northwest, and so on).

Listing 1: directions.ads

```
1  package Directions is
2
3     type Angle_Mod is mod 360;
4
5     type Direction is
6       (North,
7        Northeast,
8        East,
9        Southeast,
10       South,
11       Southwest,
12       West,
13       Northwest);
```

(continues on next page)

(continued from previous page)

```

   function To_Direction (N: Angle_Mod) return Direction;

   --  Include type declaration for Ext_Angle record type:
   --
   --  NOTE: Use the Angle_Mod and Direction types declared above!
   --
   --  type Ext_Angle is [...]
   --

   function To_Ext_Angle (N : Angle_Mod) return Ext_Angle;

   procedure Display (N : Ext_Angle);

end Directions;
```

Listing 2: directions.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Directions is

   procedure Display (N : Ext_Angle) is
   begin
      --  Uncomment the code below and fill the missing elements
      --
      --  Put_Line ("Angle: "
      --            & Angle_Mod'Image (____)
      --            & " => "
      --            & Direction'Image (____)
      --            & ".");
      null;
   end Display;

   function To_Direction (N : Angle_Mod) return Direction is
   begin
      case N is
         when   0        => return North;
         when   1 ..  89 => return Northeast;
         when  90        => return East;
         when  91 .. 179 => return Southeast;
         when 180        => return South;
         when 181 .. 269 => return Southwest;
         when 270        => return West;
         when 271 .. 359 => return Northwest;
      end case;
   end To_Direction;

   function To_Ext_Angle (N : Angle_Mod) return Ext_Angle is
   begin
      --  Implement the conversion from Angle_Mod to Ext_Angle here!
      --
      --  Hint: you can use a return statement and an aggregate.
      --
      null;
   end To_Ext_Angle;

end Directions;
```

Listing 3: main.adb

```
with Ada.Command_Line;  use Ada.Command_Line;
with Ada.Text_IO;       use Ada.Text_IO;

with Directions;        use Directions;

procedure Main is
   type Test_Case_Index is
     (Direction_Chk);

   procedure Check (TC : Test_Case_Index) is
   begin
      case TC is
      when Direction_Chk =>
         Display (To_Ext_Angle (0));
         Display (To_Ext_Angle (30));
         Display (To_Ext_Angle (45));
         Display (To_Ext_Angle (90));
         Display (To_Ext_Angle (91));
         Display (To_Ext_Angle (120));
         Display (To_Ext_Angle (180));
         Display (To_Ext_Angle (250));
         Display (To_Ext_Angle (270));
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

131.2 Colors

Goal: create a package to represent HTML colors in RGB format using the hexadecimal form.

Steps:

1. Implement the `Color_Types` package.
    1. Declare the RGB record.
    2. Implement the `To_RGB` function.
    3. Implement the `Image` function for the RGB type.

Requirements:

1. The following table contains the HTML colors and the corresponding value in hexadecimal form for each color element:

Color	Red	Green	Blue
Salmon	#FA	#80	#72
Firebrick	#B2	#22	#22
Red	#FF	#00	#00
Darkred	#8B	#00	#00
Lime	#00	#FF	#00
Forestgreen	#22	#8B	#22
Green	#00	#80	#00
Darkgreen	#00	#64	#00
Blue	#00	#00	#FF
Mediumblue	#00	#00	#CD
Darkblue	#00	#00	#8B

2. The hexadecimal information of each HTML color can be mapped to three color elements: red, green and blue.
    1. Each color element has a value between 0 and 255, or `00` and FF in hexadecimal.
    2. For example, for the color *salmon*, the hexadecimal value of the color elements are:
        - red = FA,
        - green = 80, and
        - blue = 72.
3. Record RGB stores information about HTML colors in RGB format, so that we can retrieve the individual color elements.
4. Function `To_RGB` converts from the `HTML_Color` enumeration to the RGB type based on the information from the table above.
5. Function `Image` returns a string representation of the RGB type in this format:
    - `"(Red => 16#..#, Green => 16#...#, Blue => 16#...# )"`

Remarks:

1. We use the exercise on HTML colors from the previous lab on *Strongly typed language* (page 2217) as a starting point.

Listing 4: color_types.ads

```
package Color_Types is

   type HTML_Color is
     (Salmon,
      Firebrick,
      Red,
      Darkred,
      Lime,
      Forestgreen,
      Green,
      Darkgreen,
      Blue,
      Mediumblue,
      Darkblue);

   function To_Integer (C : HTML_Color) return Integer;

   type Basic_HTML_Color is
     (Red,
```

      SB : String (Str_Range);
   begin
      --  Replace argument in the calls to Put below
      --  with the missing elements (red, green, blue)
      --  from the RGB record
      --
      Ada.Integer_Text_IO.Put (To    => SR,
                               Item  => 0,    --  REPLACE!
                               Base  => 16);
      Ada.Integer_Text_IO.Put (To    => SG,
                               Item  => 0,    --  REPLACE!
                               Base  => 16);
      Ada.Integer_Text_IO.Put (To    => SB,
                               Item  => 0,    --  REPLACE!
                               Base  => 16);
      return ("(Red => " & SR
              & ", Green => " & SG
              & ", Blue => "  & SB
              &")");
   end Image;

end Color_Types;
```

Listing 6: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;

with Color_Types;      use Color_Types;

procedure Main is
   type Test_Case_Index is
     (HTML_Color_To_RGB);

   procedure Check (TC : Test_Case_Index) is
   begin
      case TC is
         when HTML_Color_To_RGB =>
            for I in HTML_Color'Range loop
               Put_Line (HTML_Color'Image (I) & " => "
                         & Image (To_RGB (I)) & ".");
            end loop;
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

131.3 Inventory

Goal: create a simplified inventory system for a store to enter items and keep track of assets.

Steps:

1. Implement the `Inventory_Pkg` package.
    1. Declare the `Item` record.
    2. Implement the `Init` function.
    3. Implement the `Add` procedure.

Requirements:

1. Record `Item` collects information about products from the store.
    1. To keep it simple, this record only contains the name, quantity and price of each item.
    2. The record components are:
        - `Name` of `Item_Name` type;
        - `Quantity` of **`Natural`** type;
        - `Price` of **`Float`** type.
2. Function `Init` returns an initialized item (of `Item` type).
    1. Function `Init` must also display the item name by calling the `To_String` function for the `Item_Name` type.
        - This is already implemented in the code below.
3. Procedure `Add` adds an item to the assets.
    1. Since we want to keep track of the assets, the implementation must accumulate the total value of each item's inventory, the result of multiplying the item quantity and its price.

Listing 7: inventory_pkg.ads

```
package Inventory_Pkg is

   type Item_Name is
     (Ballpoint_Pen, Oil_Based_Pen_Marker, Feather_Quill_Pen);

   function To_String (I : Item_Name) return String;

   --  Replace type declaration for Item record:
   --
   type Item is null record;

   function Init (Name     : Item_Name;
                  Quantity : Natural;
                  Price    : Float) return Item;

   procedure Add (Assets : in out Float;
                  I      : Item);

end Inventory_Pkg;
```

Listing 8: inventory_pkg.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Inventory_Pkg is

   function To_String (I : Item_Name) return String is
   begin
      case I is
         when Ballpoint_Pen        => return "Ballpoint Pen";
         when Oil_Based_Pen_Marker => return "Oil-based Pen Marker";
         when Feather_Quill_Pen    => return "Feather Quill Pen";
      end case;
   end To_String;

   function Init (Name     : Item_Name;
                  Quantity : Natural;
                  Price    : Float) return Item is
   begin
      Put_Line ("Item: " & To_String (Name) & ".");

      --  Replace return statement with the actual record initialization!
      --
      return (null record);
   end Init;

   procedure Add (Assets : in out Float;
                  I      : Item) is
   begin
      --  Implement the function that adds an item to the inventory here!
      --
      null;
   end Add;

end Inventory_Pkg;
```

Listing 9: main.adb

```
with Ada.Command_Line;  use Ada.Command_Line;
with Ada.Text_IO;       use Ada.Text_IO;

with Inventory_Pkg;     use Inventory_Pkg;

   --  Remark: the following line is not relevant.
   F   : array (1 .. 10) of Float := (others => 42.42);

   type Test_Case_Index is
     (Inventory_Chk);

   procedure Display (Assets : Float) is
      package F_IO is new Ada.Text_IO.Float_IO (Float);

      use F_IO;
   begin
      Put ("Assets: $");
      Put (Assets, 1, 2, 0);
      Put (".");
      New_Line;
   end Display;

```

(continues on next page)

(continued from previous page)

```
   procedure Check (TC : Test_Case_Index) is
      I      : Item;
      Assets : Float := 0.0;

      --  Please ignore the following three lines!
      pragma Warnings (Off, "default initialization");
      for Assets'Address use F'Address;
      pragma Warnings (On, "default initialization");
   begin
      case TC is
      when Inventory_Chk =>
         I := Init (Ballpoint_Pen,        185,  0.15);
         Add (Assets, I);
         Display (Assets);

         I := Init (Oil_Based_Pen_Marker, 100,  9.0);
         Add (Assets, I);
         Display (Assets);

         I := Init (Feather_Quill_Pen,      2, 40.0);
         Add (Assets, I);
         Display (Assets);
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

CHAPTER

TWO

ARRAYS

132.1 Constrained Array

Goal: declare a constrained array and implement operations on it.

Steps:

1. Implement the `Constrained_Arrays` package.
    1. Declare the range type `My_Index`.
    2. Declare the array type `My_Array`.
    3. Declare and implement the `Init` function.
    4. Declare and implement the `Double` procedure.
    5. Declare and implement the `First_Elem` function.
    6. Declare and implement the `Last_Elem` function.
    7. Declare and implement the `Length` function.
    8. Declare the object `A` of `My_Array` type.

Requirements:

1. Range type `My_Index` has a range from 1 to 10.
2. `My_Array` is a constrained array of `Integer` type.
    1. It must make use of the `My_Index` type.
    2. It is therefore limited to 10 elements.
3. Function `Init` returns an array where each element is initialized with the corresponding index.
4. Procedure `Double` doubles the value of each element of an array.
5. Function `First_Elem` returns the first element of the array.
6. Function `Last_Elem` returns the last element of the array.
7. Function `Length` returns the length of the array.
8. Object `A` of `My_Array` type is initialized with:
    1. the values 1 and 2 for the first two elements, and
    2. 42 for all other elements.

Listing 1: constrained_arrays.ads

```
package Constrained_Arrays is

   --  Complete the type and subprogram declarations:
   --
   --  type My_Index is [...]
   --
   --  type My_Array is [...]
   --
   --  function Init ...
   --
   --  procedure Double ...
   --
   --  function First_Elem ...
   --
   --  function Last_Elem ...
   --
   --  function Length ...
   --
   --  A : ...

end Constrained_Arrays;
```

Listing 2: constrained_arrays.adb

```
package body Constrained_Arrays is

   --  Create the implementation of the subprograms!
   --

end Constrained_Arrays;
```

Listing 3: main.adb

```
with Ada.Command_Line;   use Ada.Command_Line;
with Ada.Text_IO;        use Ada.Text_IO;

with Constrained_Arrays; use Constrained_Arrays;

procedure Main is
   type Test_Case_Index is
     (Range_Chk,
      Array_Range_Chk,
      A_Obj_Chk,
      Init_Chk,
      Double_Chk,
      First_Elem_Chk,
      Last_Elem_Chk,
      Length_Chk);

   procedure Check (TC : Test_Case_Index) is
      AA : My_Array;

      procedure Display (A : My_Array) is
      begin
         for I in A'Range loop
            Put_Line (Integer'Image (A (I)));
         end loop;
      end Display;

      procedure Local_Init (A : in out My_Array) is
```

(continues on next page)

(continued from previous page)

```
      begin
         A := (100, 90, 80, 10, 20, 30, 40, 60, 50, 70);
      end Local_Init;
   begin
      case TC is
      when Range_Chk =>
         for I in My_Index loop
            Put_Line (My_Index'Image (I));
         end loop;
      when Array_Range_Chk =>
         for I in My_Array'Range loop
            Put_Line (My_Index'Image (I));
         end loop;
      when A_Obj_Chk =>
         Display (A);
      when Init_Chk =>
         AA := Init;
         Display (AA);
      when Double_Chk =>
         Local_Init (AA);
         Double (AA);
         Display (AA);
      when First_Elem_Chk =>
         Local_Init (AA);
         Put_Line (Integer'Image (First_Elem (AA)));
      when Last_Elem_Chk =>
         Local_Init (AA);
         Put_Line (Integer'Image (Last_Elem (AA)));
      when Length_Chk =>
         Put_Line (Integer'Image (Length (AA)));
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

132.2 Colors: Lookup-Table

Goal: rewrite a package to represent HTML colors in RGB format using a lookup table.

Steps:

1. Implement the `Color_Types` package.
    1. Declare the array type `HTML_Color_RGB`.
    2. Declare the `To_RGB_Lookup_Table` object and initialize it.
    3. Adapt the implementation of the `To_RGB` function.

Requirements:

1. Array type `HTML_Color_RGB` is used for the table.

2. The `To_RGB_Lookup_Table` object of `HTML_Color_RGB` type contains the lookup table.
   - This table must be implemented as an array of constant values.
3. The implementation of the `To_RGB` function must use the `To_RGB_Lookup_Table` object.

Remarks:

1. This exercise is based on the HTML colors exercise from a previous lab (*Records* (page 2229)).
2. In the previous implementation, you could use a **`case`** statement to implement the `To_RGB` function. Here, you must rewrite the function using a look-up table.
   1. The implementation of the `To_RGB` function below includes the case statement as commented-out code. You can use this as your starting point: you just need to copy it and convert the case statement to an array declaration.
   1. Don't use a case statement to implement the `To_RGB` function. Instead, write code that accesses `To_RGB_Lookup_Table` to get the correct value.
3. The following table contains the HTML colors and the corresponding value in hexadecimal form for each color element:

Color	Red	Green	Blue
Salmon	#FA	#80	#72
Firebrick	#B2	#22	#22
Red	#FF	#00	#00
Darkred	#8B	#00	#00
Lime	#00	#FF	#00
Forestgreen	#22	#8B	#22
Green	#00	#80	#00
Darkgreen	#00	#64	#00
Blue	#00	#00	#FF
Mediumblue	#00	#00	#CD
Darkblue	#00	#00	#8B

Listing 4: color_types.ads

```
1  package Color_Types is
2
3     type HTML_Color is
4       (Salmon,
5        Firebrick,
6        Red,
7        Darkred,
8        Lime,
9        Forestgreen,
10       Green,
11       Darkgreen,
12       Blue,
13       Mediumblue,
14       Darkblue);
15
16    subtype Int_Color is Integer range 0 .. 255;
17
18    type RGB is record
19       Red   : Int_Color;
20       Green : Int_Color;
21       Blue  : Int_Color;
```

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

132.3 Unconstrained Array

Goal: declare an unconstrained array and implement operations on it.

Steps:

1. Implement the `Unconstrained_Arrays` package.
    1. Declare the `My_Array` type.
    2. Declare and implement the `Init` procedure.
    3. Declare and implement the `Init` function.

4. Declare and implement the `Double` procedure.
5. Declare and implement the `Diff_Prev_Elem` function.

Requirements:

1. `My_Array` is an unconstrained array (with a **`Positive`** range) of **`Integer`** elements.
2. Procedure `Init` initializes each element with the index starting with the last one.
   - For example, for an array of 3 elements where the index of the first element is 1 (`My_Array (1 .. 3)`), the values of these elements after a call to `Init` must be `(3, 2, 1)`.
3. Function `Init` returns an array based on the length `L` and start index `I` provided to the `Init` function.
   1. `I` indicates the index of the first element of the array.
   2. `L` indicates the length of the array.
   3. Both `I` and `L` must be positive.
   4. This is its declaration: `function Init (I, L : Positive) return My_Array;`.
   5. You must initialize the elements of the array in the same manner as for the `Init` procedure described above.
4. Procedure `Double` doubles each element of an array.
5. Function `Diff_Prev_Elem` returns — for each element of an input array `A` — an array with the difference between an element of array `A` and the previous element.
   1. For the first element, the difference must be zero.
   2. For example:
      - **INPUT**: `(2, 5, 15)`
      - **RETURN** of `Diff_Prev_Elem`: `(0, 3, 10)`, where
        - `0` is the constant difference for the first element;
        - `5 - 2 = 3` is the difference between the second and the first elements of the input array;
        - `15 - 5 = 10` is the difference between the third and the second elements of the input array.

Remarks:

1. For an array `A`, you can retrieve the index of the last element with the attribute `'Last`.
   1. For example: `Y : Positive := A'Last;`
   2. This can be useful during the implementation of procedure `Init`.
2. For the implementation of the `Init` function, you can call the `Init` procedure to initialize the elements. By doing this, you avoid code duplication.
3. Some hints about attributes:
   1. You can use the range attribute (`A'Range`) to retrieve the range of an array `A`.
   2. You can also use the range attribute in the declaration of another array (e.g.: `B : My_Array (A'Range)`).
   3. Alternatively, you can use the `A'First` and `A'Last` attributes in an array declaration.

Listing 7: unconstrained_arrays.ads

```
package Unconstrained_Arrays is

   --  Complete the type and subprogram declarations:
   --
   --  type My_Array is ...;
   --
   --  procedure Init ...;

   function Init (I, L : Positive) return My_Array;

   --  procedure Double ...;
   --
   --  function Diff_Prev_Elem ...;

end Unconstrained_Arrays;
```

Listing 8: unconstrained_arrays.adb

```
package body Unconstrained_Arrays is

   --  Implement the subprograms:
   --

   --  procedure Init is...

   --  function Init (L : Positive) return My_Array is...

   --  procedure Double ... is...

   --  function Diff_Prev_Elem ... is...

end Unconstrained_Arrays;
```

Listing 9: main.adb

```
with Ada.Command_Line;     use Ada.Command_Line;
with Ada.Text_IO;          use Ada.Text_IO;

with Unconstrained_Arrays; use Unconstrained_Arrays;

procedure Main is
   type Test_Case_Index is
     (Init_Chk,
      Init_Proc_Chk,
      Double_Chk,
      Diff_Prev_Chk,
      Diff_Prev_Single_Chk);

   procedure Check (TC : Test_Case_Index) is
      AA : My_Array (1 .. 5);
      AB : My_Array (5 .. 9);

      procedure Display (A : My_Array) is
      begin
         for I in A'Range loop
            Put_Line (Integer'Image (A (I)));
         end loop;
      end Display;

```

(continues on next page)

(continued from previous page)

```
      procedure Local_Init (A : in out My_Array) is
      begin
         A := (1, 2, 5, 10, -10);
      end Local_Init;

   begin
      case TC is
      when Init_Chk =>
         AA := Init (AA'First, AA'Length);
         AB := Init (AB'First, AB'Length);
         Display (AA);
         Display (AB);
      when Init_Proc_Chk =>
         Init (AA);
         Init (AB);
         Display (AA);
         Display (AB);
      when Double_Chk =>
         Local_Init (AB);
         Double (AB);
         Display (AB);
      when Diff_Prev_Chk =>
         Local_Init (AB);
         AB := Diff_Prev_Elem (AB);
         Display (AB);
      when Diff_Prev_Single_Chk =>
         declare
            A1 : My_Array (1 .. 1) := (1 => 42);
         begin
            A1 := Diff_Prev_Elem (A1);
            Display (A1);
         end;
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

132.4 Product info

Goal: create a system to keep track of quantities and prices of products.

Steps:

1. Implement the `Product_Info_Pkg` package.
    1. Declare the array type `Product_Infos`.
    2. Declare the array type `Currency_Array`.
    3. Implement the `Total` procedure.
    4. Implement the `Total` function returning an array of `Currency_Array` type.

5. Implement the `Total` function returning a single value of `Currency` type.

Requirements:

1. Quantity of an individual product is represented by the `Quantity` subtype.
2. Price of an individual product is represented by the `Currency` subtype.
3. Record type `Product_Info` deals with information for various products.
4. Array type `Product_Infos` is used to represent a list of products.
5. Array type `Currency_Array` is used to represent a list of total values of individual products (see more details below).
6. Procedure `Total` receives an input array of products.
    1. It outputs an array with the total value of each product using the `Currency_Array` type.
    2. The total value of an individual product is calculated by multiplying the quantity for this product by its price.
7. Function `Total` returns an array of `Currency_Array` type.
    1. This function has the same purpose as the procedure `Total`.
    2. The difference is that the function returns an array instead of providing this array as an output parameter.
8. The second function `Total` returns a single value of `Currency` type.
    1. This function receives an array of products.
    2. It returns a single value corresponding to the total value for all products in the system.

Remarks:

1. You can use `Currency (Q)` to convert from an element `Q` of `Quantity` type to the `Currency` type.
    1. As you might remember, Ada requires an explicit conversion in calculations where variables of both integer and floating-point types are used.
    2. In our case, the `Quantity` subtype is based on the **`Integer`** type and the `Currency` subtype is based on the **`Float`** type, so a conversion is necessary in calculations using those types.

Listing 10: product_info_pkg.ads

```
package Product_Info_Pkg is

   subtype Quantity is Natural;

   subtype Currency is Float;

   type Product_Info is record
      Units : Quantity;
      Price : Currency;
   end record;

   --  Complete the type declarations:
   --
   --  type Product_Infos is ...
   --
   --  type Currency_Array is ...

   procedure Total (P   : Product_Infos;
```

(continues on next page)

(continued from previous page)

```
                    Tot : out Currency_Array);

   function Total (P : Product_Infos) return Currency_Array;

   function Total (P : Product_Infos) return Currency;

end Product_Info_Pkg;
```

Listing 11: product_info_pkg.adb

```
package body Product_Info_Pkg is

   --  Complete the subprogram implementations:
   --

   --  procedure Total (P   : Product_Infos;
   --                   Tot : out Currency_Array) is ...

   --  function Total (P : Product_Infos) return Currency_Array is ...

   --  function Total (P : Product_Infos) return Currency is ...

end Product_Info_Pkg;
```

Listing 12: main.adb

```
with Ada.Command_Line;   use Ada.Command_Line;
with Ada.Text_IO;        use Ada.Text_IO;

with Product_Info_Pkg;   use Product_Info_Pkg;

procedure Main is
   package Currency_IO is new Ada.Text_IO.Float_IO (Currency);

      Tot  : Currency;

      procedure Display (Tots : Currency_Array) is
      begin
         for I in Tots'Range loop
            Currency_IO.Put (Tots (I));
            New_Line;
         end loop;
      end Display;

      procedure Local_Init (P : in out Product_Infos) is
      begin
         P := ((1,   0.5),
               (2,  10.0),
               (5,  40.0),
               (10, 10.0),
```

(continues on next page)

(continued from previous page)

```
               (10, 20.0));
      end Local_Init;

   begin
      Currency_IO.Default_Fore := 1;
      Currency_IO.Default_Aft  := 2;
      Currency_IO.Default_Exp  := 0;

      case TC is
      when Total_Func_Chk =>
         Local_Init (P);
         Tots := Total (P);
         Display (Tots);
      when Total_Proc_Chk =>
         Local_Init (P);
         Total (P, Tots);
         Display (Tots);
      when Total_Value_Chk =>
         Local_Init (P);
         Tot := Total (P);
         Currency_IO.Put (Tot);
         New_Line;
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

132.5 String_10

Goal: work with constrained string types.

Steps:

1. Implement the `Strings_10` package.
    1. Declare the `String_10` type.
    2. Implement the `To_String_10` function.

Requirements:

1. The constrained string type `String_10` is an array of ten characters.
2. Function `To_String_10` returns constrained strings of `String_10` type based on an input parameter of **`String`** type.
    - For strings that are more than 10 characters, omit everything after the 11th character.
    - For strings that are fewer than 10 characters, pad the string with ' ' characters until it is 10 characters.

Remarks:

1. Declaring `String_10` as a subtype of **`String`** is the easiest way.
   - You may declare it as a new type as well. However, this requires some adaptations in the `Main` test procedure.
2. You can use **`Integer`**`'Min` to calculate the minimum of two integer values.

Listing 13: strings_10.ads

```
package Strings_10 is

   --  Complete the type and subprogram declarations:
   --

   --  subtype String_10 is ...;

   --  Using "type String_10 is..." is possible, too. However, it
   --  requires a custom Put_Line procedure that is called in Main:
   --  procedure Put_Line (S : String_10);

   --  function To_String_10 ...;

end Strings_10;
```

Listing 14: strings_10.adb

```
package body Strings_10 is

   --  Complete the subprogram declaration and implementation:
   --
   --  function To_String_10 ... is

end Strings_10;
```

Listing 15: main.adb

```
with Ada.Command_Line;   use Ada.Command_Line;
with Ada.Text_IO;        use Ada.Text_IO;

with Strings_10;         use Strings_10;

procedure Main is
   type Test_Case_Index is
     (String_10_Long_Chk,
      String_10_Short_Chk);

   procedure Check (TC : Test_Case_Index) is
      SL   : constant String := "And this is a long string just for testing...";
      SS   : constant String := "Hey!";
      S_10 : String_10;

   begin
      case TC is
      when String_10_Long_Chk =>
         S_10 := To_String_10 (SL);
         Put_Line (String (S_10));
      when String_10_Short_Chk =>
         S_10 := (others => ' ');
         S_10 := To_String_10 (SS);
         Put_Line (String (S_10));
      end case;
   end Check;
```

(continues on next page)

(continued from previous page)

```
27
28 begin
29    if Argument_Count < 1 then
30       Ada.Text_IO.Put_Line ("ERROR: missing arguments! Exiting...");
31       return;
32    elsif Argument_Count > 1 then
33       Ada.Text_IO.Put_Line ("Ignoring additional arguments...");
34    end if;
35
36    Check (Test_Case_Index'Value (Argument (1)));
37 end Main;
```

132.6 List of Names

Goal: create a system for a list of names and ages.

Steps:

1. Implement the `Names_Ages` package.
    1. Declare the `People_Array` array type.
    2. Complete the declaration of the `People` record type with the `People_A` element of `People_Array` type.
    3. Implement the `Add` procedure.
    4. Implement the `Reset` procedure.
    5. Implement the `Get` function.
    6. Implement the `Update` procedure.
    7. Implement the `Display` procedure.

Requirements:

1. Each person is represented by the `Person` type, which is a record containing the name and the age of that person.
2. `People_Array` is an unconstrained array of `Person` type with a positive range.
3. The `Max_People` constant is set to 10.
4. Record type `People` contains:
    1. The `People_A` element of `People_Array` type.
    2. This array must be constrained by the `Max_People` constant.
5. Procedure `Add` adds a person to the list.
    1. By default, the age of this person is set to zero in this procedure.
6. Procedure `Reset` resets the list.
7. Function `Get` retrieves the age of a person from the list.
8. Procedure `Update` updates the age of a person in the list.
9. Procedure `Display` shows the complete list using the following format:
    1. The first line must be `LIST OF NAMES:`. It is followed by the name and age of each person in the next lines.
    2. For each person on the list, the procedure must display the information in the following format:

```
NAME: XXXX
AGE: YY
```

Remarks:

1. In the implementation of procedure Add, you may use an index to indicate the last valid position in the array — see `Last_Valid` in the code below.
2. In the implementation of procedure `Display`, you should use the `Trim` function from the `Ada.Strings.Fixed` package to format the person's name — for example: `Trim (P.Name, Right)`.
3. You may need the `Integer'Min (A, B)` and the `Integer'Max (A, B)` functions to get the minimum and maximum values in a comparison between two integer values A and B.
4. Fixed-length strings can be initialized with whitespaces using the **others** syntax. For example: `S : String_10 := (others => ' ');`
5. You may implement additional subprograms to deal with other types declared in the `Names_Ages` package below, such as the `Name_Type` and the `Person` type.
    1. For example, a function `To_Name_Type` to convert from **String** to `Name_Type` might be useful.
    2. Take a moment to reflect on which additional subprograms could be useful as well.

Listing 16: names_ages.ads

```
package Names_Ages is

   Max_People : constant Positive := 10;

   subtype Name_Type is String (1 .. 50);

   type Age_Type is new Natural;

   type Person is record
      Name  : Name_Type;
      Age   : Age_Type;
   end record;

   --  Add type declaration for People_Array record:
   --
   --  type People_Array is ...;

   --  Replace type declaration for People record. You may use the
   --  following template:
   --
   --  type People is record
   --     People_A   : People_Array ...;
   --     Last_Valid : Natural;
   --  end record;
   --
   type People is null record;

   procedure Reset (P : in out People);

   procedure Add (P    : in out People;
                  Name : String);

   function Get (P    : People;
                 Name : String) return Age_Type;

```

         Reset (P);
         Add (P, "John");
         Add (P, "Patricia");
         Add (P, "Josh");
         Display (P);
         Update (P, "John",     18);
         Update (P, "Patricia", 35);
         Update (P, "Josh",     53);
         Display (P);
      when Get_Age_Chk =>
         Reset (P);
         Add (P, "Peter");
         Update (P, "Peter", 45);
         Put_Line ("Peter is "
                   & Age_Type'Image (Get (P, "Peter"))
                   & " years old.");
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Ada.Text_IO.Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Ada.Text_IO.Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

CHAPTER

THREE

MORE ABOUT TYPES

133.1 Aggregate Initialization

Goal: initialize records and arrays using aggregates.

Steps:

1. Implement the `Aggregates` package.
    1. Create the record type Rec.
    2. Create the array type `Int_Arr`.
    3. Implement the `Init` procedure that outputs a record of Rec type.
    4. Implement the `Init_Some` procedure.
    5. Implement the `Init` procedure that outputs an array of `Int_Arr` type.

Requirements:

1. Record type Rec has four components of **`Integer`** type. These are the components with the corresponding default values:
    - `W` = 10
    - `X` = 11
    - `Y` = 12
    - `Z` = 13
2. Array type `Int_Arr` has 20 elements of **`Integer`** type (with indices ranging from 1 to 20).
3. The first `Init` procedure outputs a record of Rec type where:
    1. `X` is initialized with 100,
    2. `Y` is initialized with 200, and
    3. the remaining elements use their default values.
4. Procedure `Init_Some` outputs an array of `Int_Arr` type where:
    1. the first five elements are initialized with the value 99, and
    2. the remaining elements are initialized with the value 100.
5. The second `Init` procedure outputs an array of `Int_Arr` type where:
    1. all elements are initialized with the value 5.

Listing 1: aggregates.ads

```
package Aggregates is

   --  type Rec is ...;

   --  type Int_Arr is ...;

   procedure Init;

   --  procedure Init_Some ...;

   --  procedure Init ...;

end Aggregates;
```

Listing 2: aggregates.adb

```
package body Aggregates is

   procedure Init is null;

end Aggregates;
```

Listing 3: main.adb

```
with Ada.Command_Line;  use Ada.Command_Line;
with Ada.Text_IO;       use Ada.Text_IO;

with Aggregates;        use Aggregates;

procedure Main is
   --  Remark: the following line is not relevant.
   F   : array (1 .. 10) of Float := (others => 42.42)
     with Unreferenced;

   type Test_Case_Index is
     (Default_Rec_Chk,
      Init_Rec_Chk,
      Init_Some_Arr_Chk,
      Init_Arr_Chk);

   procedure Check (TC : Test_Case_Index) is
      A : Int_Arr;
      R : Rec;
      DR : constant Rec := (others => <>);
   begin
      case TC is
         when Default_Rec_Chk =>
            R := DR;
            Put_Line ("Record Default:");
            Put_Line ("W => " & Integer'Image (R.W));
            Put_Line ("X => " & Integer'Image (R.X));
            Put_Line ("Y => " & Integer'Image (R.Y));
            Put_Line ("Z => " & Integer'Image (R.Z));
         when Init_Rec_Chk =>
            Init (R);
            Put_Line ("Record Init:");
            Put_Line ("W => " & Integer'Image (R.W));
            Put_Line ("X => " & Integer'Image (R.X));
            Put_Line ("Y => " & Integer'Image (R.Y));
```

(continues on next page)

(continued from previous page)

```
            Put_Line ("Z => " & Integer'Image (R.Z));
         when Init_Some_Arr_Chk =>
            Init_Some (A);
            Put_Line ("Array Init_Some:");
            for I in A'Range loop
               Put_Line (Integer'Image (I) & " "
                         & Integer'Image (A (I)));
            end loop;
         when Init_Arr_Chk =>
            Init (A);
            Put_Line ("Array Init:");
            for I in A'Range loop
               Put_Line (Integer'Image (I) & " "
                         & Integer'Image (A (I)));
            end loop;
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

133.2 Versioning

Goal: implement a simple package for source-code versioning.

Steps:

1. Implement the `Versioning` package.
    1. Declare the record type `Version`.
    2. Implement the `Convert` function that returns a string.
    3. Implement the `Convert` function that returns a floating-point number.

Requirements:

1. Record type `Version` has the following components of **`Natural`** type:
    1. `Major`,
    2. `Minor`, and
    3. `Maintenance`.
2. The first `Convert` function returns a string containing the version number.
3. The second `Convert` function returns a floating-point value.
    1. For this floating-point value:
        1. the number before the decimal point must correspond to the major number, and
        2. the number after the decimal point must correspond to the minor number.

3. the maintenance number is ignored.

2. For example, version "1.3.5" is converted to the floating-point value `1.3`.
3. An obvious limitation of this function is that it can only handle one-digit numbers for the minor component.
   - For example, we cannot convert version "1.10.0" to a reasonable value with the approach described above. The result of the call `Convert ((1, 10, 0))` is therefore unspecified.
   - For the scope of this exercise, only version numbers with one-digit components are checked.

Remarks:

1. We use overloading for the `Convert` functions.
2. For the function `Convert` that returns a string, you can make use of the `Image_Trim` function, as indicated in the source-code below — see package body of `Versioning`.

Listing 4: versioning.ads

```
package Versioning is

   --  type Version is record...

   --  function Convert ...

   --  function Convert

end Versioning;
```

Listing 5: versioning.adb

```
with Ada.Strings; use Ada.Strings;
with Ada.Strings.Fixed; use Ada.Strings.Fixed;

package body Versioning is

   function Image_Trim (N : Natural) return String is
      S_N : constant String := Trim (Natural'Image (N), Left);
   begin
      return S_N;
   end Image_Trim;

   --  function Convert ...
   --     S_Major : constant String := Image_Trim (V.Major);
   --     S_Minor : constant String := Image_Trim (V.Minor);
   --     S_Maint : constant String := Image_Trim (V.Maintenance);
   --  begin
   --  end Convert;

   --  function Convert ...
   --  begin
   --  end Convert;

end Versioning;
```

Listing 6: main.adb

```
with Ada.Command_Line;  use Ada.Command_Line;
with Ada.Text_IO;       use Ada.Text_IO;

```

(continues on next page)

(continued from previous page)

```
with Versioning;        use Versioning;

procedure Main is
   type Test_Case_Index is
     (Ver_String_Chk,
      Ver_Float_Chk);

   procedure Check (TC : Test_Case_Index) is
      V : constant Version := (1, 3, 23);
   begin
      case TC is
         when Ver_String_Chk =>
            Put_Line (Convert (V));
         when Ver_Float_Chk =>
            Put_Line (Float'Image (Convert (V)));
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

133.3 Simple todo list

Goal: implement a simple to-do list system.

Steps:

1. Implement the `Todo_Lists` package.
    1. Declare the `Todo_Item` type.
    2. Declare the `Todo_List` type.
    3. Implement the `Add` procedure.
    4. Implement the `Display` procedure.

Requirements:

1. `Todo_Item` type is used to store a to-do item.
    1. It should be implemented as an access type to strings.
2. `Todo_Items` type is an array of to-do items.
    1. It should be implemented as an unconstrained array with positive range.
3. `Todo_List` type is the container for all to-do items.
    1. This record type must have a discriminant for the maximum number of elements of the list.
    2. In order to store the to-do items, it must contain a component named `Items` of `Todo_Items` type.
    3. Don't forget to keep track of the last element added to the list!

    - You should declare a `Last` component in the record.

4. Procedure `Add` adds items (of `Todo_Item` type) to the list (of `Todo_List` type).
    1. This requires allocating a string for the access type.
    2. An item can only be added to the list if the list isn't full yet — see next point for details on error handling.
5. Since the number of items that can be stored on the list is limited, the list might eventually become full in a call to `Add`.
    1. You must write code in the implementation of the `Add` procedure that verifies this condition.
    2. If the procedure detects that the list is full, it must display the following message: "ERROR: list is full!".
6. Procedure `Display` is used to display all to-do items.
    1. The header (first line) must be `TO-DO LIST`.
    2. It must display one item per line.

Remarks:

1. We use access types and unconstrained arrays in the implementation of the `Todo_Lists` package.

Listing 7: todo_lists.ads

```
package Todo_Lists is

   --  Replace by actual type declaration
   type Todo_Item is null record;

   --  Replace by actual type declaration
   type Todo_Items is null record;

   --  Replace by actual type declaration
   type Todo_List is null record;

   procedure Add (Todos : in out Todo_List;
                  Item  : String);

   procedure Display (Todos : Todo_List);

end Todo_Lists;
```

Listing 8: todo_lists.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Todo_Lists is

   procedure Add (Todos : in out Todo_List;
                  Item  : String) is
   begin
      Put_Line ("ERROR: list is full!");
   end Add;

   procedure Display (Todos : Todo_List) is
   begin
      null;
   end Display;
```

(continues on next page)

(continued from previous page)

```
15
16 end Todo_Lists;
```

Listing 9: main.adb

```
1  with Ada.Command_Line;  use Ada.Command_Line;
2  with Ada.Text_IO;       use Ada.Text_IO;
3
4  with Todo_Lists;        use Todo_Lists;
5
6  procedure Main is
7     type Test_Case_Index is
8       (Todo_List_Chk);
9
10    procedure Check (TC : Test_Case_Index) is
11       T : Todo_List (10);
12    begin
13       case TC is
14          when Todo_List_Chk =>
15             Add (T, "Buy milk");
16             Add (T, "Buy tea");
17             Add (T, "Buy present");
18             Add (T, "Buy tickets");
19             Add (T, "Pay electricity bill");
20             Add (T, "Schedule dentist appointment");
21             Add (T, "Call sister");
22             Add (T, "Revise spreasheet");
23             Add (T, "Edit entry page");
24             Add (T, "Select new design");
25             Add (T, "Create upgrade plan");
26             Display (T);
27       end case;
28    end Check;
29
30 begin
31    if Argument_Count < 1 then
32       Put_Line ("ERROR: missing arguments! Exiting...");
33       return;
34    elsif Argument_Count > 1 then
35       Put_Line ("Ignoring additional arguments...");
36    end if;
37
38    Check (Test_Case_Index'Value (Argument (1)));
39 end Main;
```

133.4 Price list

Goal: implement a list containing prices

Steps:

1. Implement the `Price_Lists` package.
    1. Declare the `Price_Type` type.
    2. Declare the `Price_List` record.
    3. Implement the `Reset` procedure.
    4. Implement the `Add` procedure.

5. Implement the `Get` function.
6. Implement the `Display` procedure.

Requirements:

1. `Price_Type` is a decimal fixed-point data type with a delta of two digits (e.g. `0.01`) and twelve digits in total.
2. `Price_List` is a record type that contains the price list.
    1. This record type must have a discriminant for the maximum number of elements of the list.
3. Procedure `Reset` resets the list.
4. Procedure `Add` adds a price to the list.
    1. You should keep track of the last element added to the list.
5. Function `Get` retrieves a price from the list using an index.
    1. This function returns a record instance of `Price_Result` type.
    2. `Price_Result` is a variant record containing:
        1. the Boolean component `Ok`, and
        2. the component `Price` (of `Price_Type`).
    3. The returned value of `Price_Result` type is one of the following:
        1. If the index specified in a call to `Get` contains a valid (initialized) price, then
            - `Ok` is set to **`True`**, and
            - the `Price` component contains the price for that index.
        2. Otherwise:
            - `Ok` is set to **`False`**, and
            - the `Price` component is not available.
6. Procedure `Display` shows all prices from the list.
    1. The header (first line) must be `PRICE LIST`.
    2. The remaining lines contain one price per line.
    3. For example:
        - For the following code:

```
procedure Test is
   L : Price_List (10);
begin
   Reset (L);
   Add (L, 1.45);
   Add (L, 2.37);
   Display (L);
end Test;
```

        - The output is:

```
PRICE LIST
 1.45
 2.37
```

Remarks:

1. To implement the package, you'll use the following features of the Ada language:

1. decimal fixed-point types;
2. records with discriminants;
3. dynamically-sized record types;
4. variant records.

2. For record type `Price_List`, you may use an unconstrained array as a component of the record and use the discriminant in the component declaration.

Listing 10: price_lists.ads

```
package Price_Lists is

   --  Replace by actual type declaration
   type Price_Type is new Float;

   --  Replace by actual type declaration
   type Price_List is null record;

   --  Replace by actual type declaration
   type Price_Result is null record;

   procedure Reset (Prices : in out Price_List);

   procedure Add (Prices : in out Price_List;
                  Item   : Price_Type);

   function Get (Prices : Price_List;
                 Idx    : Positive) return Price_Result;

   procedure Display (Prices : Price_List);

end Price_Lists;
```

Listing 11: price_lists.adb

```
package body Price_Lists is

   procedure Reset (Prices : in out Price_List) is
   begin
      null;
   end Reset;

   procedure Add (Prices : in out Price_List;
                  Item   : Price_Type) is
   begin
      null;
   end Add;

   function Get (Prices : Price_List;
                 Idx    : Positive) return Price_Result is
   begin
      null;
   end Get;

   procedure Display (Prices : Price_List) is
   begin
      null;
   end Display;

end Price_Lists;
```

Listing 12: main.adb

```
with Ada.Command_Line;  use Ada.Command_Line;
with Ada.Text_IO;       use Ada.Text_IO;

with Price_Lists;       use Price_Lists;

procedure Main is
   type Test_Case_Index is
     (Price_Type_Chk,

CHAPTER

FOUR

PRIVACY

134.1 Directions

Goal: create a package that handles directions and geometric angles using a previous implementation.

Steps:

1. Fix the implementation of the `Test_Directions` procedure.

Requirements:

1. The implementation of the `Test_Directions` procedure must compile correctly.

Remarks:

1. This exercise is based on the *Directions* exercise from the *Records* (page 2229) labs.
    1. In this version, however, `Ext_Angle` is a private type.
2. In the implementation of the `Test_Directions` procedure below, the Ada developer tried to initialize `All_Directions` — an array of `Ext_Angle` type — with aggregates.
    1. Since we now have a private type, the compiler complains about this initialization.
3. To fix the implementation of the `Test_Directions` procedure, you should use the appropriate function from the `Directions` package.
4. The initialization of `All_Directions` in the code below contains a consistency error where the angle doesn't match the assessed direction.
    1. See if you can spot this error!
    2. This kind of errors can happen when record components that have correlated information are initialized individually without consistency checks — using private types helps to avoid the problem by requiring initialization routines that can enforce consistency.

Listing 1: directions.ads

```
package Directions is

   type Angle_Mod is mod 360;

   type Direction is
     (North,
      Northwest,
      West,
      Southwest,
      South,
      Southeast,
      East);
```

(continues on next page)

(continued from previous page)

```
13
14    function To_Direction (N : Angle_Mod) return Direction;
15
16    type Ext_Angle is private;
17
18    function To_Ext_Angle (N : Angle_Mod) return Ext_Angle;
19
20    procedure Display (N : Ext_Angle);
21
22 private
23
24    type Ext_Angle is record
25       Angle_Elem     : Angle_Mod;
26       Direction_Elem : Direction;
27    end record;
28
29 end Directions;
```

Listing 2: directions.adb

```
1  with Ada.Text_IO; use Ada.Text_IO;
2
3  package body Directions is
4
5     procedure Display (N : Ext_Angle) is
6     begin
7        Put_Line ("Angle: "
8                  & Angle_Mod'Image (N.Angle_Elem)
9                  & " => "
10                 & Direction'Image (N.Direction_Elem)
11                 & ".");
12    end Display;
13
14    function To_Direction (N : Angle_Mod) return Direction is
15    begin
16       case N is
17          when   0        => return East;
18          when   1 ..  89 => return Northwest;
19          when  90        => return North;
20          when  91 .. 179 => return Northwest;
21          when 180        => return West;
22          when 181 .. 269 => return Southwest;
23          when 270        => return South;
24          when 271 .. 359 => return Southeast;
25       end case;
26    end To_Direction;
27
28    function To_Ext_Angle (N : Angle_Mod) return Ext_Angle is
29    begin
30       return (Angle_Elem     => N,
31               Direction_Elem => To_Direction (N));
32    end To_Ext_Angle;
33
34 end Directions;
```

Listing 3: test_directions.adb

```
1  with Directions; use Directions;
2
3  procedure Test_Directions is
```

(continues on next page)

(continued from previous page)

```
   type Ext_Angle_Array is array (Positive range <>) of Ext_Angle;

   All_Directions : constant Ext_Angle_Array (1 .. 6)
     := ((0,   East),
         (45,  Northwest),
         (90,  North),
         (91,  North),
         (180, West),
         (270, South));

begin
   for I in All_Directions'Range loop
      Display (All_Directions (I));
   end loop;

end Test_Directions;
```

Listing 4: main.adb

```
with Ada.Command_Line;  use Ada.Command_Line;
with Ada.Text_IO;       use Ada.Text_IO;

with Test_Directions;

procedure Main is
     type Test_Case_Index is
     (Direction_Chk);

   procedure Check (TC : Test_Case_Index) is
   begin
      case TC is
      when Direction_Chk =>
         Test_Directions;
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

134.2 Limited Strings

Goal: work with `limited private` types.

Steps:

1. Implement the `Limited_Strings` package.
    1. Implement the `Copy` function.
    2. Implement the `=` operator.

Requirements:

1. For both Copy and =, the two parameters may refer to strings with different lengths. We'll limit the implementation to just take the minimum length:
    1. In case of copying the string "Hello World" to a string with 5 characters, the copied string is "Hello":

```
   S1 : constant Lim_String := Init ("Hello World");
   S2 :          Lim_String := Init (5);
begin
   Copy (From => S1, To => S2);
   Put_Line (S2);     --  This displays "Hello".
```

    2. When comparing "Hello World" to "Hello", the = operator indicates that these strings are equivalent:

```
   S1 : constant Lim_String := Init ("Hello World");
   S2 : constant Lim_String := Init ("Hello");
begin
   if S1 = S2 then
      --  True => This branch gets selected.
```

2. When copying from a short string to a longer string, the remaining characters of the longer string must be initialized with underscores (_). For example:

```
   S1 : constant Lim_String := Init ("Hello");
   S2 :          Lim_String := Init (10);
begin
   Copy (From => S1, To => S2);
   Put_Line (S2);     --  This displays "Hello_____".
```

Remarks:

1. As we've discussed in the course:
    1. Variables of limited types have the following limitations:
        - they cannot be assigned to;
        - they don't have an equality operator (=).
    2. We can, however, define our own, custom subprograms to circumvent these limitations:
        - In order to copy instances of a limited type, we can define a custom Copy procedure.
        - In order to compare instances of a limited type, we can define an = operator.
2. You can use the Min_Last constant — which is already declared in the implementation of these subprograms — in the code you write.
3. Some details about the Limited_Strings package:
    1. The Lim_String type acts as a container for strings.
        1. In the the private part, Lim_String is declared as an access type to a **String**.
    2. There are two versions of the Init function that initializes an object of Lim_String type:
        1. The first one takes another string.
        2. The second one receives the number of characters for a string *container*.
    3. Procedure Put_Line displays object of Lim_String type.
    4. The design and implementation of the Limited_Strings package is very simplistic.

1. A good design would have better handling of access types, for example.

Listing 5: limited_strings.ads

```
package Limited_Strings is

   type Lim_String is limited private;

   function Init (S : String) return Lim_String;

   function Init (Max : Positive) return Lim_String;

   procedure Put_Line (LS : Lim_String);

   procedure Copy (From :        Lim_String;
                   To   : in out Lim_String);

   function "=" (Ref, Dut : Lim_String) return Boolean;

private

   type Lim_String is access String;

end Limited_Strings;
```

Listing 6: limited_strings.adb

```
with Ada.Text_IO;

package body Limited_Strings
is

   function Init (S : String) return Lim_String is
      LS : constant Lim_String := new String'(S);
   begin
      return Ls;
   end Init;

   function Init (Max : Positive) return Lim_String is
      LS : constant Lim_String := new String (1 .. Max);
   begin
      LS.all := (others => '_');
      return LS;
   end Init;

   procedure Put_Line (LS : Lim_String) is
   begin
      Ada.Text_IO.Put_Line (LS.all);
   end Put_Line;

   function Get_Min_Last (A, B : Lim_String) return Positive is
   begin
      return Positive'Min (A'Last, B'Last);
   end Get_Min_Last;

   procedure Copy (From :        Lim_String;
                   To   : in out Lim_String) is
      Min_Last : constant Positive := Get_Min_Last (From, To);
   begin
      --  Complete the implementation!
      null;
   end;
```

(continues on next page)

(continued from previous page)

```

   function "=" (Ref, Dut : Lim_String) return Boolean is
      Min_Last : constant Positive := Get_Min_Last (Ref, Dut);
   begin
      --  Complete the implementation!
      return True;
   end;

end Limited_Strings;
```

Listing 7: check_lim_string.adb

```
with Ada.Text_IO;     use Ada.Text_IO;

with Limited_Strings; use Limited_Strings;

procedure Check_Lim_String is
   S  : constant String := "----------";
   S1 : constant Lim_String := Init ("Hello World");
   S2 : constant Lim_String := Init (30);
   S3 : Lim_String := Init (5);
   S4 : Lim_String := Init (S & S & S);
begin
   Put ("S1 => ");
   Put_Line (S1);
   Put ("S2 => ");
   Put_Line (S2);

   if S1 = S2 then
      Put_Line ("S1 is equal to S2.");
   else
      Put_Line ("S1 isn't equal to S2.");
   end if;

   Copy (From => S1, To => S3);
   Put ("S3 => ");
   Put_Line (S3);

   if S1 = S3 then
      Put_Line ("S1 is equal to S3.");
   else
      Put_Line ("S1 isn't equal to S3.");
   end if;

   Copy (From => S1, To => S4);
   Put ("S4 => ");
   Put_Line (S4);

   if S1 = S4 then
      Put_Line ("S1 is equal to S4.");
   else
      Put_Line ("S1 isn't equal to S4.");
   end if;
end Check_Lim_String;
```

Listing 8: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;

```

(continues on next page)

(continued from previous page)

```
with Check_Lim_String;

procedure Main is
   type Test_Case_Index is
     (Lim_String_Chk);

   procedure Check (TC : Test_Case_Index) is
   begin
      case TC is
      when Lim_String_Chk =>
         Check_Lim_String;
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

134.3 Bonus exercise

In previous labs, we had many source-code snippets containing records that could be declared private. The source-code for the exercise above (*Directions*) is an example: we've modified the type declaration of `Ext_Angle`, so that the record is now private. Encapsulating the record components — by declaring record components in the private part — makes the code safer. Also, because many of the code snippets weren't making use of record components directly (but handling record types via the API instead), they continue to work fine after these modifications.

This exercise doesn't contain any source-code. In fact, the **goal** here is to modify previous labs, so that the record declarations are made private. You can look into those labs, modify the type declarations, and recompile the code. The corresponding test-cases must still pass.

If no other changes are needed apart from changes in the declaration, then that indicates we have used good programming techniques in the original code. On the other hand, if further changes are needed, then you should investigate why this is the case.

Also note that, in some cases, you can move support types into the private part of the specification without affecting its compilation. This is the case, for example, for the `People_Array` type of the *List of Names* lab mentioned below. You should, in fact, keep only relevant types and subprograms in the public part and move all support declarations to the private part of the specification whenever possible.

Below, you find the selected labs that you can work on, including changes that you should make. In case you don't have a working version of the source-code of previous labs, you can look into the corresponding solutions.

134.3.1 Colors

Chapter: *Records* (page 2229)

Steps:

1. Change declaration of RGB type to **`private`**.

Requirements:

1. Implementation must compile correctly and test cases must pass.

134.3.2 List of Names

Chapter: *Arrays* (page 2239)

Steps:

1. Change declaration of `Person` and `People` types to **`limited private`**.
2. Move type declaration of `People_Array` to private part.

Requirements:

1. Implementation must compile correctly and test cases must pass.

134.3.3 Price List

Chapter: *More About Types* (page 2257)

Steps:

1. Change declaration of `Price_List` type to **`limited private`**.

Requirements:

1. Implementation must compile correctly and test cases must pass.

CHAPTER

FIVE

GENERICS

135.1 Display Array

Goal: create a generic procedure that displays the elements of an array.

Steps:

1. Implement the generic procedure `Display_Array`.

Requirements:

1. Generic procedure `Display_Array` displays the elements of an array.
    1. It uses the following scheme:
        - First, it displays a header.
        - Then, it displays the elements of the array.
    2. When displaying the elements, it must:
        - use one line per element, and
        - include the corresponding index of the array.
    3. This is the expected format:

        ```
        <HEADER>
        <index #1>: <element #1>
        <index #2>: <element #2>
        ...
        ```

    4. For example:
        - For the following code:

            ```
            procedure Test is
               A : Int_Array (1 .. 2) := (1, 5);
            begin
               Display_Int_Array ("Elements of A", A);;
            end Test;
            ```

        - The output is:

            ```
            Elements of A
             1:  1
             2:  5
            ```

2. These are the formal parameters of the procedure:
    1. a range type `T_Range` for the the array;
    2. a formal type `T_Element` for the elements of the array;

- This type must be declared in such a way that it can be mapped to any type in the instantiation — including record types.

3. an array type T_Array using the T_Range and T_Element types;
4. a function Image that converts a variable of T_Element type to a **String**.

Listing 1: display_array.ads

```
generic
procedure Display_Array (Header : String;
                         A      : T_Array);
```

Listing 2: display_array.adb

```
with Ada.Text_IO; use Ada.Text_IO;

procedure Display_Array (Header : String;
                         A      : T_Array) is
begin
   null;
end Display_Array;
```

Listing 3: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;

with Display_Array;

procedure Main is
   type Test_Case_Index is (Int_Array_Chk,
                            Point_Array_Chk);

   procedure Test_Int_Array is
      type Int_Array is array (Positive range <>) of Integer;

      procedure Display_Int_Array is new
        Display_Array (T_Range => Positive,
                       T_Element => Integer,
                       T_Array   => Int_Array,
                       Image     => Integer'Image);

      A : constant Int_Array (1 .. 5) := (1, 2, 5, 7, 10);
   begin
      Display_Int_Array ("Integers", A);
   end Test_Int_Array;

   procedure Test_Point_Array is
      type Point is record
         X : Float;
         Y : Float;
      end record;

      type Point_Array is array (Natural range <>) of Point;

      function Image (P : Point) return String is
      begin
         return "(" & Float'Image (P.X)
           & ", " & Float'Image (P.Y) & ")";
      end Image;

```

(continues on next page)

(continued from previous page)

```
38       procedure Display_Point_Array is new
39         Display_Array (T_Range   => Natural,
40                        T_Element => Point,
41                        T_Array   => Point_Array,
42                        Image     => Image);
43
44       A : constant Point_Array (0 .. 3) := ((1.0, 0.5), (2.0, -0.5),
45                                             (5.0, 2.0), (-0.5, 2.0));
46    begin
47       Display_Point_Array ("Points", A);
48    end Test_Point_Array;
49
50    procedure Check (TC : Test_Case_Index) is
51    begin
52       case TC is
53          when Int_Array_Chk =>
54             Test_Int_Array;
55          when Point_Array_Chk =>
56             Test_Point_Array;
57       end case;
58    end Check;
59
60 begin
61    if Argument_Count < 1 then
62       Put_Line ("ERROR: missing arguments! Exiting...");
63       return;
64    elsif Argument_Count > 1 then
65       Put_Line ("Ignoring additional arguments...");
66    end if;
67
68    Check (Test_Case_Index'Value (Argument (1)));
69 end Main;
```

135.2 Average of Array of Float

Goal: create a generic function that calculates the average of an array of floating-point elements.

Steps:

1. Declare and implement the generic function `Average`.

Requirements:

1. Generic function `Average` calculates the average of an array containing floating-point values of arbitrary precision.
2. Generic function `Average` must contain the following formal parameters:
    1. a range type `T_Range` for the array;
    2. a formal type `T_Element` that can be mapped to floating-point types of arbitrary precision;
    3. an array type `T_Array` using `T_Range` and `T_Element`;

Remarks:

1. You should use the `Float` type for the accumulator.

Listing 4: average.ads

```
generic
function Average (A : T_Array) return T_Element;
```

Listing 5: average.adb

```
function Average (A : T_Array) return T_Element is
begin
   return 0.0;
end Average;
```

Listing 6: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;

with Average;

procedure Main is
   type Test_Case_Index is (Float_Array_Chk,
                            Digits_7_Float_Array_Chk);

   procedure Test_Float_Array is
      type Float_Array is array (Positive range <>) of Float;

      function Average_Float is new
        Average (T_Range   => Positive,
                 T_Element => Float,
                 T_Array   => Float_Array);

      A : constant Float_Array (1 .. 5) := (1.0, 3.0, 5.0, 7.5, -12.5);
   begin
      Put_Line ("Average: " & Float'Image (Average_Float (A)));
   end Test_Float_Array;

   procedure Test_Digits_7_Float_Array is
      type Custom_Float is digits 7 range 0.0 .. 1.0;

      type Float_Array is
        array (Integer range <>) of Custom_Float;

      function Average_Float is new
        Average (T_Range   => Integer,
                 T_Element => Custom_Float,
                 T_Array   => Float_Array);

      A : constant Float_Array (-1 .. 3) := (0.5, 0.0, 1.0, 0.6, 0.5);
   begin
      Put_Line ("Average: "
                & Custom_Float'Image (Average_Float (A)));
   end Test_Digits_7_Float_Array;

   procedure Check (TC : Test_Case_Index) is
   begin
      case TC is
         when Float_Array_Chk =>
            Test_Float_Array;
         when Digits_7_Float_Array_Chk =>
            Test_Digits_7_Float_Array;
      end case;
```

```

135.3 Average of Array of Any Type

Goal: create a generic function that calculates the average of an array of elements of any arbitrary type.

Steps:

1. Declare and implement the generic function `Average`.
2. Implement the test procedure `Test_Item`.
    1. Declare the `F_IO` package.
    2. Implement the `Get_Total` function for the `Item` type.
    3. Implement the `Get_Price` function for the `Item` type.
    4. Declare the `Average_Total` function.
    5. Declare the `Average_Price` function.

Requirements:

1. Generic function `Average` calculates the average of an array containing elements of any arbitrary type.
2. Generic function `Average` has the same formal parameters as in the previous exercise, except for:
    1. `T_Element`, which is now a formal type that can be mapped to any arbitrary type.
    2. `To_Float`, which is an *additional* formal parameter.
        - `To_Float` is a function that converts the arbitrary element of `T_Element` type to the **`Float`** type.
3. Procedure `Test_Item` is used to test the generic `Average` procedure for a record type (`Item`).
    1. Record type `Item` contains the `Quantity` and `Price` components.
4. The following functions have to implemented to be used for the formal `To_Float` function parameter:
    1. For the `Decimal` type, the function is pretty straightforward: it simply returns the floating-point value converted from the decimal type.
    2. For the `Item` type, two functions must be created to convert to floating-point type:
        1. `Get_Total`, which returns the multiplication of the quantity and the price components of the `Item` type;
        2. `Get_Price`, which returns just the price.

5. The generic function Average must be instantiated as follows:
    1. For the Item type, you must:
        1. declare the Average_Total function (as an instance of Average) using the Get_Total for the To_Float parameter;
        2. declare the Average_Price function (as an instance of Average) using the Get_Price for the To_Float parameter.
6. You must use the Put procedure from Ada.Text_IO.Float_IO.
    1. The generic standard package Ada.Text_IO.Float_IO must be instantiated as F_IO in the test procedures.
    2. This is the specification of the Put procedure, as described in the appendix A.10.9 of the Ada Reference Manual:

```
procedure Put(Item : in Num;
              Fore : in Field := Default_Fore;
              Aft  : in Field := Default_Aft;
              Exp  : in Field := Default_Exp);
```

    3. This is the expected format when calling Put from Float_IO:

Function	Fore	Aft	Exp
Test_Item	3	2	0

Remarks:

1. In this exercise, you'll abstract the Average function from the previous exercises a step further.
    1. In this case, the function shall be able to calculate the average of any arbitrary type — including arrays containing elements of record types.
    2. Since record types can be composed by many components of different types, we need to provide a way to indicate which component (or components) of the record will be used when calculating the average of the array.
    3. This problem is solved by specifying a To_Float function as a formal parameter, which converts the arbitrary element of T_Element type to the **Float** type.
    4. In the implementation of the Average function, we use the To_Float function and calculate the average using a floating-point variable.

Listing 7: average.ads

```
generic
function Average (A : T_Array) return Float;
```

Listing 8: average.adb

```
function Average (A : T_Array) return Float is
begin
   null;
end Average;
```

Listing 9: test_item.ads

```
procedure Test_Item;
```

Listing 10: test_item.adb

```
with Ada.Text_IO;      use Ada.Text_IO;

with Average;

procedure Test_Item is
   type Amount is delta 0.01 digits 12;

   type Item is record
      Quantity : Natural;
      Price    : Amount;
   end record;

   type Item_Array is
     array (Positive range <>) of Item;

   A : constant Item_Array (1 .. 4)
     := ((Quantity =>  5,   Price => 10.00),
         (Quantity => 80,   Price =>  2.50),
         (Quantity => 40,   Price =>  5.00),
         (Quantity => 20,   Price => 12.50));

begin
   Put ("Average per item & quantity: ");
   F_IO.Put (Average_Total (A));
   New_Line;

   Put ("Average price:               ");
   F_IO.Put (Average_Price (A));
   New_Line;
end Test_Item;
```

Listing 11: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;

with Test_Item;

procedure Main is
   type Test_Case_Index is (Item_Array_Chk);

   procedure Check (TC : Test_Case_Index) is
   begin
      case TC is
         when Item_Array_Chk =>
            Test_Item;
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

135.4 Generic list

Goal: create a system based on a generic list to add and displays elements.

Steps:

1. Declare and implement the generic package `Gen_List`.
    1. Implement the `Init` procedure.
    2. Implement the `Add` procedure.
    3. Implement the `Display` procedure.

Requirements:

1. Generic package `Gen_List` must have the following subprograms:
    1. Procedure `Init` initializes the list.
    2. Procedure `Add` adds an item to the list.
        1. This procedure must contain a `Status` output parameter that is set to **`False`** when the list was full — i.e. if the procedure failed while trying to add the item;
    3. Procedure `Display` displays the complete list.
        1. This includes the *name* of the list and its elements — using one line per element.
        2. This is the expected format:

```
<NAME>
<element #1>
<element #2>
...
```

2. Generic package `Gen_List` has these formal parameters:
    1. an arbitrary formal type `Item`;
    2. an unconstrained array type `Items` of `Item` element with positive range;
    3. the `Name` parameter containing the name of the list;
        - This must be a formal input object of **`String`** type.
        - It must be used in the `Display` procedure.
    4. an actual array `List_Array` to store the list;
        - This must be a formal **`in out`** object of `Items` type.
    5. the variable `Last` to store the index of the last element;
        - This must be a formal **`in out`** object of **`Natural`** type.
    6. a procedure `Put` for the `Item` type.
        - This procedure is used in the `Display` procedure to display individual elements of the list.
3. The test procedure `Test_Int` is used to test a list of elements of **`Integer`** type.
4. For both test procedures, you must:
    1. add missing type declarations;
    2. declare and implement a `Put` procedure for individual elements of the list;
    3. declare instances of the `Gen_List` package.
        - For the `Test_Int` procedure, declare the `Int_List` package.

Remarks:

1. In previous labs, you've been implementing lists for a variety of types.
   - The *List of Names* exercise from the *Arrays* (page 2239) labs is an example.
   - In this exercise, you have to abstract those implementations to create the generic `Gen_List` package.

Listing 12: gen_list.ads

```
generic
package Gen_List is

   procedure Init;

   procedure Add (I      :     Item;
                  Status : out Boolean);

   procedure Display;

end Gen_List;
```

Listing 13: gen_list.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Gen_List is

   procedure Init is
   begin
      null;
   end Init;

   procedure Add (I      :     Item;
                  Status : out Boolean) is
   begin
      null;
   end Add;

   procedure Display is
   begin
      null;
   end Display;

end Gen_List;
```

Listing 14: test_int.ads

```
procedure Test_Int;
```

Listing 15: test_int.adb

```
with Ada.Text_IO; use Ada.Text_IO;

with Gen_List;

procedure Test_Int is

   type Integer_Array is array (Positive range <>) of Integer;

   A : Integer_Array (1 .. 3);
```

(continues on next page)

(continued from previous page)

```
   L : Natural;

   Success : Boolean;

   procedure Display_Add_Success (Success : Boolean) is
   begin
      if Success then
         Put_Line ("Added item successfully!");
      else
         Put_Line ("Couldn't add item!");
      end if;

   end Display_Add_Success;

begin
   Int_List.Init;

   Int_List.Add (2, Success);
   Display_Add_Success (Success);

   Int_List.Add (5, Success);
   Display_Add_Success (Success);

   Int_List.Add (7, Success);
   Display_Add_Success (Success);

   Int_List.Add (8, Success);
   Display_Add_Success (Success);

   Int_List.Display;
end Test_Int;
```

Listing 16: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;

with Test_Int;

procedure Main is
   type Test_Case_Index is (Int_Chk);

   procedure Check (TC : Test_Case_Index) is
   begin
      case TC is
         when Int_Chk =>
            Test_Int;
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

CHAPTER

SIX

EXCEPTIONS

136.1 Uninitialized Value

Goal: implement an enumeration to avoid the use of uninitialized values.

Steps:

1. Implement the `Options` package.
    1. Declare the `Option` enumeration type.
    2. Declare the `Uninitialized_Value` exception.
    3. Implement the `Image` function.

Requirements:

1. Enumeration `Option` contains:
    1. the `Uninitialized` value, and
    2. the actual options:
        - `Option_1`,
        - `Option_2`,
        - `Option_3`.
2. Function `Image` returns a string for the `Option` type.
    1. In case the argument to `Image` is `Uninitialized`, the function must raise the `Uninitialized_Value` exception.

Remarks:

1. In this exercise, we employ exceptions as a mechanism to avoid the use of uninitialized values for a certain type.

Listing 1: options.ads

```
package Options is

   --  Declare the Option enumeration type!
   type Option is null record;

   function Image (O : Option) return String;

end Options;
```

Listing 2: options.adb

```
package body Options is

   function Image (O : Option) return String is
   begin
      return "";
   end Image;

end Options;
```

Listing 3: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;
with Ada.Exceptions;   use Ada.Exceptions;

with Options;          use Options;

procedure Main is
   type Test_Case_Index is
     (Options_Chk);

   procedure Check (TC : Test_Case_Index) is

      procedure Check (O : Option) is
      begin
         Put_Line (Image (O));
      exception
         when E : Uninitialized_Value =>
            Put_Line (Exception_Message (E));
      end Check;

   begin
      case TC is
      when Options_Chk =>
         for O in Option loop
            Check (O);
         end loop;
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

136.2 Numerical Exception

Goal: handle numerical exceptions in a test procedure.

Steps:

1. Add exception handling to the `Check_Exception` procedure.

Requirements:

1. The test procedure `Num_Exception_Test` from the `Tests` package below must be used in the implementation of `Check_Exception`.
2. The `Check_Exception` procedure must be extended to handle exceptions as follows:
    1. If the exception raised by `Num_Exception_Test` is `Constraint_Error`, the procedure must display the message "Constraint_Error detected!" to the user.
    2. Otherwise, it must display the message associated with the exception.

Remarks:

1. You can use the `Exception_Message` function to retrieve the message associated with an exception.

Listing 4: tests.ads

```
package Tests is

   type Test_ID is (Test_1, Test_2);

   Custom_Exception : exception;

   procedure Num_Exception_Test (ID : Test_ID);

end Tests;
```

Listing 5: tests.adb

```
package body Tests is

   pragma Warnings (Off, "variable ""C"" is assigned but never read");

   procedure Num_Exception_Test (ID : Test_ID) is
      A, B, C : Integer;
   begin
      case ID is
         when Test_1 =>
            A := Integer'Last;
            B := Integer'Last;
            C := A + B;
         when Test_2 =>
            raise Custom_Exception with "Custom_Exception raised!";
      end case;
   end Num_Exception_Test;

   pragma Warnings (On, "variable ""C"" is assigned but never read");

end Tests;
```

Listing 6: check_exception.adb

```
with Tests; use Tests;

```

(continues on next page)

(continued from previous page)

```
procedure Check_Exception (ID : Test_ID) is
begin
   Num_Exception_Test (ID);
end Check_Exception;
```

Listing 7: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;
with Ada.Exceptions;   use Ada.Exceptions;

with Tests;            use Tests;
with Check_Exception;

procedure Main is
   type Test_Case_Index is
     (Exception_1_Chk,
      Exception_2_Chk);

   procedure Check (TC : Test_Case_Index) is

      procedure Check_Handle_Exception (ID : Test_ID) is
      begin
         Check_Exception (ID);
      exception
         when Constraint_Error =>
            Put_Line ("Constraint_Error"
                      & " (raised by Check_Exception) detected!");
         when E : others =>
            Put_Line (Exception_Name (E)
                      & " (raised by Check_Exception) detected!");
      end Check_Handle_Exception;

   begin
      case TC is
      when Exception_1_Chk =>
         Check_Handle_Exception (Test_1);
      when Exception_2_Chk =>
         Check_Handle_Exception (Test_2);
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

136.3 Re-raising Exceptions

Goal: make use of exception re-raising in a test procedure.

Steps:

1. Declare new exception: `Another_Exception`.
2. Add exception re-raise to the `Check_Exception` procedure.

Requirements:

1. Exception `Another_Exception` must be declared in the `Tests` package.
2. Procedure `Check_Exception` must be extended to *re-raise* any exception. When an exception is detected, the procedure must:
    1. display a user message (as implemented in the previous exercise), and then
    2. Raise or *re-raise* exception depending on the exception that is being handled:
        1. In case of `Constraint_Error` exception, *re-raise* the exception.
        2. In all other cases, raise `Another_Exception`.

Remarks:

1. In this exercise, you should extend the implementation of the `Check_Exception` procedure from the previous exercise.
    1. Naturally, you can use the code for the `Check_Exception` procedure from the previous exercise as a starting point.

Listing 8: tests.ads

```
package Tests is

   type Test_ID is (Test_1, Test_2);

   Custom_Exception : exception;

   procedure Num_Exception_Test (ID : Test_ID);

end Tests;
```

Listing 9: tests.adb

```
package body Tests is

   pragma Warnings (Off, "variable ""C"" is assigned but never read");

   procedure Num_Exception_Test (ID : Test_ID) is
      A, B, C : Integer;
   begin
      case ID is
         when Test_1 =>
            A := Integer'Last;
            B := Integer'Last;
            C := A + B;
         when Test_2 =>
            raise Custom_Exception with "Custom_Exception raised!";
      end case;
   end Num_Exception_Test;

   pragma Warnings (On, "variable ""C"" is assigned but never read");
```

CHAPTER

SEVEN

TASKING

137.1 Display Service

Goal: create a simple service that displays messages to the user.

Steps:

1. Implement the `Display_Services` package.
    1. Declare the task type `Display_Service`.
    2. Implement the `Display` entry for strings.
    3. Implement the `Display` entry for integers.

Requirements:

1. Task type `Display_Service` uses the `Display` entry to display messages to the user.
2. There are two versions of the `Display` entry:
    1. One that receives messages as a string parameter.
    2. One that receives messages as an **`Integer`** parameter.
3. When a message is received via a `Display` entry, it must be displayed immediately to the user.

Listing 1: display_services.ads

```
package Display_Services is

end Display_Services;
```

Listing 2: display_services.adb

```
package body Display_Services is

end Display_Services;
```

Listing 3: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;

with Display_Services; use Display_Services;

procedure Main is
   type Test_Case_Index is (Display_Service_Chk);

   procedure Check (TC : Test_Case_Index) is
```

(continues on next page)

(continued from previous page)

```
      Display : Display_Service;
   begin
      case TC is
         when Display_Service_Chk =>
            Display.Display ("Hello");
            delay 0.5;
            Display.Display ("Hello again");
            delay 0.5;
            Display.Display (55);
            delay 0.5;
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

137.2 Event Manager

Goal: implement a simple event manager.

Steps:

1. Implement the `Event_Managers` package.
    1. Declare the task type `Event_Manager`.
    2. Implement the `Start` entry.
    3. Implement the `Event` entry.

Requirements:

1. The event manager has a similar behavior as an alarm
    1. The sole purpose of this event manager is to display the event ID at the correct time.
    2. After the event ID is displayed, the task must finish.
2. The event manager (`Event_Manager` type) must have two entries:
    1. `Start`, which starts the event manager with an event ID;
    2. `Event`, which delays the task until a certain time and then displays the event ID as a user message.
3. The format of the user message displayed by the event manager is `Event #<event_id>`.
    1. You should use `Natural'Image` to display the ID (as indicated in the body of the `Event_Managers` package below).

Remarks:

1. In the `Start` entry, you can use the **`Natural`** type for the ID.

2. In the Event entry, you should use the Time type from the Ada.Real_Time package for the time parameter.
3. Note that the test application below creates an array of event managers with different delays.

Listing 4: event_managers.ads

```
package Event_Managers is

end Event_Managers;
```

Listing 5: event_managers.adb

```
package body Event_Managers is

      --   Don't forget to display the event ID:
      --
      --   Put_Line ("Event #" & Natural'Image (Event_ID));

end Event_Managers;
```

Listing 6: main.adb

```
with Ada.Command_Line; use Ada.Command_Line;
with Ada.Text_IO;      use Ada.Text_IO;

with Event_Managers;   use Event_Managers;
with Ada.Real_Time;    use Ada.Real_Time;

procedure Main is
   type Test_Case_Index is (Event_Manager_Chk);

   procedure Check (TC : Test_Case_Index) is
      Ev_Mng : array (1 .. 5) of Event_Manager;
   begin
      case TC is
         when Event_Manager_Chk =>
            for I in Ev_Mng'Range loop
               Ev_Mng (I).Start (I);
            end loop;
            Ev_Mng (1).Event (Clock + Seconds (5));
            Ev_Mng (2).Event (Clock + Seconds (3));
            Ev_Mng (3).Event (Clock + Seconds (1));
            Ev_Mng (4).Event (Clock + Seconds (2));
            Ev_Mng (5).Event (Clock + Seconds (4));
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

137.3 Generic Protected Queue

Goal: create a queue container using a protected type.

Steps:

1. Implement the generic package `Gen_Queues`.
    1. Declare the protected type `Queue`.
    2. Implement the `Empty` function.
    3. Implement the `Full` function.
    4. Implement the `Push` entry.
    5. Implement the `Pop` entry.

Requirements:

1. These are the formal parameters for the generic package `Gen_Queues`:
    1. a formal modular type;
        - This modular type should be used by the `Queue` to declare an array that stores the elements of the queue.
        - The modulus of the modular type must correspond to the maximum number of elements of the queue.
    2. the data type of the elements of the queue.
        - Select a formal parameter that allows you to store elements of any data type in the queue.
2. These are the operations of the `Queue` type:
    1. Function `Empty` indicates whether the queue is empty.
    2. Function `Full` indicates whether the queue is full.
    3. Entry `Push` stores an element in the queue.
    4. Entry `Pop` removes an element from the queue and returns the element via output parameter.

Remarks:

1. In this exercise, we create a queue container by declaring and implementing a protected type (`Queue`) as part of a generic package (`Gen_Queues`).
2. As a bonus exercise, you can analyze the body of the `Queue_Tests` package and understand how the `Queue` type is used there.
    1. In particular, the procedure `Concurrent_Test` implements two tasks: `T_Producer` and `T_Consumer`. They make use of the queue concurrently.

                            Concurrent_Queue_Chk);

   procedure Check (TC : Test_Case_Index) is

   begin
      case TC is
         when Simple_Queue_Chk =>
            Simple_Test;
         when Concurrent_Queue_Chk =>
            Concurrent_Test;
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

CHAPTER

EIGHT

DESIGN BY CONTRACTS

138.1 Price Range

Goal: use predicates to indicate the correct range of prices.

Steps:

1. Complete the `Prices` package.
    1. Rewrite the type declaration of `Price`.

Requirements:

1. Type `Price` must use a predicate instead of a range.

Remarks:

1. As discussed in the course, ranges are a form of contract.
    1. For example, the subtype `Price` below indicates that a value of this subtype must always be positive:

        ```
        subtype Price is Amount range 0.0 .. Amount'Last;
        ```

    2. Interestingly, you can replace ranges by predicates, which is the goal of this exercise.

Listing 1: prices.ads

```
package Prices is

   type Amount is delta 10.0 ** (-2) digits 12;

   subtype Price is Amount range 0.0 .. Amount'Last;

end Prices;
```

Listing 2: main.adb

```
with Ada.Command_Line;  use Ada.Command_Line;
with Ada.Text_IO;       use Ada.Text_IO;
with System.Assertions; use System.Assertions;

with Prices;            use Prices;

procedure Main is

   type Test_Case_Index is
     (Price_Range_Chk);

```

(continues on next page)

(continued from previous page)

```
12    procedure Check (TC : Test_Case_Index) is
13
14       procedure Check_Range (A : Amount) is
15          P : constant Price := A;
16       begin
17          Put_Line ("Price: " & Price'Image (P));
18       end Check_Range;
19
20    begin
21       case TC is
22       when Price_Range_Chk =>
23          Check_Range (-2.0);
24       end case;
25    exception
26       when Constraint_Error =>
27          Put_Line ("Constraint_Error detected (NOT as expected).");
28       when Assert_Failure =>
29          Put_Line ("Assert_Failure detected (as expected).");
30    end Check;
31
32 begin
33    if Argument_Count < 1 then
34       Put_Line ("ERROR: missing arguments! Exiting...");
35       return;
36    elsif Argument_Count > 1 then
37       Put_Line ("Ignoring additional arguments...");
38    end if;
39
40    Check (Test_Case_Index'Value (Argument (1)));
41 end Main;
```

138.2 Pythagorean Theorem: Predicate

Goal: use the Pythagorean theorem as a predicate.

Steps:

1. Complete the `Triangles` package.
    1. Add a predicate to the `Right_Triangle` type.

Requirements:

1. The `Right_Triangle` type must use the Pythagorean theorem as a predicate to ensure that its components are consistent.

Remarks:

1. As you probably remember, the Pythagoras' theorem[539] states that the square of the hypotenuse of a right triangle is equal to the sum of the squares of the other two sides.

Listing 3: triangles.ads

```
1  package Triangles is
2
3     subtype Length is Integer;
4
5     type Right_Triangle is record
6        H      : Length := 0;
```

     ("("    & Length'Image (T.H)
      & ", " & Length'Image (T.C1)
      & ", " & Length'Image (T.C2)
      & ")");

end Triangles.IO;
```

Listing 6: main.adb

```
with Ada.Command_Line;  use Ada.Command_Line;
with Ada.Text_IO;       use Ada.Text_IO;
with System.Assertions; use System.Assertions;

with Triangles;         use Triangles;
with Triangles.IO;      use Triangles.IO;

procedure Main is

   type Test_Case_Index is
     (Triangle_8_6_Pass_Chk,
      Triangle_8_6_Fail_Chk,
      Triangle_10_24_Pass_Chk,
      Triangle_10_24_Fail_Chk,
      Triangle_18_24_Pass_Chk,
      Triangle_18_24_Fail_Chk);

   procedure Check (TC : Test_Case_Index) is

      procedure Check_Triangle (H, C1, C2 : Length) is
         T : Right_Triangle;
      begin
         T := Init (H, C1, C2);
         Put_Line (Image (T));
      exception
         when Constraint_Error =>
            Put_Line ("Constraint_Error detected (NOT as expected).");
         when Assert_Failure =>
```

(continues on next page)

(continued from previous page)

```
            Put_Line ("Assert_Failure detected (as expected).");
      end Check_Triangle;

   begin
      case TC is
         when Triangle_8_6_Pass_Chk   => Check_Triangle (10,  8,  6);
         when Triangle_8_6_Fail_Chk   => Check_Triangle (12,  8,  6);
         when Triangle_10_24_Pass_Chk => Check_Triangle (26, 10, 24);
         when Triangle_10_24_Fail_Chk => Check_Triangle (12, 10, 24);
         when Triangle_18_24_Pass_Chk => Check_Triangle (30, 18, 24);
         when Triangle_18_24_Fail_Chk => Check_Triangle (32, 18, 24);
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

138.3 Pythagorean Theorem: Precondition

Goal: use the Pythagorean theorem as a precondition.

Steps:

1. Complete the `Triangles` package.
    1. Add a precondition to the `Init` function.

Requirements:

1. The `Init` function must use the Pythagorean theorem as a precondition to ensure that the input values are consistent.

Remarks:

1. In this exercise, you'll work again with the `Right_Triangle` type.
    1. This time, your job is to use a precondition instead of a predicate.
    2. The precondition is applied to the `Init` function, not to the `Right_Triangle` type.

Listing 7: triangles.ads

```
package Triangles is

   subtype Length is Integer;

   type Right_Triangle is record
      H      : Length := 0;
      --  Hypotenuse
      C1, C2 : Length := 0;
      --  Catheti / legs
   end record;

```

(continues on next page)

(continued from previous page)

```
   function Init (H, C1, C2 : Length) return Right_Triangle is
     ((H, C1, C2));

end Triangles;
```

   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

138.4 Pythagorean Theorem: Postcondition

Goal: use the Pythagorean theorem as a postcondition.

Steps:

1. Complete the `Triangles` package.
    1. Add a postcondition to the `Init` function.

Requirements:

1. The `Init` function must use the Pythagorean theorem as a postcondition to ensure that the returned object is consistent.

Remarks:

1. In this exercise, you'll work again with the `Triangles` package.
    1. This time, your job is to apply a postcondition instead of a precondition to the `Init` function.

Listing 11: triangles.ads

```
package Triangles is

   subtype Length is Integer;

   type Right_Triangle is record
      H      : Length := 0;
      --  Hypotenuse
      C1, C2 : Length := 0;
      --  Catheti / legs
   end record;

   function Init (H, C1, C2 : Length) return Right_Triangle is
     ((H, C1, C2));

end Triangles;
```

Listing 12: triangles-io.ads

   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

138.5 Pythagorean Theorem: Type Invariant

Goal: use the Pythagorean theorem as a type invariant.

Steps:

1. Complete the `Triangles` package.
    1. Add a type invariant to the `Right_Triangle` type.

Requirements:

1. `Right_Triangle` is a private type.
    1. It must use the Pythagorean theorem as a type invariant to ensure that its encapsulated components are consistent.

Remarks:

1. In this exercise, `Right_Triangle` is declared as a private type.
    1. In this case, we use a type invariant for `Right_Triangle` to check the Pythagorean theorem.
2. As a bonus, after completing the exercise, you may analyze the effect that default values have on type invariants.
    1. For example, the declaration of `Right_Triangle` uses zero as the default values of the three triangle lengths.
    2. If you replace those default values with `Length'Last`, you'll get different results.
    3. Make sure you understand why this is happening.

Listing 15: triangles.ads

```
package Triangles is

   subtype Length is Integer;

   type Right_Triangle is private;

   function Init (H, C1, C2 : Length) return Right_Triangle;

private

   type Right_Triangle is record
      H      : Length := 0;
```

(continues on next page)

(continued from previous page)

```
      --  Hypotenuse
      C1, C2 : Length := 0;
      --  Catheti / legs
   end record;

   function Init (H, C1, C2 : Length) return Right_Triangle is
     ((H, C1, C2));

end Triangles;
```

Listing 16: triangles-io.ads

```

      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

138.6 Primary Color

Goal: extend a package for HTML colors so that it can handle primary colors.

Steps:

1. Complete the `Color_Types` package.
    1. Declare the `HTML_RGB_Color` subtype.
    2. Implement the `To_Int_Color` function.

Requirements:

1. The `HTML_Color` type is an enumeration that contains a list of HTML colors.
2. The `To_RGB_Lookup_Table` array implements a lookup-table to convert the colors into a hexadecimal value using RGB color components (i.e. `Red`, `Green` and `Blue`)
3. Function `To_Int_Color` extracts one of the RGB components of an HTML color and returns its hexadecimal value.
    1. The function has two parameters:
        - First parameter is the HTML color (`HTML_Color` type).
        - Second parameter indicates which RGB component is to be extracted from the HTML color (`HTML_RGB_Color` subtype).
    2. For example, if we call `To_Int_Color (Salmon, Red)`, the function returns #FA,
        - This is the hexadecimal value of the red component of the `Salmon` color.
        - You can find further remarks below about this color as an example.
4. The `HTML_RGB_Color` subtype is limited to the primary RGB colors components (i.e. `Red`, `Green` and `Blue`).
    1. This subtype is used to select the RGB component in calls to `To_Int_Color`.

2. You must use a predicate in the type declaration.

Remarks:

1. In this exercise, we reuse the code of the `Colors: Lookup-Table` exercise from the *Arrays* (page 2239) labs.
2. These are the hexadecimal values of the colors that we used in the original exercise:

Color	Value
Salmon	#FA8072
Firebrick	#B22222
Red	#FF0000
Darkred	#8B0000
Lime	#00FF00
Forestgreen	#228B22
Green	#008000
Darkgreen	#006400
Blue	#0000FF
Mediumblue	#0000CD
Darkblue	#00008B

3. You can extract the hexadecimal value of each primary color by splitting the values from the table above into three hexadecimal values with two digits each.
   - For example, the hexadecimal value of `Salmon` is `#FA8072`, where:
     - the first part of this hexadecimal value (`#FA`) corresponds to the red component,
     - the second part (`#80`) corresponds to the green component, and
     - the last part (`#72`) corresponds to the blue component.

Listing 19: color_types.ads

```
package Color_Types is

   type HTML_Color is
     (Salmon,
      Firebrick,
      Red,
      Darkred,
      Lime,
      Forestgreen,
      Green,
      Darkgreen,
      Blue,
      Mediumblue,
      Darkblue);

   subtype Int_Color is Integer range 0 .. 255;

   function Image (I : Int_Color) return String;

   type RGB is record
      Red   : Int_Color;
      Green : Int_Color;
      Blue  : Int_Color;
   end record;

```

CHAPTER

NINE

OBJECT-ORIENTED PROGRAMMING

139.1 Simple type extension

Goal: work with type extensions using record types containing numeric components.

Steps:

1. Implement the `Type_Extensions` package.
    1. Declare the record type `T_Float`.
    2. Declare the record type `T_Mixed`
    3. Implement the `Init` function for the `T_Float` type with a floating-point input parameter.
    4. Implement the `Init` function for the `T_Float` type with an integer input parameter.
    5. Implement the `Image` function for the `T_Float` type.
    6. Implement the `Init` function for the `T_Mixed` type with a floating-point input parameter.
    7. Implement the `Init` function for the `T_Mixed` type with an integer input parameter.
    8. Implement the `Image` function for the `T_Mixed` type.

Requirements:

1. Record type `T_Float` contains the following component:
    1. `F`, a floating-point type.
2. Record type `T_Mixed` is derived from the `T_Float` type.
    1. `T_Mixed` extends `T_Float` with the following component:
        1. `I`, an integer component.
    2. Both components must be numerically *synchronized*:
        - For example, if the floating-point component contains the value 2.0, the value of the integer component must be 2.
        - In order to simplify the implementation, you can simply use `Integer (F)` to convert a floating-point variable F to integer.
3. Function `Init` returns an object of the corresponding type (`T_Float` or `T_Mixed`).
    1. For each type, two versions of `Init` must be declared:
        1. one with a floating-point input parameter,
        2. another with an integer input parameter.
    2. The parameter to `Init` is used to initialize the record components.

4. Function Image returns a string for the components of the record type.
    1. In case of the Image function for the T_Float type, the string must have the format "{ F => <float value> }".
        - For example, the call Image (T_Float'(Init (8.0)))) should return the string "{ F => 8.00000E+00 }".
    2. In case of the Image function for the T_Mixed type, the string must have the format "{ F => <float value>, I => <integer value> }".
        - For example, the call Image (T_Mixed'(Init (8.0)))) should return the string "{ F => 8.00000E+00, I => 8 }".

Listing 1: type_extensions.ads

```
package Type_Extensions is

   --  Create declaration of T_Float type!
   type T_Float is null record;

   --  function Init ...

   --  function Image ...

   --  Create declaration of T_Mixed type!
   type T_Mixed is null record;

end Type_Extensions;
```

with Ada.Text_IO;      use Ada.Text_IO;

with Type_Extensions;  use Type_Extensions;

procedure Main is

   type Test_Case_Index is
     (Type_Extension_Chk);

   procedure Check (TC : Test_Case_Index) is
      F1, F2 : T_Float;
      M1, M2 : T_Mixed;
   begin
      case TC is
      when Type_Extension_Chk =>
         F1 := Init (2.0);
         F2 := Init (3);
         M1 := Init (4.0);
         M2 := Init (5);

         if M2 in T_Float'Class then
           Put_Line ("T_Mixed is in T_Float'Class as expected");
         end if;

```

(continues on next page)

(continued from previous page)

```
         Put_Line ("F1: " & Image (F1));
         Put_Line ("F2: " & Image (F2));
         Put_Line ("M1: " & Image (M1));
         Put_Line ("M2: " & Image (M2));
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

139.2 Online Store

Goal: create an online store for the members of an association.

Steps:

1. Implement the `Online_Store` package.
    1. Declare the `Member` type.
    2. Declare the `Full_Member` type.
    3. Implement the `Get_Status` function for the `Member` type.
    4. Implement the `Get_Price` function for the `Member` type.
    5. Implement the `Get_Status` function for the `Full_Member` type.
    6. Implement the `Get_Price` function for the `Full_Member` type.
2. Implement the `Online_Store.Tests` child package.
    1. Implement the `Simple_Test` procedure.

Requirements:

1. Package `Online_Store` implements an online store application for the members of an association.
    1. In this association, members can have one of the following status:
        - associate member, or
        - full member.
2. Function `Get_Price` returns the correct price of an item.
    1. Associate members must pay the full price when they buy items from the online store.
    2. Full members can get a discount.
        1. The discount rate can be different for each full member — depending on factors that are irrelevant for this exercise.
3. Package `Online_Store` has following types:
    1. `Percentage` type, which represents a percentage ranging from 0.0 to 1.0.

2. `Member` type for associate members containing following components:
    - `Start`, which indicates the starting year of the membership.
        - This information is common for both associate and full members.
        - You can use the `Year_Number` type from the standard `Ada.Calendar` package for this component.
3. `Full_Member` type for full members.
    1. This type must extend the `Member` type above.
    2. It contains the following additional component:
        - `Discount`, which indicates the discount rate that the full member gets in the online store.
            - This component must be of `Percentage` type.
4. For the `Member` and `Full_Member` types, you must implement the following functions:
    1. `Get_Status`, which returns a string with the membership status.
        - The string must be `"Associate Member"` or `"Full Member"`, respectively.
    2. `Get_Price`, which returns the *adapted price* of an item — indicating the actual due amount.
        - For example, for a full member with a 10% discount rate, the actual due amount of an item with a price of 100.00 is 90.00.
        - Associated members don't get a discount, so they always pay the full price.
5. Procedure `Simple_Test` (from the `Online_Store.Tests` package) is used for testing.
    1. Based on a list of members that bought on the online store and the corresponding full price of the item, `Simple_Test` must display information about each member and the actual due amount after discounts.
    2. Information about the members must be displayed in the following format:

```
Member # <number>
Status: <status>
Since:  <year>
Due Amount:  <value>
--------
```

    3. For this exercise, `Simple_Test` must use the following list:

#	Membership status	Start (year)	Discount	Full Price
1	Associate	2010	*N/A*	250.00
2	Full	1998	10.0 %	160.00
3	Full	1987	20.0 %	400.00
4	Associate	2013	*N/A*	110.00

    4. In order to pass the tests, the information displayed by a call to `Simple_Test` must conform to the format described above.
        - You can find another example in the remarks below.

Remarks:

1. In previous labs, we could have implemented a simplified version of the system described above by simply using an enumeration type to specify the membership status. For example:

```
type Member_Status is (Associate_Member, Full_Member);
```

1. In this case, the `Get_Price` function would then evaluate the membership status and adapt the item price — assuming a fixed discount rate for all full members. This could be the corresponding function declaration:

   ```
   type Amount is delta 10.0**(-2) digits 10;

   function Get_Price (M : Member_Status;
                       P : Amount) return Amount;
   ```

2. In this exercise, however, we'll use type extension to represent the membership status in our application.

2. For the procedure `Simple_Test`, let's consider the following list of members as an example:

#	Membership status	Start (year)	Discount	Full Price
1	Associate	2002	*N/A*	100.00
2	Full	2005	10.0 %	100.00

   - For this list, the test procedure displays the following information (in this exact format):

     ```
     Member # 1
     Status: Associate Member
     Since:  2002
     Due Amount:  100.00
     --------
     Member # 2
     Status: Full Member
     Since:  2005
     Due Amount:  90.00
     --------
     ```

   - Here, although both members had the same full price (as indicated by the last column), member #2 gets a reduced due amount of 90.00 because of the full membership status.

Listing 4: online_store.ads

```
with Ada.Calendar; use Ada.Calendar;

package Online_Store is

   type Amount is delta 10.0**(-2) digits 10;

   subtype Percentage is Amount range 0.0 .. 1.0;

   --  Create declaration of Member type!
   --
   --  You can use Year_Number from Ada.Calendar for the membership
   --  starting year.
   --
   type Member is null record;

   function Get_Status (M : Member) return String;

   function Get_Price (M : Member;
                       P : Amount) return Amount;
```

(continues on next page)

(continued from previous page)

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

STANDARD LIBRARY: CONTAINERS

140.1 Simple todo list

Goal: implement a simple to-do list system using vectors.

Steps:

1. Implement the `Todo_Lists` package.
    1. Declare the `Todo_Item` type.
    2. Declare the `Todo_List` type.
    3. Implement the `Add` procedure.
    4. Implement the `Display` procedure.
2. `Todo_Item` type is used to store to-do items.
    1. It should be implemented as an access type to strings.
3. `Todo_List` type is the container for all to-do items.
    1. It should be implemented as a **vector**.
4. Procedure `Add` adds items (of `Todo_Item` type) to the list (of `Todo_List` type).
    1. This requires allocating a string for the access type.
5. Procedure `Display` is used to display all to-do items.
    1. It must display one item per line.

Remarks:

1. This exercise is based on the *Simple todo list* exercise from the *More About Types* (page 2257).
    1. Your goal is to rewrite that exercise using vectors instead of arrays.
    2. You may reuse the code you've already implemented as a starting point.

Listing 1: todo_lists.ads

```
package Todo_Lists is

   type Todo_Item is access String;

   type Todo_List is null record;

   procedure Add (Todos : in out Todo_List;
                  Item  : String);

   procedure Display (Todos : Todo_List);

end Todo_Lists;
```

Listing 2: todo_lists.adb

```
with Ada.Text_IO; use Ada.Text_IO;

package body Todo_Lists is

   procedure Add (Todos : in out Todo_List;
                  Item  : String) is
   begin
      null;
   end Add;

   procedure Display (Todos : Todo_List) is
   begin
      Put_Line ("TO-DO LIST");
   end Display;

end Todo_Lists;
```

Listing 3: main.adb

```
with Ada.Command_Line;  use Ada.Command_Line;
with Ada.Text_IO;       use Ada.Text_IO;

with Todo_Lists;        use Todo_Lists;

procedure Main is
   type Test_Case_Index is
     (Todo_List_Chk);

   procedure Check (TC : Test_Case_Index) is
      T : Todo_List;
   begin
      case TC is
         when Todo_List_Chk =>
            Add (T, "Buy milk");
            Add (T, "Buy tea");
            Add (T, "Buy present");
            Add (T, "Buy tickets");
            Add (T, "Pay electricity bill");
            Add (T, "Schedule dentist appointment");
            Add (T, "Call sister");
            Add (T, "Revise spreasheet");
            Add (T, "Edit entry page");
            Add (T, "Select new design");
            Add (T, "Create upgrade plan");
            Display (T);
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

140.2 List of unique integers

Goal: create function that removes duplicates from and orders a collection of elements.

Steps:

1. Implement package `Ops`.
    1. Declare the `Int_Array` type.
    2. Declare the `Integer_Sets` type.
    3. Implement the `Get_Unique` function that returns a set.
    4. Implement the `Get_Unique` function that returns an array of integer values.

Requirements:

1. The `Int_Array` type is an unconstrained array of positive range.
2. The `Integer_Sets` package is an instantiation of the `Ordered_Sets` package for the **`Integer`** type.
3. The `Get_Unique` function must remove duplicates from an input array of integer values and order the elements.
    1. For example:
        - if the input array contains `(7, 7, 1)`
        - the function must return `(1, 7)`.
    2. You must implement this function by using sets from the `Ordered_Sets` package.
    3. `Get_Unique` must be implemented in two versions:
        - one version that returns a set — `Set` type from the `Ordered_Sets` package.
        - one version that returns an array of integer values — `Int_Array` type.

Remarks:

1. Sets — as the one found in the generic `Ordered_Sets` package — are useful for quickly and easily creating an algorithm that removes duplicates from a list of elements.

Listing 4: ops.ads

```
with Ada.Containers.Ordered_Sets;

package Ops is

   --  type Int_Array is ...

   --  package Integer_Sets is ...

   subtype Int_Set is Integer_Sets.Set;

   function Get_Unique (A : Int_Array) return Int_Set;

   function Get_Unique (A : Int_Array) return Int_Array;

end Ops;
```

Listing 5: ops.adb

```
package body Ops is

   function Get_Unique (A : Int_Array) return Int_Set is
```

(continues on next page)

(continued from previous page)

```
   begin
      null;
   end Get_Unique;

   function Get_Unique (A : Int_Array) return Int_Array is
   begin
      null;
   end Get_Unique;

end Ops;
```

Listing 6: main.adb

```
with Ada.Command_Line;        use Ada.Command_Line;
with Ada.Text_IO;             use Ada.Text_IO;

with Ops;                     use Ops;

procedure Main is
   type Test_Case_Index is
     (Get_Unique_Set_Chk,
      Get_Unique_Array_Chk);

   procedure Check (TC : Test_Case_Index;
                    A  : Int_Array) is

      procedure Display_Unique_Set (A : Int_Array) is
         S  : constant Int_Set := Get_Unique (A);
      begin
         for E of S loop
            Put_Line (Integer'Image (E));
         end loop;
      end Display_Unique_Set;

      procedure Display_Unique_Array (A : Int_Array) is
         AU : constant Int_Array := Get_Unique (A);
      begin
         for E of AU loop
            Put_Line (Integer'Image (E));
         end loop;
      end Display_Unique_Array;

   begin
      case TC is
         when Get_Unique_Set_Chk   => Display_Unique_Set (A);
         when Get_Unique_Array_Chk => Display_Unique_Array (A);
      end case;
   end Check;

begin
   if Argument_Count < 3 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   else
      declare
         A : Int_Array (1 .. Argument_Count - 1);
      begin
         for I in A'Range loop
            A (I) := Integer'Value (Argument (1 + I));
         end loop;
         Check (Test_Case_Index'Value (Argument (1)), A);
```

(continues on next page)

(continued from previous page)

```
      end;
   end if;
end Main;
```

CHAPTER

ONE

STANDARD LIBRARY: DATES & TIMES

141.1 Holocene calendar

Goal: create a function that returns the year in the Holocene calendar.

Steps:

1. Implement the `To_Holocene_Year` function.

Requirements:

1. The `To_Holocene_Year` extracts the year from a time object (`Time` type) and returns the corresponding year for the Holocene calendar[540].
    1. For positive (AD) years, the Holocene year is calculated by adding 10,000 to the year number.

Remarks:

1. In this exercise, we don't deal with BC years.
2. Note that the year component of the `Time` type from the `Ada.Calendar` package is limited to years starting with 1901.

Listing 1: to_holocene_year.adb

```
with Ada.Calendar; use Ada.Calendar;

function To_Holocene_Year (T : Time) return Integer is
begin
   return 0;
end To_Holocene_Year;
```

Listing 2: main.adb

```
with Ada.Command_Line;        use Ada.Command_Line;
with Ada.Text_IO;             use Ada.Text_IO;
with Ada.Calendar;            use Ada.Calendar;

with To_Holocene_Year;

procedure Main is
   type Test_Case_Index is
     (Holocene_Chk);

   procedure Display_Holocene_Year (Y : Year_Number) is
      HY : Integer;
   begin
```

(continues on next page)

[540] https://en.wikipedia.org/wiki/Holocene_calendar

(continued from previous page)

```
      HY := To_Holocene_Year (Time_Of (Y, 1, 1));
      Put_Line ("Year (Gregorian): " & Year_Number'Image (Y));
      Put_Line ("Year (Holocene):  " & Integer'Image (HY));
   end Display_Holocene_Year;

   procedure Check (TC : Test_Case_Index) is
   begin
      case TC is
         when Holocene_Chk =>
            Display_Holocene_Year (2012);
            Display_Holocene_Year (2020);
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

141.2 List of events

Goal: create a system to manage a list of events.

Steps:

1. Implement the `Events` package.
    1. Declare the `Event_Item` type.
    2. Declare the `Event_Items` type.
2. Implement the `Events.Lists` package.
    1. Declare the `Event_List` type.
    2. Implement the `Add` procedure.
    3. Implement the `Display` procedure.

Requirements:

1. The `Event_Item` type (from the `Events` package) contains the *description of an event*.
    1. This description shall be stored in an access-to-string type.
2. The `Event_Items` type stores a list of events.
    1. This will be used later to represent multiple events for a specific date.
    2. You shall use a vector for this type.
3. The `Events.Lists` package contains the subprograms that are used in the test application.
4. The `Event_List` type (from the `Events.Lists` package) maps a list of events to a specific date.
    1. You must use the `Event_Items` type for the list of events.

2. You shall use the `Time` type from the `Ada.Calendar` package for the dates.
3. Since we expect the events to be ordered by the date, you shall use ordered maps for the `Event_List` type.

5. Procedure `Add` adds an event into the list of events for a specific date.
6. Procedure `Display` must display all events for each date (ordered by date) using the following format:

```
<event_date #1>
    <description of item #1a>
    <description of item #1b>
<event_date #2>
    <description of item #2a>
    <description of item #2b>
```

1. You should use the auxiliary `Date_Image` function — available in the body of the `Events.Lists` package — to display the date in the `YYYY-MM-DD` format.

Remarks:

1. Let's briefly illustrate the expected output of this system.
   1. Consider the following example:

```
with Ada.Calendar;
with Ada.Calendar.Formatting; use Ada.Calendar.Formatting;

with Events.Lists;            use Events.Lists;

procedure Test is
   EL : Event_List;
begin
   EL.Add (Time_Of (2019, 4, 16),
           "Item #2");
   EL.Add (Time_Of (2019, 4, 15),
           "Item #1");
   EL.Add (Time_Of (2019, 4, 16),
           "Item #3");
   EL.Display;
end Test;
```

   2. The expected output of the `Test` procedure must be:

```
EVENTS LIST
- 2019-04-15
    - Item #1
- 2019-04-16
    - Item #2
    - Item #3
```

Listing 3: events.ads

```
package Events is

   type Event_Item is null record;

   type Event_Items is null record;

end Events;
```

Listing 4: events-lists.ads

```
with Ada.Calendar; use Ada.Calendar;

package Events.Lists is

   type Event_List is tagged private;

   procedure Add (Events     : in out Event_List;
                  Event_Time :        Time;
                  Event      :        String);

   procedure Display (Events : Event_List);

private

   type Event_List is tagged null record;

end Events.Lists;
```

Listing 5: events-lists.adb

```
with Ada.Text_IO;              use Ada.Text_IO;
with Ada.Calendar.Formatting; use Ada.Calendar.Formatting;

package body Events.Lists is

   procedure Add (Events     : in out Event_List;
                  Event_Time : Time;
                  Event      : String) is
   begin
      null;
   end Add;

   function Date_Image (T : Time) return String is
      Date_Img : constant String := Image (T);
   begin
      return Date_Img (1 .. 10);
   end;

   procedure Display (Events : Event_List) is
      T : Time;
   begin
      Put_Line ("EVENTS LIST");
      --  You should use Date_Image (T) here!
   end Display;

end Events.Lists;
```

Listing 6: main.adb

```
with Ada.Command_Line;         use Ada.Command_Line;
with Ada.Text_IO;              use Ada.Text_IO;
with Ada.Calendar;
with Ada.Calendar.Formatting; use Ada.Calendar.Formatting;

with Events.Lists;             use Events.Lists;

procedure Main is
   type Test_Case_Index is
     (Event_List_Chk);
```

(continues on next page)

(continued from previous page)

```
11
12    procedure Check (TC : Test_Case_Index) is
13       EL : Event_List;
14    begin
15       case TC is
16          when Event_List_Chk =>
17             EL.Add (Time_Of (2018, 2, 16),
18                     "Final check");
19             EL.Add (Time_Of (2018, 2, 16),
20                     "Release");
21             EL.Add (Time_Of (2018, 12, 3),
22                     "Brother's birthday");
23             EL.Add (Time_Of (2018, 1, 1),
24                     "New Year's Day");
25             EL.Display;
26       end case;
27    end Check;
28
29 begin
30    if Argument_Count < 1 then
31       Put_Line ("ERROR: missing arguments! Exiting...");
32       return;
33    elsif Argument_Count > 1 then
34       Put_Line ("Ignoring additional arguments...");
35    end if;
36
37    Check (Test_Case_Index'Value (Argument (1)));
38 end Main;
```

CHAPTER

TWO

STANDARD LIBRARY: STRINGS

142.1 Concatenation

Goal: implement functions to concatenate an array of unbounded strings.

Steps:

1. Implement the `Str_Concat` package.
    1. Implement the `Concat` function for `Unbounded_String`.
    2. Implement the `Concat` function for **`String`**.

Requirements:

1. The first `Concat` function receives an unconstrained array of unbounded strings and returns the concatenation of those strings as an unbounded string.
    1. The second `Concat` function has the same parameters, but returns a standard string (**`String`** type).
2. Both `Concat` functions have the following parameters:
    1. An unconstrained array of `Unbounded_String` strings (`Unbounded_Strings` type).
    2. `Trim_Str`, a Boolean parameter indicating whether each unbounded string must be trimmed.
    3. `Add_Whitespace`, a Boolean parameter indicating whether a whitespace shall be added between each unbounded string and the next one.
        1. No whitespace shall be added after the last string of the array.

Remarks:

1. You can use the `Trim` function from the `Ada.Strings.Unbounded` package.

Listing 1: str_concat.ads

```
with Ada.Strings.Unbounded; use Ada.Strings.Unbounded;

package Str_Concat is

   type Unbounded_Strings is array (Positive range <>) of Unbounded_String;

   function Concat (USA            : Unbounded_Strings;
                    Trim_Str       : Boolean;
                    Add_Whitespace : Boolean) return Unbounded_String;

   function Concat (USA            : Unbounded_Strings;
                    Trim_Str       : Boolean;
                    Add_Whitespace : Boolean) return String;
```

(continues on next page)

(continued from previous page)

```
14
15 end Str_Concat;
```

Listing 2: str_concat.adb

```
1  with Ada.Strings; use Ada.Strings;
2
3  package body Str_Concat is
4
5     function Concat (USA            : Unbounded_Strings;
6                      Trim_Str       : Boolean;
7                      Add_Whitespace : Boolean) return Unbounded_String is
8     begin
9        return "";
10    end Concat;
11
12    function Concat (USA            : Unbounded_Strings;
13                     Trim_Str       : Boolean;
14                     Add_Whitespace : Boolean) return String is
15    begin
16       return "";
17    end Concat;
18
19 end Str_Concat;
```

Listing 3: main.adb

```
1  with Ada.Command_Line;         use Ada.Command_Line;
2  with Ada.Text_IO;              use Ada.Text_IO;
3  with Ada.Strings.Unbounded;    use Ada.Strings.Unbounded;
4
5  with Str_Concat;               use Str_Concat;
6
7  procedure Main is
8     type Test_Case_Index is
9       (Unbounded_Concat_No_Trim_No_WS_Chk,
10       Unbounded_Concat_Trim_No_WS_Chk,
11       String_Concat_Trim_WS_Chk,
12       Concat_Single_Element);
13
14    procedure Check (TC : Test_Case_Index) is
15    begin
16       case TC is
17          when Unbounded_Concat_No_Trim_No_WS_Chk =>
18             declare
19                S : constant Unbounded_Strings := (
20                   To_Unbounded_String ("Hello"),
21                   To_Unbounded_String (" World"),
22                   To_Unbounded_String ("!"));
23             begin
24                Put_Line (To_String (Concat (S, False, False)));
25             end;
26          when Unbounded_Concat_Trim_No_WS_Chk =>
27             declare
28                S : constant Unbounded_Strings := (
29                   To_Unbounded_String (" This "),
30                   To_Unbounded_String (" _is_ "),
31                   To_Unbounded_String ("  a   "),
32                   To_Unbounded_String (" _check "));
33             begin
```

(continues on next page)

(continued from previous page)

```
               Put_Line (To_String (Concat (S, True, False)));
            end;
         when String_Concat_Trim_WS_Chk =>
            declare
               S : constant Unbounded_Strings := (
                   To_Unbounded_String ("  This  "),
                   To_Unbounded_String ("  is a  "),
                   To_Unbounded_String ("  test.  "));
            begin
               Put_Line (Concat (S, True, True));
            end;
         when Concat_Single_Element =>
            declare
               S : constant Unbounded_Strings := (
                   1 => To_Unbounded_String ("  Hi "));
            begin
               Put_Line (Concat (S, True, True));
            end;
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

142.2 List of events

Goal: create a system to manage a list of events.

Steps:

1. Implement the `Events` package.
    1. Declare the `Event_Item` subtype.
2. Implement the `Events.Lists` package.
    1. Adapt the `Add` procedure.
    2. Adapt the `Display` procedure.

Requirements:

1. The `Event_Item` type (from the `Events` package) contains the *description of an event*.
    1. This description is declared as a subtype of unbounded string.
2. Procedure `Add` adds an event into the list of events for a specific date.
    1. The declaration of `E` needs to be adapted to use unbounded strings.
3. Procedure `Display` must display all events for each date (ordered by date) using the following format:
    1. The arguments to `Put_Line` need to be adapted to use unbounded strings.

Remarks:

1. We use the lab on the list of events from the previous chapter (*Standard library: Dates & Times* (page 2329)) as a starting point.

Listing 4: events.ads

```
with Ada.Containers.Vectors;

package Events is

   --  subtype Event_Item is

   package Event_Item_Containers is new
     Ada.Containers.Vectors
       (Index_Type   => Positive,
        Element_Type => Event_Item);

   subtype Event_Items is Event_Item_Containers.Vector;

end Events;

CHAPTER

THREE

STANDARD LIBRARY: NUMERICS

143.1 Decibel Factor

Goal: implement functions to convert from Decibel values to factors and vice-versa.

Steps:

1. Implement the `Decibels` package.
    1. Implement the `To_Decibel` function.
    2. Implement the `To_Factor` function.

Requirements:

1. The subtypes `Decibel` and `Factor` are based on a floating-point type.
2. Function `To_Decibel` converts a multiplication factor (or ratio) to decibels.
    - For the implementation, use $20 * log_{10}(F)$, where *F* is the factor/ratio.
3. Function `To_Factor` converts a value in decibels to a multiplication factor (or ratio).
    - For the implementation, use $10^{D/20}$, where *D* is the value in Decibel.

Remarks:

1. The Decibel[541] is used to express the ratio of two values on a logarithmic scale.
    1. For example, an increase of 6 dB corresponds roughly to a multiplication by two (or an increase by 100 % of the original value).
2. You can find the functions that you'll need for the calculation in the `Ada.Numerics.Elementary_Functions` package.

Listing 1: decibels.ads

```
package Decibels is

   subtype Decibel is Float;
   subtype Factor  is Float;

   function To_Decibel (F : Factor) return Decibel;

   function To_Factor (D : Decibel) return Factor;

end Decibels;
```

         when Db_Chk =>
            Put_Decibel_Cnvt (Decibel (V));
         when Factor_Chk =>
            Put_Factor_Cnvt (Factor (V));
      end case;
   end Check;

begin
```

(continues on next page)

(continued from previous page)

```
   if Argument_Count < 2 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 2 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)), Float'Value (Argument (2)));
end Main;
```

143.2 Root-Mean-Square

Goal: implement a function to calculate the root-mean-square of a sequence of values.

Steps:

1. Implement the `Signals` package.
    1. Implement the `Rms` function.

Requirements:

1. Subtype `Sig_Value` is based on a floating-point type.
2. Type `Signal` is an unconstrained array of `Sig_Value` elements.
3. Function `Rms` calculates the RMS of a sequence of values stored in an array of type `Signal`.
    1. See the remarks below for a description of the RMS calculation.

Remarks:

1. The root-mean-square[542] (RMS) value is an important information associated with sequences of values.
    1. It's used, for example, as a measurement for signal processing.
    2. It is calculated by:
        1. Creating a sequence S with the square of each value of an input sequence S_{in}.
        2. Calculating the mean value M of the sequence S.
        3. Calculating the square-root R of M.
    3. You can optimize the algorithm above by combining steps #1 and #2 into a single step.

Listing 4: signals.ads

```
package Signals is

   subtype Sig_Value is Float;

   type Signal is array (Natural range <>) of Sig_Value;

   function Rms (S : Signal) return Sig_Value;

end Signals;
```

            Put ("RMS of Square Signal: ");
            Sig_IO.Put (Rms (S_Sq), 0, 2, 0);
            New_Line;
         when Triangular_Signal_Chk =>
            Put ("RMS of Triangular Signal: ");
            Sig_IO.Put (Rms (S_Tr), 0, 2, 0);
            New_Line;
      end case;
   end Check;

begin
   if Argument_Count < 1 then
      Put_Line ("ERROR: missing arguments! Exiting...");
      return;
   elsif Argument_Count > 1 then
      Put_Line ("Ignoring additional arguments...");
   end if;

   Check (Test_Case_Index'Value (Argument (1)));
end Main;
```

143.3 Rotation

Goal: use complex numbers to calculate the positions of an object in a circle after rotation.

Steps:

1. Implement the `Rotation` package.
    1. Implement the `Rotation` function.

Requirements:

1. Type `Complex_Points` is an unconstrained array of complex values.
2. Function `Rotation` returns a list of positions (represented by the `Complex_Points` type) when dividing a circle in `N` equal slices.
    1. See the remarks below for a more detailed explanation.
    2. You must use functions from `Ada.Numerics.Complex_Types` to implement `Rotation`.
3. Subtype `Angle` is based on a floating-point type.
4. Type `Angles` is an unconstrained array of angles.
5. Function `To_Angles` returns a list of angles based on an input list of positions.

Remarks:

1. Complex numbers are particularly useful in computer graphics to simplify the calculation of rotations.
    1. For example, let's assume you've drawn an object on your screen on position (1.0, 0.0).
    2. Now, you want to move this object in a circular path — i.e. make it rotate around position (0.0, 0.0) on your screen.
        - You could use *sine* and *cosine* functions to calculate each position of the path.
        - However, you could also calculate the positions using complex numbers.
2. In this exercise, you'll use complex numbers to calculate the positions of an object that starts on zero degrees — on position (1.0, 0.0) — and rotates around (0.0, 0.0) for *N* slices of a circle.
    1. For example, if we divide the circle in four slices, the object's path will consist of following points / positions:

        ```
        Point #1: ( 1.0,  0.0)
        Point #2: ( 0.0,  1.0)
        Point #3: (-1.0,  0.0)
        Point #4: ( 0.0, -1.0)
        Point #5: ( 1.0,  0.0)
        ```

        1. As expected, point #5 is equal to the starting point (point #1), since the object rotates around (0.0, 0.0) and returns to the starting point.
    2. We can also describe this path in terms of angles. The following list presents the angles for the path on a four-sliced circle:

        ```
        Point #1:    0.00 degrees
        Point #2:   90.00 degrees
        Point #3:  180.00 degrees
        Point #4:  -90.00 degrees (= 270 degrees)
        Point #5:    0.00 degrees
        ```

1. To rotate a complex number simply multiply it by a unit vector whose arg is the radian angle to be rotated: $Z = e^{\frac{2\pi}{N}}$

Listing 9: rotation.ads

```

CHAPTER

FIVE

LET'S BUILD A STACK

In this lab we will build a stack data structure and use the SPARK provers to find the errors in the below implementation.

145.1 Background

So, what is a stack?

A stack is like a pile of dishes...

1. The pile starts out empty.
2. You add (`push`) a new plate (`data`) to the stack by placing it on the top of the pile.
3. To get plates (`data`) out, you take the one off the top of the pile (`pop`).
4. Out stack has a maximum height (`size`) of 9 dishes

Pushing items onto the stack

Here's what should happen if we pushed the string `MLH` onto the stack.

Step 0:
Empty

1:	
2:	
3:	
4:	
5:	

Last = 0

Step 1:
Push("M")

1:	M
2:	
3:	
4:	
5:	

Last = 1

Step 2:
Push("L")

1:	M
2:	L
3:	
4:	
5:	

Last = 2

Step 3:
Push("H")

1:	M
2:	L
3:	H
4:	
5:	

Last = 3

Step 4:
Top()

1:	M
2:	L
3:	H
4:	
5:	

Last = 3
returns:
'H'

The list starts out empty. Each time we push a character onto the stack, `Last` increments by 1.

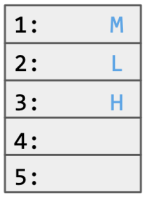
Popping items from the stack

Here's what should happen if we popped 2 characters off our stack & then clear it.

Step 0:
Start

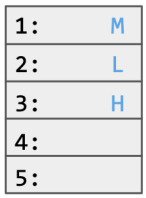
Last = 3

Step 1:
Pop()



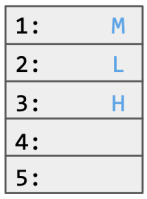
Last = 2
returns:
'H'

Step 2:
Pop()



Last = 1
returns:
'L'

Step 3:
Clear()



Last = 0

Note that pop and `clear` don't unset the `Storage` array's elements, they just change the value of `Last`.

145.2 Input Format

N inputs will be read from stdin/console as inputs, C to the stack.

145.3 Constraints

1 <= N <= 1000

C is any character. Characters d and p will be special characters corresponding to the below commands:

p => Pops a character off the stack

d => Prints the current characters in the stack

145.4 Output Format

If the stack currently has the characters "M", "L", and "H" then the program should print the stack like this:

[M, L, H]

145.5 Sample Input

M L H d p d p d p d

145.6 Sample Output

[M, L, H] [M, L] [M] []

Listing 1: stack.ads

```
package Stack with SPARK_Mode => On is

   procedure Push (V : Character)
     with Pre  => not Full,
